Parallel processing impact on timeouts

Analysis Services processing commands can be run in parallel or sequentially. In the processing command syntax, check to see if you're specifying to run in sequential order or run in parallel. Check the SSIS package or XMLA job that runs the processing.

This image shows the settings for an SSIS Analysis Services processing task:

This example shows an XMLA command that runs up to eight tasks in parallel:

```
<Batch xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Parallel MaxParallel="8">
    <Process xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
      xmlns:ddl2="http://schemas.microsoft.com/analysisservices/2003/engine/2"
      xmlns:ddl2_2="http://schemas.microsoft.com/analysisservices/2003/engine/2/2"
      xmlns:ddl100_100="http://schemas.microsoft.com/analysisservices/2008/engine/100/100"
      xmlns:ddl1200="http://schemas.microsoft.com/analysisservices/2010/engine/200"
      xmlns:ddl1200_200="http://schemas.microsoft.com/analysisservices/2010/engine/200/200"
      xmlns:ddl300="http://schemas.microsoft.com/analysisservices/2011/engine/300"
      xmlns:ddl300_300="http://schemas.microsoft.com/analysisservices/2011/engine/300/300">
      <Object>
        <DatabaseID>AdventureworksDW2012Multidimensional-EE</DatabaseID>
      </Object>
      <Type>ProcessFull</Type>
      <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
    </Process>
  </Parallel>
</Batch>
```

If the system is timing out, you might need to scale back the number of parallel tasks, especially when you manually override the default setting, **Let the server decide**.

You might be able to throttle the system better by reducing the **MaxThreads** configuration by 50% and reprocessing the objects so that fewer threads run at once.

In the worst case, run processing in **Sequential** mode to see if the errors go away. The system takes less memory to run a sequence of one task at a time rather than many tasks at once. The tradeoff might be that it runs longer because you can't push the system hardware to the same throughput limits.

To learn more about processing best practices, see [SQL Server best practices](#).

For more information on the architecture of cube processing, see [Analysis Services 2005 processing architecture](#).

Aggregation memory impact on timeouts

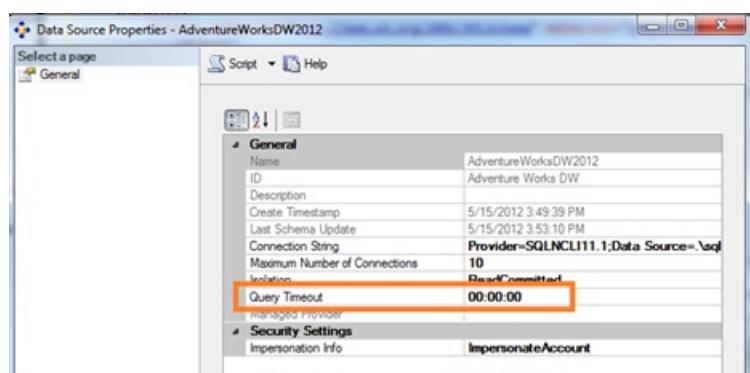

There's an advanced setting of **AggregationMemoryLimitMax**. For more information, see [this blog post](#)

SQL Server Analysis Services uses memory quota to control the number of concurrent jobs. Each job calculates how much memory it needs to finish the job and requests the memory quota based on its estimate. The job proceeds only when the memory quota is granted. We estimate the quota for an aggregation job. The configuration settings that control the memory usage estimates are **AggregationMemoryLimitMin** and **AggregationMemoryLimitMax**.

To achieve more parallelism for processing, tune the settings.

Additional timeout settings

Query Timeout is another setting on the data source. This setting seems not to apply readily to processing. This setting applies to the connection pool and helps to expire idle connections that are no longer needed. This setting doesn't apply to the commands that run during processing or ROLAP commands.

There are many other timeouts in Analysis Services, such as:

- **ForceCommitTimeout** for processing to kill user queries if MDX queries hold locks that block processing of commits.
- **CommitTimeout** for processing to give up if it gets blocked at the commit phase.
- **ServerTimeout** for queries to time out after some time.
- Connection pool settings, such as **IdleConnectionTimeout**, **IdleOrphanSessionTimeout**, **MaxIdleSessionTimeout**, **MinIdleSessionTimeout**, and **DatabaseConnectionPoolConnectTimeout**, and the ones we discussed previously, **ExternalConnectionTimeout** and **ExternalCommandTimeout**.

Special characters

In some situations, the processing timeout error was due to some special characters present in the columns of one of the dimension tables. Even **null values** in a dimension column can cause processing failures.

You might isolate the problem better by processing each object one at a time until you find the problem.

For example, while processing the dimension table, it throws the error

OLE DB error: OLE DB or ODBC error: Operation canceled; HY008.

After the user removed the special characters, processing worked as expected.

Isolate to a partition

You might be able to further isolate the error to a specific partition. If you partitioned your cube, there might be a poorly performing query under one of the partitions.

Experiment with the partition query. Change from a direct **Named Query Table** in the **Data Source** view to an underlying SQL query instead.

Analysis Services stops accepting new connections

10/22/2019 • 9 minutes to read • [Edit Online](#)

NOTE

This article is derived from an MSDN blog originally posted on July 3, 2012.

When you process an Analysis Services object, such as FullProcess on a database or cube, old files need to be replaced with new files near the end of the processing phase. In addition, a lock is needed for the highest level in the database. The users who run queries have the priority until the queries are finished.

Sometimes, the users and the server administrator can't even sign in with SQL Server Management Studio to run a new query.

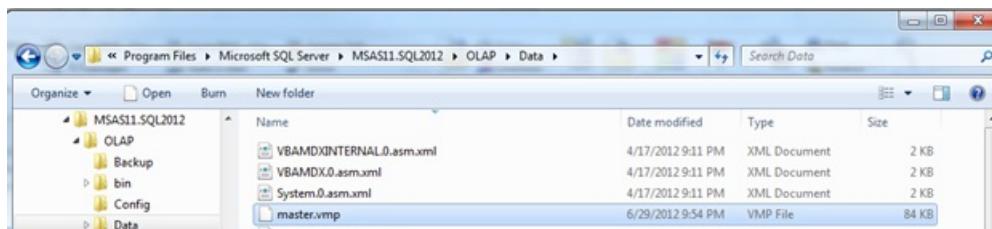

An Analysis Services database is a collection of files (some XML files that point to files, and some compressed binary files) that represent the objects in the cube that you query with MDX queries. Processing is the act of refreshing those objects by using a new set of data values from the relational database. It runs large relational database Transact-SQL queries to query from the data sources, do joins, aggregate the data, and save the compressed and aggregated data into the cube. The old copy of the Analysis Services database objects stays until the very end of the processing. When the processing is almost finished, the commit phase begins.

The commit phase needs an exclusive write lock. Users can't query the objects at the moment when it swaps the old version of the cube data for the new version.

Another problem is that the instance-wide Master.vmp lock is required to finish the commit from processing. This special file is a pointer to all the other database objects and their current versions. This file is important when you swap out the old database objects with the new database objects.

As the server enters phase 2 of the commit, it tries to obtain a server-level lock to update Master.vmp. If another transaction is in process at that point, the server waits for an interval that's equal to the **ForceCommitTimeout** setting. The default is 30 seconds. Then, it rolls back any uncommitted transactions and aborts executing queries. The server-wide lock remains in effect until the transaction is finished. It blocks any read lock request that's initiated. When a new sign-in or existing user tries to connect to the server, they start a read lock request and wait.

This small file is the central point of the list of databases in Analysis Services. Never tamper with it or else your database is likely to be deleted.

The inside of the master.vmp (shown with XML formatting for clarity) shows each object (represented by a GUID value) and the version number (an integer 1, 2, 3... 43, and so on). The version number gets incremented every time when the object is processed (or synchronized) and committed by the server, and the time is updated. This is the central point of all objects in an Analysis Services instance.

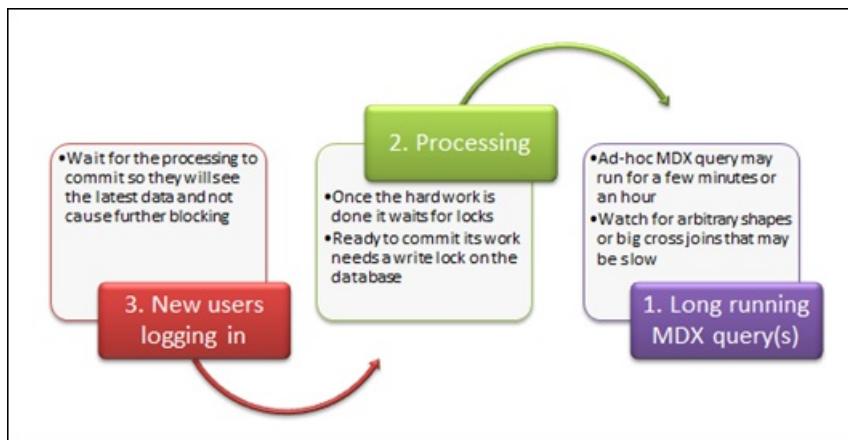

```

Why can't you sign in when locking happens?

Locking can be the center of the problem. Here's a visual simplification of the blocking chain that prevents new users from getting into the database and running any query.

You might encounter this locking pattern. Slow queries aggravate the processing commit waits, and the server becomes unresponsive. The head queries in Set 1 are taking many hours. The Set 2 locks are waiting for more than one hour.

- Set 1: Queries running holds database read locks (running for several hours)
- Set 2: Processing commit needs commit write locks (waiting about 1 hour or more)
- Set 3: New connections wait in line, blocked to read the soon-to-be-committed database

Sometimes the administrator can't even sign in with Management Studio because the connection gets queued in Set 3.

When most new connections come in from Management Studio, the server does their initialization to see database names and object names with discover commands. They might get stuck in line and wait to read the soon-to-be-committed and -processed database behind the processing Set 2.

The new connections will likely do a discovery command as follows:

Discover on DBSCHEMA_CATALOGS

Discover on MDSchema_MEMBERS

During the commit phase of the processing transaction, queries can still be sent to the object, but they will be queued until the commit is completed. For more information about locking and unlocking during processing, see [Processing Analysis Services objects](#).

Fix the problem

Step 1: Minimize the MDX query duration

Tune the queries. Reduce the time that's required for Set 1 to finish. Then, you have the least conflict between queries and processing. In one example, the slow query was requesting an arbitrary shape. Tune or avoid arbitrary shape queries in Set 1 to:

- Run faster.
- Change syntax to avoid arbitrary shapes.
- Configure a timeout in the application to kill long-running queries.

Add aggregations and partitions to reduce the amount of reading of data that's required.

Tune any calculations that might cause the formula engine a long time to work on.

Run a profiler trace to investigate the MDX query.

Sometimes you can't control the queries at all. In an ad-hoc environment, when Excel pivot table users and custom MDX are enabled, you have the occasional runaway MDX query that might take a long time.

Step 2: Avoid processing at peak hours to avoid query and processing collisions

In one example, the Set 2 full processing happens at 11:30 AM and noon. There's bound to be a locking collision during those busy times because there are significant queries running in the business then. Avoid processing at peak times.

Step 3: Tell the server to favor one or the other when blocking occurs

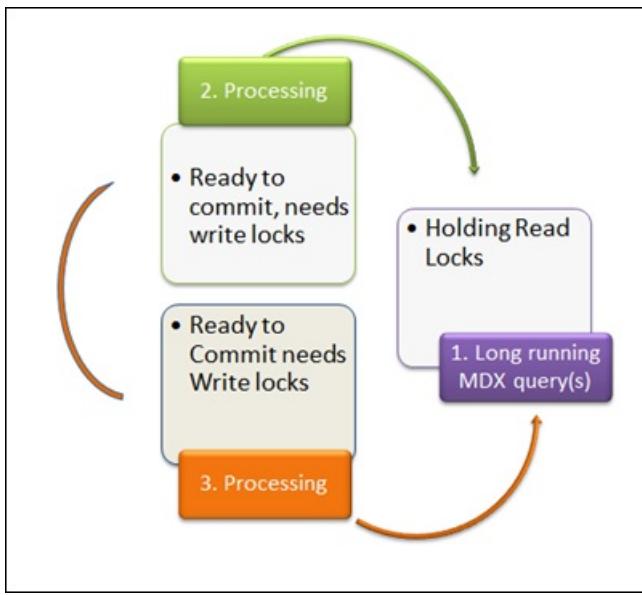

Try these two configuration settings to enable the server to try killing either the long queries of Set 1 or the waiting processing of Set 2.

- **Kill the queries:** Set 2 can influence the server to cancel Set 1 after a time of waiting on locks with this setting.
 - **ForceCommitTimeout:** This server property is used to control what happens when a processing operation is waiting to finish its operation to enter the commit phase. When this value is greater than zero, SQL Server Analysis Services starts canceling prior transactions, but only after the specified value in milliseconds. If read locks become available before the **ForceCommitTimeout** period is reached, canceling won't occur.
- **Kill the processing:** Set 1 can influence the server to cancel Set 2 after waiting on locks occurs.
 - **CommitTimeout:** Analysis Server processing operations need to acquire a write lock before it can commit a transaction. To acquire a write lock, no other read locks can be taken by another process or query. Analysis Services must wait until all read locks are released. The transaction waits for a while to acquire a write lock, as specified by the **CommitTimeout** property, before rolling back.

Sometimes the cancellation doesn't occur immediately, so even with **ForceCommitTimeout** and **CommitTimeout**, there can be a period where work is stalled.

Another variation: Multiple processing requests can block each other

If you run two or more processing batches at the same time in different transactions, a similar locking chain and deadlock might occur. The following example is simplified. Assume there are two processing transactions that are ready near the same time, but they get blocked waiting on a user's long MDX query.

The locking granularity at the end of processing is coarse at the database level and at the master.vmp file, so it's difficult to get parallel processing to go through successfully.

Processing start time isn't as important as the end time, so aim to avoid overlap at the end of processing jobs. If the two processing transactions are ready to commit around the same time, they might hold some locks and request other locks that cause a deadlock.

Adding a long-running MDX query into the mix makes it more likely to cause a deadlock chain because the intermediate locks can cause a circle to occur.

You might receive this error as a Notification event in the profiler trace:

```
Transaction errors: Aborting transaction on session <victimsessionid>
```

The victim processing job will likely be canceled with this error:

```
Transaction errors: While attempting to acquire one or more locks, the transaction was canceled.
```

Proposed remedies for locking conflict between processing jobs

1. Schedule processing in a staggered manner. Remember that the end time is more important than the start time because the commit phase is the time where the high-granularity commit locks are needed.
2. Combine processing into a single transaction/batch XMLA tag. If you process objects in the scope of a single transaction, maybe they won't collide and kill each other. You can process parallel objects in a single transaction instead of in a sequence of small commits. You could have a larger, more granular commit to reduce the window in which locks occur, but you're increasing the surface area of the number of locks at lower-level granularity. This might increase conflict with user queries. For example, you can have multiple processing commands in a single batch.

```

<Batch xmlns="http://schemas.microsoft.com/analysiservices/2003/engine">
  <Parallel>

      <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
    </Process>
  </Parallel>
</Batch>

```

3. Process on one server and sync to another server to ensure these processes don't interfere with each other.

How do you see these locks and blocking chains?

Starting with SQL Server 2008 R2 Service Pack 1, there are some great profiler trace events that help you see these locks. XML tags within the text of the trace events show who's waiting and which locks are held. Collect a profiler trace with the ordinary events, but add these events to see who's blocking whom and for how long, and on which objects the locks are conflicting.

The Lock Acquired event indicates when the transaction has obtained a batch of locks for the processing of the transaction. The Lock Released event indicates when the transaction has released a batch of locks that the transaction requested. This event also indicates the duration that the locks are held. The Lock Waiting event indicates when a transaction tries and waits in a queue to obtain a lock in a batch. This information is in the TextData column of those events. This information includes the following additional related data:

- The transaction ID
- The LockList XML node
- The WaitList XML node
- The HoldList XML node

The Lock Acquired event and the Lock Released event contain the LockList information. The Lock Waiting event contains the LockList, WaitList, and HoldList information.

LockList

The LockList node contains the following information:

- Lock type
- Lock status
- Object path of the object that's being requested
- Object ID

NOTE

The object path is reported without a namespace. The Lock Released event additionally contains the **Duration** property. The **Duration** property indicates the duration that the lock is held in milliseconds.

The following is an example of the LockList node:

```
<LockList>
<Lock>
<Type>Read</Type>
<LockStatus>Acquired</LockStatus>
<Object><DatabaseID>AdventureWorks</DatabaseID></Object>
<ObjectID>asadfb-vfbvadr-ft3323-54235</ObjectID>
</Lock>
<Lock>
<Type>Read</Type>
<LockStatus>Waiting</LockStatus>
<Object><DatabaseID>FoodMart</DatabaseID><Object>
<ObjectID>asadfb-vfbvadr-ft3323-54235</ObjectID>
</Lock>
<Lock>
<Type>Read</Type>
<LockStatus>Requested</LockStatus>
<Object><DatabaseID>FoodMart</DatabaseID><Object>
<ObjectID>asadfb-vfbvadr-ft3323-54235</ObjectID>
</Lock>
</LockList>
```

In this example, the transaction requests three locks, obtains one, and waits for the second lock.

WaitList

The WaitList node lists the waiting transactions that are ahead of the current transaction. The following is an example of the WaitList node:

```

<WaitList>
  <Object><DatabaseID>FoodMart</DatabaseID><Object>
  <ObjectID>asadfb-vfbvadr-ft3323-54235</ObjectID>
  <Type>Read</Type>
  <Transaction>
    <TransactionID>2342-3we-dsdf-sdf<TransactionID>
    <SPID>234</SPID>
    <Type>Write</Type>
      </Transaction>
    <Transaction>
      <TransactionID>2ger342-3rtee-dsdf-sdf<TransactionID>
      <SPID>222</SPID>
      <Type>Read</Type>
        </Transaction>
    </Transaction>
  </WaitList>

```

HoldList

The HoldList node lists transactions that hold a lock that the current transaction tries to obtain. The following is an example of the HoldList node:

```

<HoldList>
  <Object><DatabaseID>FoodMart</DatabaseID><Object>
  <ObjectID>asadfb-vfbvadr-ft3323-54235</ObjectID>
  <Type>Read</Type>
  <Transaction>
    <TransactionID>2342-3we-dsdf-sdf<TransactionID>
    <SPID>234</SPID>
    <Type>Write</Type>
      </Transaction>
    <Transaction>
      <TransactionID>2ger342-3rtee-dsdf-sdf<TransactionID>
      <SPID>222</SPID>
      <Type>Read</Type>
        </Transaction>
    </Transaction>
  </HoldList>

```

In SQL Server 2008 Analysis Services or later versions, you can run an MDX query on the dynamic management views to see the various connections, their transactions, and who's granted locks and who's waiting on locks (blocking).

```

select * from $system.discover_connections;
go
select * from $system.discover_sessions;
go
select * from $system.discover_transactions;
go
select * from $system.discover_locks;
go
select * from $system.discover_jobs
go

```

Roles and Permissions (Analysis Services)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Analysis Services provides a role-based authorization model that grants access to operations, objects, and data. All users who access an Analysis Services instance or database must do so within the context of a role.

As an Analysis Services system administrator, you are in charge of granting membership to the **server administrator role** that conveys unrestricted access to operations on the server. This role has fixed permissions and cannot be customized. By default, members of the local Administrators group are automatically Analysis Services system administrators.

Non-administrative users who query or process data are granted access through **database roles**. Both system administrators and database administrators can create the roles that describe different levels of access within a given database, and then assign membership to every user who requires access. Each role has a customized set of permissions for accessing objects and operations within a particular database. You can assign permissions at these levels: database, interior objects such as cubes and dimensions (but not perspectives), and rows.

It is common practice to create roles and assign membership as separate operations. Often, the model designer adds roles during the design phase. This way, all role definitions are reflected in the project files that define the model. Role membership is typically rolled out later as the database moves into production, usually by database administrators who create scripts that can be developed, tested, and run as an independent operation.

All authorization is predicated on a valid Windows user identity. Analysis Services uses Windows authentication exclusively to authenticate user identities. Analysis Services provides no proprietary authentication method. See [Authentication methodologies supported by Analysis Services](#).

IMPORTANT

Permissions are additive for each Windows user or group, across all roles in the database. If one role denies a user or group permission to perform certain tasks or view certain data, but another role grants this permission to that user or group, the user or group will have permission to perform the task or view the data.

[Create and Manage Roles](#)

Authorizing access to objects and operations (Analysis Services)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Non-administrative user access to cubes, dimensions, and mining models within an Analysis Services database is granted through membership in one or more database roles. Analysis Services administrators create these database roles, granting Read or Read/Write permissions on Analysis Services objects, and then assigning Microsoft Windows users and groups to each role.

Analysis Services determines the effective permissions for a specific Windows user or group by combining the permissions that are associated with each database role to which the user or group belongs. As a result, if one database role does not give a user or group permission to view a dimension, measure, or attribute, but a different database role does give that user or group permission, the user or group will have permission to view the object.

IMPORTANT

Members of the Analysis Services Server Administrator role and members of a database role having Full Control (Administrator) permissions can access all data and metadata in the database and need no additional permissions to view specific objects. Moreover, members of the Analysis Services server role cannot be denied access to any object in any database, and members of an Analysis Services database role that has Full Control (Administrator) permissions within a database cannot be denied access to any object within that database. Specialized administrative operations, such as processing, can be authorized through separate roles having less permission. See [Grant process permissions \(Analysis Services\)](#) for details.

List roles defined for your database

Administrators can run a simple DMV query in SQL Server Management Studio to get a list of all roles defined on the server.

1. In SSMS, right-click a database and select **New Query | MDX**.
2. Type the following query and press F5 to execute:

```
Select * from $SYSTEM.DBSchema_CATALOGS
```

Results include the database name, description, role name, and the date last modified. Using this information as a starting point, you can proceed to individual databases to check membership and permissions of a specific role.

Top-down overview of Analysis Services authorization

This section covers the basic workflow for configuring permissions.

Step 1: Server Administration

As a first step, decide who will have administrator rights at the server level. During installation, the local administrator who installs SQL Server is required to specify one or more Windows accounts as the Analysis Services server administrator. Server administrators have all possible permissions on a server, including the

permission to view, modify, and delete any object on the server, or view associated data. After installation is complete, a server administrator can add or remove accounts to change membership of this role. See [Grant server admin rights to an Analysis Services instance](#) for details about this permission level.

Step 2: Database Administration

Next, after a tabular or multidimensional solution is created, it is deployed to the server as a database. A server administrator can delegate database administration tasks by defining a role that has Full Control permissions for the database in question. Members of this role can process or query objects in the database, as well as create additional roles for accessing cubes, dimensions, and other objects within the database itself. See [Grant database permissions \(Analysis Services\)](#) for more information.

Step 3: Enable cube or model access for query and processing workloads

By default, only server and database administrators have access to cubes or tabular models. Making these data structures available to other people in your organization requires additional role assignments that map Windows user and group accounts to cubes or models, along with permissions that specify **Read** privileges. See [Grant cube or model permissions \(Analysis Services\)](#) for details.

Processing tasks can be isolated from other administrative functions, allowing server and database administrators to delegate this task to other people, or to configure unattended processing by specifying service accounts that run scheduling software. See [Grant process permissions \(Analysis Services\)](#) for details.

NOTE

Users do not require any permissions to the relational tables in the underlying relational database from which Analysis Services loads its data, and do not require any file level permissions on the computer on which the instance of Analysis Services is running.

Step 4 (Optional): Allow or deny access to interior cube objects

Analysis Services provides security settings for setting permissions on individual objects, including dimension members and cells within a data model. For details, see [Grant custom access to dimension data \(Analysis Services\)](#) and [Grant custom access to cell data \(Analysis Services\)](#).

You can also vary permissions based on user identity. This is often referred to as dynamic security, and is implemented using the [UserName \(MDX\)](#) function

Best practices

To better manage permissions, we suggest an approach similar to the following:

1. Create roles by function (for example, dbadmin, cubedeveloper, processadmin) so that whoever maintains the roles can see at glance what the role allows. As noted elsewhere, you can define roles in the model definition, thus preserving those roles over subsequent solution deployments.
2. Create a corresponding Windows security group in Active Directory, and then maintain the security group in Active Directory to insure it contains the appropriate individual accounts. This places the responsibility of security group membership on security specialists who are already have proficiency with the tools and processes used for account maintenance in your organization.
3. Generate scripts in SQL Server Management Studio so that you can quickly replicate role assignments whenever the model is redeployed from its source files to a server. See [Grant cube or model permissions \(Analysis Services\)](#) for details on how to quickly generate a script.
4. Adopt a naming convention that reflects the scope and membership of the role. Role names are only visible in design and administration tools, so use a naming convention that makes sense to your cube

security specialists. For example, **processadmin-windowsgroup1** indicates read access, plus processing rights, to people in your organization whose individual Windows user accounts are members of the **windowsgroup1** security group.

Including account information can help you keep track of which accounts are used in various roles. Because roles are additive, the combined roles associated with **windowsgroup1** make up the effective permission set for people belonging to that security group.

5. Cube developers will require Full Control permissions for models and databases under development, but only need Read permissions once a database is rolled out to a production server. Remember to develop role definitions and assignments for all scenarios, including development, test, and production deployments.

Using an approach like this one minimizes churn to role definitions and role membership in the model, and provides visibility into role assignments that makes cube permissions easier to implement and maintain.

Grant database permissions (Analysis Services)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

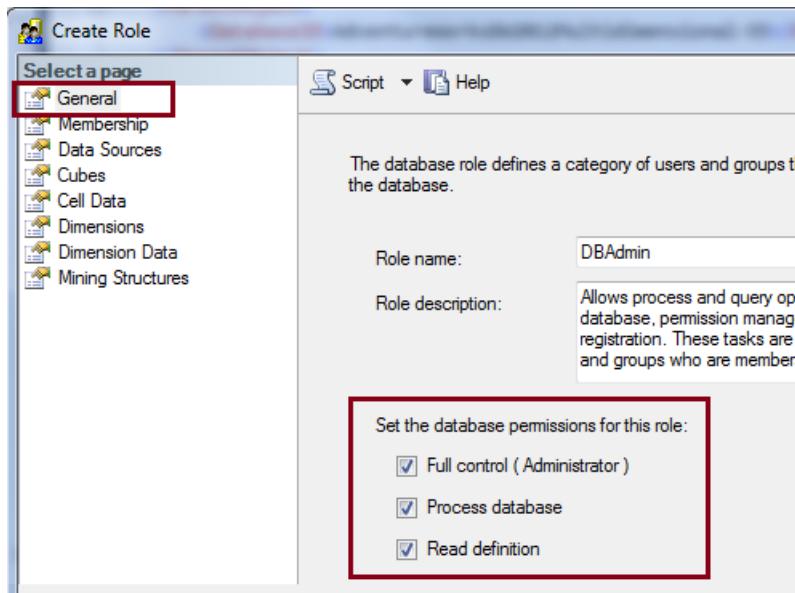

If you are approaching Analysis Services database administration with a background in relational databases, the first thing you need to understand is that, in terms of data access, the database is not the primary securable object in Analysis Services.

The primary query structure in Analysis Services is a cube (or a tabular model), with user permissions set on those particular objects. Contrasted with the relational database engine — where database logins and user permissions (often **db_datareader**) are set on the database itself — an Analysis Services database is mostly a container for the main query objects in a data model. If your immediate objective is to enable data access for a cube or tabular model, you can bypass database permissions for now and go straight to this topic: [Grant cube or model permissions \(Analysis Services\)](#).

Database permissions in Analysis Services enable administrative functions; broadly, as is the case with the Full Control database permission, or of a more granular nature if you are delegating processing operations.

Permission levels for an Analysis Services database are specified on the **General** pane of the **Create Role** dialog box, shown in the following illustration and described below.

There are no logins in Analysis Services. You simply create roles and assign Windows accounts in the **Membership** pane. All users, including administrators, connect to Analysis Services using a Windows account.

There are three types of permissions specified at the database level.

Full Control (Administrator) — Full Control is an all-encompassing permission that conveys broad powers over an Analysis Services database, such as the ability to query or process any object within the database, and manage role security. Full Control is synonymous with database administrator status. When you select **Full Control**, the **Process Database** and **Read Definition** permissions are also selected and cannot be removed.

NOTE

Server administrators (members of the Server Administrator role) also have implicit Full Control over every database on the server.

Process Database — This permission is used to delegate processing at the database level. As an administrator, you can offload this task by creating a role that allows another person or service to invoke processing operations for any object in the database. Alternatively, you can also create roles that enable processing on specific objects. See [Grant process permissions \(Analysis Services\)](#) for more information.

Read Definition — This permission grants the ability to read object metadata, minus the ability to view associated data. Typically this permission is used in roles created for dedicated processing, adding the ability to use tools such as Visual Studio with Analysis Services projects or SQL Server Management Studio to process a database interactively. Without **Read Definition**, the **Process Database** permission is effective only in scripted scenarios. If you plan to automate processing, perhaps through SSIS or another scheduler, you probably want to create a role that has **Process Database** without **Read Definition**. Otherwise, consider combining the two properties together in the same role to support both unattended and interactive processing via SQL Server tools that visualize the data model in a user interface.

Full Control (Administrator) permissions

In Analysis Services, a database administrator is any Windows user identity assigned to a role that includes Full Control (Administrator) permissions. A database administrator can perform any task within the database, including:

- Process objects
- Read data and metadata for all objects in the database, including cubes, dimensions, measure groups, perspectives and data mining models
- Create or modify database roles by adding users or permissions, including adding users to roles also having Full Control permissions
- Delete database roles or role membership
- Register assemblies (or stored procedures) for the database.

Notice that a database administrator cannot add or delete databases on the server, or grant administrator rights to other databases on the same server. That privilege belongs to server administrators alone. See [Grant server admin rights to an Analysis Services instance](#) for more information about this permission level.

Because all roles are user-defined, we recommend that you create a role dedicated for this purpose (for example, a role named "dbadmin"), and then assign Windows user and group accounts accordingly.

Create roles in SSMS

1. In SQL Server Management Studio, connect to the instance of Analysis Services, open the **Databases** folder, select a database, and right-click **Roles** | **New Role**.
2. In the **General** pane, enter a name, such as DBAdmin.
3. Select the **Full Control (Administrator)** check box for the cube. Notice that **Process Database** and **Read Definition** are selected automatically. Both of these permissions are always included in roles that include **Full Control**.
4. In the **Membership** pane, enter the Windows user and group accounts that connect to Analysis Services using this role.
5. Click **OK** to finish creating the role.

Process database

When defining a role that grants database permissions, you can skip **Full Control** and choose just **Process Database**. This permission, set at the database level, allows processing on all objects within the database. See

Read definition

Like **Process Database**, setting **Read Definition** permissions at the database level has a cascading effect on other objects within the database. If you want to set Read Definition permissions at a more granular level, you must clear Read Definition as a database property in the General pane. See [Grant read definition permissions on object metadata \(Analysis Services\)](#) for more information.

[Grant server admin rights to an Analysis Services instance](#)

[Grant process permissions \(Analysis Services\)](#)

Grant cube or model permissions (Analysis Services)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A cube or tabular model is the primary query object in an Analysis Services data model. When connecting to multidimensional or tabular data from Excel for ad hoc data exploration, users typically start by selecting a specific cube or tabular model as the data structure behind the Pivot report object. This topic explains how to grant the necessary permissions for cube or tabular data access.

By default, no one except a Server Administrator or Database Administrator has permission to query cubes in a database. Cube access by a non-administrator requires membership in a role created for the database containing the cube. Membership is supported for Windows user or group accounts, defined in either Active Directory or on the local computer. Before you start, identify which accounts will be assigned membership in the roles you are about to create.

Having **Read** access to a cube also conveys permissions on the dimensions, measure groups, and perspectives within it. Most administrators will grant read permissions at the cube level and then restrict permissions on specific objects, on associated data, or by user identity.

To preserve role definitions over successive solution deployments, a best practice is to define roles in Visual Studio with Analysis Services projects as an integral part of the model, and then have a database administrator assign role memberships in SQL Server Management Studio after the database is published. But you can use either tool for both tasks. To simplify the exercise, we'll use SQL Server Management Studio for both role definition and membership.

NOTE

Only server administrators, or database administrators having Full Control permissions, can deploy a cube from source files to a server, or create roles and assign members. See [Grant server admin rights to an Analysis Services instance](#) and [Grant database permissions \(Analysis Services\)](#) for details about these permission levels.

Step 1: Create the role

1. In SSMS, connect to Analysis Services. See [Connect from client applications \(Analysis Services\)](#) if you need help with this step.
2. Open the **Databases** folder in Object Explorer, and select a database.
3. Right-click **Roles** and choose **New Role**. Notice that roles are created at the database level and apply to objects within it. You cannot share roles across databases.
4. In the **General** pane, enter a name, and optionally, a description. This pane also contains several database permissions, such as Full Control, Process Database, and Read Definition. None of these permissions are needed for querying a cube or tabular model. See [Grant database permissions \(Analysis Services\)](#) for more information about these permissions.
5. Continue to the next step after entering a name and optional description.

Step 2: Assign Membership

1. In the **Membership** pane, click **Add** to enter the Windows user or group accounts that will be accessing the cube using this role. Analysis Services only supports Windows security identities. Notice that you are not creating database logins in this step. In Analysis Services, users connect through Windows accounts.

2. Continue to the next step, setting cube permissions.

Notice that we are skipping the Data Source pane. Most regular consumers of Analysis Services data do not need permissions on the data source object. See [Grant permissions on a data source object \(Analysis Services\)](#) for details on when you might set this permission.

Step 3: Set Cube Permissions

1. In the **Cubes** pane, select a cube, and then click **Read** or **Read/Write** access.

Read access is sufficient for most operations. **Read/Write** is used only for writeback, not processing. See [Set Partition Writeback](#) for more information about this capability.

Notice that you can select multiple cubes, as well as other objects available in the Create Role dialog box. Granting permissions to a cube authorizes access to the dimensions and perspectives associated with the cube. It's not necessary to manually add objects already represented in the cube.

If you need to vary authorization by objects or user, for example to make certain measures unavailable, you can allow or deny access atomically on specific objects, even on cells. See [Grant custom access to dimension data \(Analysis Services\)](#) and [Grant custom access to cell data \(Analysis Services\)](#) for details.

2. At this point, after you click **OK**, all members of this role have access to the cubes, at the permission levels you specified.

Notice that on the **Cubes** pane, you can grant users permission to create local cubes from a server cube via **Drillthrough and Local Cube**, or allow drillthrough only, via the **Drillthrough** permission.

Finally, this pane lets you grant **Process Database** rights on the cube to give all members of this role the ability to process data for this cube. Because processing is typically a restricted operation, we recommend that you leave that task to the administrators, or define separate roles specifically for that task. See [Grant process permissions \(Analysis Services\)](#) for more information about processing permission best practices.

Step 4: Test

1. Use Excel to test cube access permissions. You can also use SQL Server Management Studio, following the same technique described next – running the application as a non-administrator user.

NOTE

If you are an Analysis Services administrator, administrator permissions will be combined with roles having lesser permissions, making it difficult to test role permissions in isolation. To simplify testing, we suggest that you open a second instance of SSMS, using the account assigned to the role you are testing.

2. Hold-down the Shift key and right-click the **Excel** shortcut to access the **Run as different user** option. Enter one of the Windows user or group accounts having membership in this role.
3. When Excel opens, use the Data tab to connect to Analysis Services. Because you are running Excel as a different Windows user, the **Use Windows Authentication** option is the right credential type to use when testing roles. See [Connect from client applications \(Analysis Services\)](#) if you need help with this step.

If you get errors on the connection, check the port configuration for Analysis Services and verify that the server accepts remote connections. See [Configure the Windows Firewall to Allow Analysis Services Access](#) for port configuration.

Step 5: Script role definition and assignments

1. As a final step, you should generate a script that captures the role definition you just created.

Redeploying a project from Visual Studio with Analysis Services projects will overwrite any roles or role memberships that are not defined inside the project. The quickest way to rebuild roles and role

membership after redeployment is through script.

2. In SSMS, navigate to the **Roles** folder and right-click an existing role.
3. Select **Script Role as | CREATE TO | file**.
4. Save the file with an .xmla file extension. To test the script, delete the current role, open the file in SSMS, and press F5 to execute the script.

Next step

You can refine cube permissions to restrict access to cell or dimension data. See [Grant custom access to dimension data \(Analysis Services\)](#) and [Grant custom access to cell data \(Analysis Services\)](#) for details.

[Grant permissions on data mining structures and models \(Analysis Services\)](#)

[Grant permissions on a data source object \(Analysis Services\)](#)

Grant process permissions (Analysis Services)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

As an administrator, you can create a role dedicated to Analysis Services processing operations, allowing you to delegate that particular task to other users, or to applications used for unattended scheduled processing. Process permissions can be granted at the database, cube, dimension, and mining structure levels. Unless you are working with a very large cube or tabular database, we recommend granting processing rights at the database level, inclusive of all objects, including those having dependencies on each other.

Permissions are granted through roles that associate objects with permissions and Windows user or group accounts. Remember that permissions are additive. If one role grants permission to process a cube, while a second role gives the same user permission to process a dimension, the permissions from the two different roles combine to give the user permission to both process the cube and process the specified dimension within that database.

IMPORTANT

A user whose role only has Process permissions will be unable to use SQL Server Management Studio or Visual Studio with Analysis Services projects to connect to Analysis Services and process objects. These tools require the **Read Definition** permission to access object metadata. Without the ability to use either tool, XMLA script must be used to execute a processing operation.

We suggest you also grant **Read Definition** permissions for testing purposes. A user having both **Read Definition** and **Process Database** permissions can process objects in SQL Server Management Studio, interactively. See [Grant read definition permissions on object metadata \(Analysis Services\)](#) for details.

Set processing permissions at the database level

This section explains how to enable processing by non-administrators, for all cubes, dimensions, mining structures, and mining models in the database.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, open the Databases folder, and select a database.
2. Right-click **Roles** | **New Role**. Enter a name and description.
3. In the **General** pane, select the **Process Database** check box. Additionally, select **Read Definition** to also enable interactive processing through one of the SQL Server tools, such as SQL Server Management Studio.
4. In the **Membership** pane, add the Windows user and group accounts having permission to process any object in this database.
5. Click **OK** to complete the role definition.

Set processing permissions on individual objects

You can set processing permissions on individual cubes, dimensions, data mining structures or models.

Processing can fail if you inadvertently exclude objects that need to be processed together (for example, if you enable processing on a cube, but not on its related dimensions). Because it can be easy to miss object

dependencies, thorough testing is essential when setting processing permissions on individual objects.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, open the Databases folder, and select a database.
2. Right-click **Roles | New Role**. Enter a name and description.
3. In the **General** pane, clear the **Process Database** check box. Database permissions override the ability to set permissions on lower-level objects by making role options grayed out or un-selectable.

Technically, no database permissions are needed for dedicated processing roles. But without **Read Definition** at the database level, you cannot view the database in SQL Server Management Studio, making testing more difficult.

4. Select individual objects to process:
 - In the **Cubes** pane, select the **Process** check box for each cube.
 - In the **Dimensions** pane, select **All database dimensions**, and then **Process** check box for each dimension. Or, select all rows, then use shift-click to toggle the check box selections.
5. In the **Membership** pane, add the Windows user and group accounts having permission to process these objects.
6. Click **OK** to complete the role definition.

Test processing

1. Hold down the shift-key and right-click SQL Server Management Studio, select **Run as a different user** and connect to the instance of Analysis Services using a Windows account assigned to the role you are testing.
2. Open the Databases folder, and select a database. You will only see the databases that are visible to the roles for which your account has membership.
3. Right-click a cube or dimension and select **Process**. Choose a processing option. Test all of the options, for all combinations of objects. If errors occur due to missing objects, add the objects to the role.

Set processing permissions on a data mining structure

You can create a role granting permission to process data mining structures. This includes the processing of all mining models.

Drill Through and **Read Definition** permissions used for browsing a mining model and structure are atomic and can be added to the same role, or separated out into a different role.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, open the Databases folder, and select a database.
2. Right-click **Roles | New Role**. Enter a name and description. In the **General** pane, make sure that the database permission check boxes are clear. Database permissions will override the ability to set permissions on lower-level objects by making role options grayed out or un-selectable.
3. In the **Mining Structures** pane, select the **Process** check box for each mining structure.
4. In the **Membership** pane, add the Windows user and group accounts having permission to process any object in this database.
5. Click **OK** to complete the role definition.

See Also

- [Process Database, Table, or Partition \(Analysis Services\)](#)

Grant read definition permissions on object metadata (Analysis Services)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Permission to read an object definition, or metadata, on selected objects lets an administrator grant permission to view object information, without also granting permission to modify the object's definition, modify the object's structure, or view the actual data for the object. **Read Definition** permissions can be granted at the database, data source, dimension, mining structure, and mining model levels. If you require **Read Definition** permissions for a cube, you must enable **Read Definition** for the database. Remember that permissions are additive. For example, one role grants permission to read the metadata for a cube, while a second role grants the same user permission to read the metadata for a dimension. The permissions from the two different roles combine to give the user permission to both read metadata for the cube and the metadata for the dimension within that database.

NOTE

Permission to read a database's metadata is the minimum permission required to connect to an Analysis Services database using either Management Studio or Visual Studio with Analysis Services projects. A user who has permission to read metadata can also use the DISCOVER_XML_METADATA schema rowset to query the object and view its metadata. For more information, see [DISCOVER_XML_METADATA Rowset](#).

Set read definition permissions on a database

Granting permission to read database metadata also grants permission to read the metadata of all objects in the database.

We suggest that you include the **Read Definition** permission at the database level whenever you are setting up roles for dedicated processing. Having **Read Definition** allows non-administrators to view a model's object hierarchy in SQL Server Management Studio and navigate to individual objects for subsequent processing.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, expand **Roles** for the appropriate database in Object Explorer, and then click a database role (or create a new database role).
2. On the **General** tab, select the **Read Definition** option.
3. In the **Membership** pane, enter the Windows user and group accounts that connect to Analysis Services using this role.
4. Click **OK** to finish creating the role.

Set read definition permissions on individual objects

1. In SQL Server Management Studio, connect to the instance of Analysis Services, open the **Databases** folder, select a database, expand **Roles** for the appropriate database in Object Explorer, and then click a database role (or create a new database role).
2. In the **General** pane, clear the database permission for **Read Definition**. This step removes permission inheritance so that you can set permissions on individual objects.
3. Select the object for which you are specifying **Read Definition** properties:

- In the **Data Sources** pane, click the **Read Definition** check box for that data source. Role members can view the connection string to the data source, including the server name and possibly the user name. This permission is available in case you want to provide connection string information, without also granting permission to modify the connection string or view the definitions of any other objects.
 - In the **Dimensions** pane, click the **Read Definition** check box for that dimension. Experienced analysts and developers may need to view the definition without permission to modify it or view the definitions of other objects (such as other dimensions, cube objects, or mining structures and models).
 - In the Mining Structures pane, click the **Read Definition** check box for data mining structures or models. **Read Definition** is required for browsing the data model. See [Grant permissions on data mining structures and models \(Analysis Services\)](#) for details.
4. In the **Membership** pane, enter the Windows user and group accounts that connect to Analysis Services using this role.
5. Click **OK** to finish creating the role.

[Grant database permissions \(Analysis Services\)](#)
[Grant process permissions \(Analysis Services\)](#)

Grant permissions on a dimension (Analysis Services)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Dimension security is used to set permissions on a dimension object, not its data. Typically, allowing or denying access to processing operations is the main objective when setting permissions on a dimension.

But perhaps your objective is not to control processing operations, but rather data access to a dimension, or the attributes and hierarchies it contains. For example, a company with regional sales divisions might want to make sales performance information off limits to those outside the division. To allow or deny access to portions of dimension data for different constituents, you can set permissions on dimension attributes and dimension members. Notice that you cannot deny access to an individual dimension object itself, only to its data. If your immediate goal is to allow or deny access to members in a dimension, including access rights to individual attribute hierarchies, see [Grant custom access to dimension data \(Analysis Services\)](#) for more information.

The remainder of this topic covers permissions that you can set on the dimension object itself, including:

- Read or Read/Write permissions (you can only choose from Read or Read/Write; specifying "none" is not an option). As noted, if your goal is to restrict access to dimension data, see [Grant custom access to dimension data \(Analysis Services\)](#) for details.
- Processing permissions (do this when scenarios require a processing strategy that calls for custom permissions on individual objects)
- Read definition permissions (typically you would do this to support interactive processing in a tool, or to provide visibility into a model. Read definition lets you see the structure of a dimension, without permission to its data or the ability to modify its definition).

When defining roles for a dimension, available permissions vary depending on whether the object is a standalone database dimension—internal to the database but external to a cube—or a cube dimension.

NOTE

By default, permissions on a database dimension are inherited by a cube dimension. For example, if you enable **Read/Write** on a Customer database dimension, the Customer cube dimension inherits **Read/Write** in the context of the current role. You can clear inherited permissions if you want to override a permission setting.

Set permissions on a database dimension

Database dimensions are standalone objects within a database, allowing for dimension reuse within the same model. Consider a DATE database dimension that is used multiple times in a model, as Order Date, Ship Date, and Due Date cube dimensions. Because cubes and database dimensions are peer objects in a database, you can set processing permissions independently on each object.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, expand **Roles** for the appropriate database in Object Explorer, and then click a database role (or create a new database role).
2. In the **Dimensions** pane, the dimension set should be set to **All database dimensions**.

By default, permissions are set to **Read**.

Although **Read/Write** is available, we recommend that you do not use this permission. **Read/Write** is

used for dimension writeback scenarios, which have been deprecated.

Optionally, you can set **Read Definition** and **Process** permissions on individual dimension objects, as long as those permissions are not already set at the database level. See [Grant process permissions \(Analysis Services\)](#) and [Grant read definition permissions on object metadata \(Analysis Services\)](#) for details.

Set permissions on a cube dimension

Cube dimensions are database dimensions that have been added to a cube. As such, they are structurally dependent on associated measure groups. Although you can process these objects atomically, in terms of authorization, it makes sense to treat the cube and cube dimensions as a single entity.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, expand **Roles** for the appropriate database in Object Explorer, and then click a database role (or create a new database role).
2. In the **Dimensions** pane, change the dimension set to <cube-name> **cube dimensions**.

By default, permissions are inherited from a corresponding database dimension. Clear the **Inherit** check box to alter permissions from **Read** to **Read/Write**. Before using **Read/Write**, be sure to read the note in the previous section.

IMPORTANT

If you configure database role permissions by using Analysis Management Objects (AMO), any reference to a cube dimension in a cube's DimensionPermission attribute severs the permission inheritance from the database's DimensionPermission attribute. For more information about AMO, see [Developing with Analysis Management Objects \(AMO\)](#).

Grant custom access to dimension data (Analysis Services)

8/27/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

After enabling read access to a cube, you can set additional permissions that explicitly allow or deny access to dimension members (including measures contained in the Measures Dimension containing all of the measures used in a cube). For example, given multiple categories of resellers, you might want to set permissions to exclude data for a specific business type. The following illustration is a before-and-after effect of denying access to the Warehouse business type in the Reseller dimension.

Row Labels	Reseller Sales Amount	Reseller Total Product Cost	Reseller Gross Profit
Specialty Bike Shop	\$6,756,166.18	\$6,728,368.53	\$27,797.65
Value Added Reseller	\$34,967,517.33	\$34,520,042.39	\$447,474.93
Warehouse	\$38,726,913.48	\$38,731,703.45	(\$4,789.98)
Grand Total	\$80,450,596.98	\$79,980,114.38	\$470,482.60

Row Labels	Reseller Sales Amount	Reseller Total Product Cost	Reseller Gross Profit
Specialty Bike Shop	\$6,756,166.18	\$6,728,368.53	\$27,797.65
Value Added Reseller	\$34,967,517.33	\$34,520,042.39	\$447,474.93
Grand Total	\$80,450,596.98	\$79,980,114.38	\$470,482.60

By default, if you can read data from an Analysis Services cube, you automatically have read permissions on all measures and dimension members associated with that cube. While this behavior might be sufficient for many scenarios, sometimes security requirements call for a more segmented authorization strategy, with varying levels of access for different users, on the same dimension.

You can restrict access by choosing which members to allow (AllowedSet) or deny (DeniedSet) access. You do this by either selecting or deselecting dimension members to include or exclude from the role.

Basic dimension security is the easiest; you simply select which dimension attributes and attribute hierarchies to include or exclude in the role. Advanced security is more complex and requires expertise in MDX scripting. Both approaches are described below.

NOTE

The following instructions assume a client connection that issues queries in MDX. If the client uses DAX, such as Power View in Power BI, then dimension security is not evident in the query results.

Prerequisites

Not all measures or dimension members can be used in custom access scenarios. A connection will fail if a role restricts access to a default measure or member, or restricts access to measures that are part of measure expressions.

Check for obstructions to dimension security: default measures, default members, and measures used in measure expressions

1. In SQL Server Management Studio, right-click a cube and select **Script Cube as | ALTER To | New Query Editor Window**.
2. Search for **DefaultMeasure**. You should find one for the cube, and one for each perspective. When

defining dimension security, avoid restricting access to default measures.

3. Next, search for **MeasureExpression**. A measure expression is a measure, based on a calculation, where the calculation often includes other measures. Verify that the measure you want to restrict is not used in an expression. Alternatively, go ahead and restrict access, just make sure to also exclude all references to that measure throughout the cube.
4. Finally, search for **DefaultMember**. Make a note of any attributes that serve as a default member of an attribute. Avoid putting restrictions on those attributes when setting up dimension security.

Basic dimension security

1. In SQL Server Management Studio, connect to the instance of Analysis Services, expand **Roles** for the appropriate database in Object Explorer, and then click a database role (or create a new database role).
The role should already have read access to the cube. See [Grant cube or model permissions \(Analysis Services\)](#) if you need help with this step.
2. On **Dimension Data | Basic**, select the dimension for which you are setting permissions.
3. Choose the attribute hierarchy. Not all attributes will be available. Only those attributes having **AttributeHierarchyEnabled** appear in the **Attribute Hierarchy** list.
4. Choose which members to allow or deny access. Allowing access, through the **Select all members** option, is the default. We suggest you keep this default and then clear individual members that should not be visible to the Windows user and group accounts in the **Memberships** pane via this role. The advantage is that new members added in future processing operations are automatically available to people connecting through this role.
Alternatively, you can **Deselect all members** to revoke access overall, and then pick which members to allow. In future processing operations, new members are not visible until you manually edit dimension data security to allow access to them.
5. Optionally, click **Advanced** to enable **Visual Totals** for this attribute hierarchy. This option recalculates aggregations based on the members available through the role.

NOTE

When applying permissions that trim dimension members, aggregated totals are not recalculated automatically. Suppose the **All** member of an attribute hierarchy returns a count of 200 before permissions are applied. After applying permissions that deny access to some members, **All** still returns 200, even though the member values visible to the user are much less. To avoid confusing the consumers of your cube, you can configure the **All** member be the aggregate of just those members to which role members, rather than the aggregate of all of the members of the attribute hierarchy. To invoke this behavior, you can enable **Visual Totals** on the **Advanced** tab when configuring dimension security. Once enabled, the aggregate is calculated at query time rather than retrieved from pre-calculated aggregations. This can have a noticeable effect on query performance, so use it only when necessary.

Hiding measures

In [Grant custom access to cell data \(Analysis Services\)](#), it was explained that fully hiding all visual aspects of a measure, and not just its cell data, requires permissions on dimension members. This section explains how to deny access to the object metadata of a measure.

1. On **Dimension Data | Basic**, scroll down the Dimension list until you reach cube dimensions, and then select **Measures Dimension**.

- From the list of measures, clear the check box for measures that should not appear to users connecting via this role.

NOTE

Check the Prerequisites to learn how to identify measures that can break role security.

Advanced dimension security

If you have MDX expertise, another approach is to write MDX expressions that set the criteria for which members are allowed or denied access. Click **Create Role | Dimension Data | Advanced** to provide the script.

You can use the MDX Builder to write the MDX statement. See [MDX Builder \(Analysis Services - Multidimensional Data\)](#) for details. The **Advanced** tab has the following options:

Attribute

Select the attribute for which you want to manage member security.

Allowed member set

The AllowedSet can resolve to no members (default), all members, or some members. If you allow access to an attribute and do not define any members of the allowed set, access to all members is granted. If you allow access to an attribute and define a specific set of attribute members, only the explicitly allowed members are visible.

Creating an AllowedSet has a ripple effect when the attribute participates in a multi-level hierarchy. For example, suppose a role allows access to Washington state (assume a scenario where the role is granting permissions to a company's Washington state sales division). For people connecting through this role, queries that include ancestors (United States) or descendants (Seattle and Redmond) will only see members in a chain including Washington state. Because other states are not explicitly allowed, the effect will be the same as if they were denied.

NOTE

If you define an empty set {} of attribute members, no members of the attribute will be visible to the database role. The absence of an allowed set is not interpreted as an empty set.

Denied member set

The DeniedSet property can resolve to no members, all members (default), or some attribute members. When the denied set contains only a specific set of attribute members, the database role is denied access only to those specific members, as well as descendants if the attribute is in a multi-level hierarchy. Consider the Washington state sales division example. If Washington is placed in the DeniedSet, people connecting through this role will see all other states except Washington and its descendent attributes.

Recall from the previous section that the denied set is a fixed collection. If processing subsequently introduces new members that should also be denied access, you will need to edit this role to add those members to the list.

Default member

The DefaultMember property determines the data set returned to a client when an attribute is not explicitly included in a query. When the attribute is not explicitly included, Analysis Services uses one of the following default members for the attribute:

- If the database role defines a default member for the attribute, Analysis Services uses this default member.
- If the database role does not define a default member for the attribute, Analysis Services uses the default member that is defined for the attribute itself. The default member for an attribute, unless you specify

otherwise, is the **All** member (unless the attribute is defined as non-aggregatable).

For example, suppose a database role specifies **Male** as the default member for the **Gender** attribute. Unless a query both explicitly includes the **Gender** attribute and specifies a different member for this attribute, Analysis Services would return a data set that included only male customers. For more information about setting the default member, see [Define a Default Member](#).

Enable Visual Total

The **VisualTotals** property indicates whether the aggregated cell values that are displayed are calculated according to all cell values or only according to the cell values that are visible to the database role.

By default, the **VisualTotals** property is disabled (set to **False**). This default setting maximizes performance because Analysis Services can quickly calculate the total of all cell values, instead of having to spend time selecting which cells values to calculate.

However, having the **VisualTotals** property disabled could create a security issue if a user can use the aggregated cell values to deduce values for attribute members to which the user's database role does not have access. For example, Analysis Services uses the values for three attribute members to calculate an aggregated cell value. The database role has access to view two of these three attribute members. Using the aggregated cell value, a member of this database role would be able to deduce the value for the third attribute member.

Setting **VisualTotals** property to **True** can eliminate this risk. When you enable the **VisualTotals** property, a database role can only view aggregated totals for dimension members to which the role has permission.

Grant custom access to cell data (Analysis Services)

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Cell security is used to allow or deny access to measure data within a cube. The following illustration shows a combination of allowed and denied measures in a PivotTable, when connected as a user whose role only allows access to certain measures. In this example, **Reseller Sales Amount** and **Reseller Total Product Cost** are the only measures available through this role. All other measures are implicitly denied (the steps used to get this result are provided below in the next section, Allow access to specific measures).

Row Labels	Internet Order Count	Internet Gross Profit	Reseller Average Unit Price	Reseller Sales Amount	Reseller Total Product Cost
Specialty Bike Shop	#N/A	#N/A	#N/A	\$6,756,166.18	\$6,728,368.53
Value Added Reseller	#N/A	#N/A	#N/A	\$34,967,517.33	\$34,520,042.39
Warehouse	#N/A	#N/A	#N/A	\$38,726,913.48	\$38,731,703.45
Grand Total	#N/A	#N/A	#N/A	\$80,450,596.98	\$79,980,114.38

Cell permissions apply to data inside the cell, and not to its metadata. Notice how the cell is still visible in the results of a query, displaying a value of **#N/A** instead of the actual cell value. The **#N/A** value appears in the cell unless the client application translates the value, or another value is specified by setting the Secured Cell Value property in the connection string.

To hide the cell entirely, you have to limit the members-dimensions, dimension attributes, and dimension attribute members—that are viewable. For more information, see [Grant custom access to dimension data \(Analysis Services\)](#).

As an administrator, you can specify whether role members have read, read contingent, or read/write permissions on cells within a cube. Putting permissions on a cell is the lowest level of security allowed, so before you start applying permissions at this level, it's important to keep a few facts in mind:

- Cell-level security cannot expand rights that have been restricted at a higher level. An example: if a role denies access to dimension data, cell-level security cannot override the denied set. Another example: consider a role with **Read** permission on a cube and **Read/Write** permission on a cell — the cell data permission will not be **Read/Write**; it will be **Read**.
- Custom permissions often need to be coordinated between dimension members and cells within the same role. For example, suppose you want to deny access to several discount-related measures for different combinations of resellers. Given **Resellers** as dimension data and **Discount Amount** as a measure, you would need to combine within the same role permissions on both the measure (using the instructions in this topic), as well as on dimension members. See [Grant custom access to dimension data \(Analysis Services\)](#) for details on setting dimension permissions.

Cell-level security is specified through MDX expressions. Because a cell is a tuple (that is, an intersection point across potentially multiple dimensions and measures), it is necessary to use MDX to identify specific cells.

Allow access to specific measures

You can use cell security to explicitly choose which measures are available. Once you specifically identify which members are allowed, all other measures become unavailable. This is perhaps the simplest scenario to implement via MDX script, as the following steps illustrate.

1. In SQL Server Management Studio connect to the instance of Analysis Services, select a database, open the **Roles** folder, and then click a database role (or create a new database role). Membership should already be specified, and the role should have **Read** access to the cube. See [Grant cube or model](#)

permissions (Analysis Services) if you need help with this step.

2. In **Cell Data**, check the cube selection to be sure you have chosen the right one, and then select **Enable read permissions**.

If you select just this check box, and do not provide an MDX expression, the effect is the same as denying access to all cells in the cube. This is because the default allowed set is an empty set whenever Analysis Services resolves a subset of cube cells.

3. Enter the following MDX expression.

```
(Measures.CurrentMember IS [Measures].[Reseller Sales Amount]) OR (Measures.CurrentMember IS [Measures].[Reseller Total Product Cost])
```

This expression explicitly identifies which measures are visible to users. No other measures will be available to users connecting through this role. Notice that **CurrentMember (MDX)** sets the context and is followed by the measure that is allowed. The effect of this expression is, if the current member includes either the **Reseller Sales Amount** or the **Reseller Total Product Cost**, show the value. Otherwise, deny access. The expression has multiple parts, with each part enclosed in parentheses. The **OR** operator is used to specify multiple measures.

Deny access to specific measures

The following MDX expression, also specified in **Create Role | Cell Data | Allow reading of cube content**, has the opposite effect, making certain measures unavailable. In this example, **Discount Amount** and **Discount Percentage** are made unavailable using the **NOT** and **AND** operators. All other measures will be visible to users connecting through this role.

```
(NOT Measures.CurrentMember IS [Measures].[Discount Amount]) AND (NOT Measures.CurrentMember IS [Measures].[Discount Percentage])
```

In Excel, cell-security is evident in the following illustration:

A	B	C	D
Row Labels	Reseller Sales Amount	Discount Amount	Discount Percentage
Specialty Bike Shop	\$6,756,166.18	#N/A	#N/A
Value Added Reseller	\$34,967,517.33	#N/A	#N/A
Warehouse	\$38,726,913.48	#N/A	#N/A
Grand Total	\$80,450,596.98	#N/A	#N/A

Set Read permissions on calculated measures

Permissions on a calculated measure can be set independently of its constituent parts. Skip ahead to the next section on Read-Contingent if you want to coordinate permissions between a calculated measure and its dependent measures.

To understand how Read permissions work for a calculated measure, consider **Reseller Gross Profit** in AdventureWorks. It's derived from **Reseller Sales Amount** and **Reseller Total Product Cost** measures. As long as a role has Read permission on **Reseller Gross Profit** cells, this measure is viewable even if permissions are expressly denied on the other measures. As a demonstration, copy the following MDX expression into **Create Role | Cell Data | Allow reading of cube content**.

```
(NOT Measures.CurrentMember IS [Measures].[Reseller Sales Amount])  
AND (NOT Measures.CurrentMember IS [Measures].[Reseller Total Product Cost])
```

In Excel, connect to the cube using the current role, and choose all three measures to see the effects of cell

security. Notice that measures in the denied set are unavailable, but the calculated measure is visible to the user.

Row Labels	Reseller Sales Amount	Reseller Total Product Cost	Reseller Gross Profit
Specialty Bike Shop	#N/A	#N/A	\$27,797.65
Value Added Reseller	#N/A	#N/A	\$447,474.93
Warehouse	#N/A	#N/A	(\$4,789.98)
Grand Total	#N/A	#N/A	\$470,482.60

Set Read-Contingent permissions on calculated measures

Cell-security offers an alternative, Read-Contingent, for setting permissions on the related cells participating in a calculation. Consider again the **Reseller Gross Profit** example. When you enter the same MDX expression provided in the previous section, placed this time into the second text area of the **Create Role | Cell data** dialog box (in the text area below **Allow reading of cell content contingent on cell security**), the result is apparent when viewed in Excel. Because **Reseller Gross Profit** is contingent upon **Reseller Sales Amount** and **Reseller Total Product Cost**, gross profit is now inaccessible because its constituent parts are inaccessible.

NOTE

What happens if you set both the Read and Read-Contingent permissions on a cell within the same role? The role will provide Read permissions on the cell, and not Read-Contingent.

Recall from previous sections that selecting just the **Enable read-contingent permissions** checkbox, without providing any MDX expression, denies access to all cells in the cube. This is because the default allowed set is an empty set whenever Analysis Services resolves a subset of cube cells.

Set Read/Write permissions on a cell

Read/write permissions on a cell are used to enable writeback, provided that members have read/write permissions to the cube itself. Permissions that are granted at the cell level cannot be greater than the permissions that are granted at the cube level. See [Set Partition Writeback](#) for details.

Grant permissions on a data source object (Analysis Services)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Typically, most users of Analysis Services do not require access to the data sources that underlie an Analysis Services project. Users ordinarily just query the data within an Analysis Services database. However, in the context of data mining, such as performing predictions based on a mining model, a user has to join the learned data of a mining model with user-provided data. To connect to the data source that contains the user-provided data, the user uses a Data Mining Extensions (DMX) query that contains either the [OPENQUERY \(DMX\)](#) and [OPENROWSET \(DMX\)](#) clause.

To execute a DMX query that connects to a data source, the user must have access to the data source object within the Analysis Services database. By default, only Server Administrators or Database Administrators have access to data source objects. This means that a user cannot access a data source object unless an administrator grants permissions.

IMPORTANT

For security reasons, the submission of DMX queries by using an open connection string in the OPENROWSET clause is disabled.

Set Read permissions to a data source

A database role can be granted either no access permissions on a data source object or read permissions.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, expand **Roles** for the appropriate database in Object explorer, and then click a database role (or create a new database role).
2. In the **Data Source Access** pane, locate the data source object in the **Data Source** list, and then select the **Read** in the **Access** list for the data source. If this option is unavailable, check the **General** pane to see if Full Control is selected. Full Control is already providing permission, you cannot override permissions on the data source.

Working With the Connection String Used by a Data Source Object

The data source object contains the connection string that is used to connect to the underlying data source. This connection string can specify one of the following:

- **Specify a user name and password**

If the connection string that a data source object uses specifies a user name and password, you may want to create multiple data source objects, each with different user accounts. Creating multiple data source objects lets users access certain data source objects and prevents those users from accessing other data source objects. These other data source objects can be used by Analysis Services itself for processing objects, such as cubes and mining models.

- **Specify Windows Authentication**

If the connection string that a data source object uses specifies Windows Authentication, Analysis Services

must be able to impersonate the client. If the data source is on a remote computer, the two computers must be trusted for impersonation by using Kerberos authentication, or the query will typically fail. See [Configure Analysis Services for Kerberos constrained delegation](#) for more information.

If the client does not allow for impersonation (through the Impersonation Level property in OLE DB and other client components), Analysis Services will try to make an anonymous connection to the underlying data source. Anonymous connections to remote data sources rarely succeed, as most data sources do not accept anonymous connections).

Grant permissions on data mining structures and models (Analysis Services)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

By default, only an Analysis Services server administrator has permissions to view data mining structures or mining models in the database. Follow the instructions below to grant permissions to non-administrator users.

Set permissions to access a mining structure

1. In SSMS, connect to Analysis Services. See [Connect from client applications \(Analysis Services\)](#) if you need help with the steps.
2. Open the **Databases** folder, and select a database in Object Explorer.
3. Right-click **Roles** and choose **New Role**.
4. In the General page, enter a name, and optionally, a description. The page also contains several database permissions, such as Full Control, Process Database, and Read Definition. None of these permissions are needed for data mining access. See [Grant database permissions \(Analysis Services\)](#) for more information about database permissions.
5. In the **Mining Structure** pane, select **Read** or **Read/Write** for each data mining structure.
6. In the **Membership** pane, enter the Windows user and group accounts that connect to Analysis Services using this role.
7. Click **OK** to finish creating the role.

Set permissions to access a mining model

For a data mining model, a role can have either **Read** or **Read/Write** permissions, as well as **Drillthrough** and **Read Definition** permissions that allow viewing and browsing the underlying data.

Note If you enable drillthrough on both the mining structure and the mining model, any user who is a member of a role that has drillthrough permissions on the mining model and the mining structure can also view columns in the mining structure, even if those columns are not included in the mining model. Therefore, to protect sensitive information, you should set up the data source view to mask personal information, and allow drillthrough access on the mining structure only when necessary.

To grant read or read/write permissions to a database role, a user must be a member of the Analysis Services server role or a member of an Analysis Services database role that has Full Control (Administrator) permissions.

1. In SQL Server Management Studio, connect to the instance of Analysis Services, expand **Roles** for the appropriate database in Object Explorer, and then click a database role (or create a new database role).
2. In the **Mining Structure** pane, locate the mining model in the **Mining Models** list, and then select **Read**, **Read/Write**, **Drill Through**, or **Browse** for that mining model.
3. In the **Membership** pane, enter the Windows user and group accounts that connect to Analysis Services using this role.
4. Click **OK** to finish creating the role.

To use a data source in a drillthrough query that uses the Data Mining Extensions (DMX) OPENQUERY clause, the database role also needs read/write permission on the appropriate data source object. For more information, see [Grant permissions on a data source object \(Analysis Services\)](#) and [OPENQUERY \(DMX\)](#).

NOTE

By default, the submission of DMX queries by using OPENROWSET is disabled.

Data Mining (SSAS)

8/9/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

IMPORTANT

Data mining is deprecated in SQL Server Analysis Services 2017. Documentation is not updated for deprecated features. To learn more, see [Analysis Services backward compatibility](#).

SQL Server has been a leader in predictive analytics since the 2000 release, by providing data mining in Analysis Services. The combination of Integration Services, Reporting Services, and SQL Server Data Mining provides an integrated platform for predictive analytics that encompasses data cleansing and preparation, machine learning, and reporting. SQL Server Data Mining includes multiple standard algorithms, including EM and K-means clustering models, neural networks, logistic regression and linear regression, decision trees, and naive bayes classifiers. All models have integrated visualizations to help you develop, refine, and evaluate your models. Integrating data mining into business intelligence solution helps you make intelligent decisions about complex problems.

Benefits of Data Mining

Data mining (also called predictive analytics and machine learning) uses well-researched statistical principles to discover patterns in your data. By applying the data mining algorithms in Analysis Services to your data, you can forecast trends, identify patterns, create rules and recommendations, analyze the sequence of events in complex data sets, and gain new insights.

In SQL Server 2017, data mining is powerful, accessible, and integrated with the tools that many people prefer to use for analysis and reporting.

Key Data Mining Features

SQL Server Data Mining provides the following features in support of integrated data mining solutions:

- Multiple data sources: You can use any tabular data source for data mining, including spreadsheets and text files. You can also easily mine OLAP cubes created in Analysis Services. However, you cannot use data from an in-memory database.
- Integrated data cleansing, data management, and reporting: Integration Services provides tools for profiling and cleansing data. You can build ETL processes for cleaning data in preparation for modeling, and ssISnoverversion also makes it easy to retrain and update models.
- Multiple customizable algorithms: In addition to providing algorithms such as clustering, neural networks, and decisions trees, SQL Server Data Mining supports development of your own custom plug-in algorithms.
- Model testing infrastructure: Test your models and data sets using important statistical tools as cross-validation, classification matrices, lift charts, and scatter plots. Easily create and manage testing and training sets.
- Querying and drillthrough: SQL Server Data Mining provides the DMX language for integrating prediction queries into applications. You can also retrieve detailed statistics and patterns from the models, and drill

through to case data.

- Client tools: In addition to the development and design studios provided by SQL Server, you can use the Data Mining Add-ins for Excel to create, query, and browse models. Or, create custom clients, including Web services.
- Scripting language support and managed API: All data mining objects are fully programmable. Scripting is possible through MDX, XMLA, or the PowerShell extensions for Analysis Services. Use the Data Mining Extensions (DMX) language for fast querying and scripting.
- Security and deployment: Provides role-based security through Analysis Services, including separate permissions for drillthrough to model and structure data. Easy deployment of models to other servers, so that users can access the patterns or perform predictions

Data Mining Concepts

8/9/2019 • 13 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

IMPORTANT

Data mining is deprecated in SQL Server Analysis Services 2017. Documentation is not updated for deprecated features. [Analysis Services backward compatibility](#).

Data mining is the process of discovering actionable information from large sets of data. Data mining uses mathematical analysis to derive patterns and trends that exist in data. Typically, these patterns cannot be discovered by traditional data exploration because the relationships are too complex or because there is too much data.

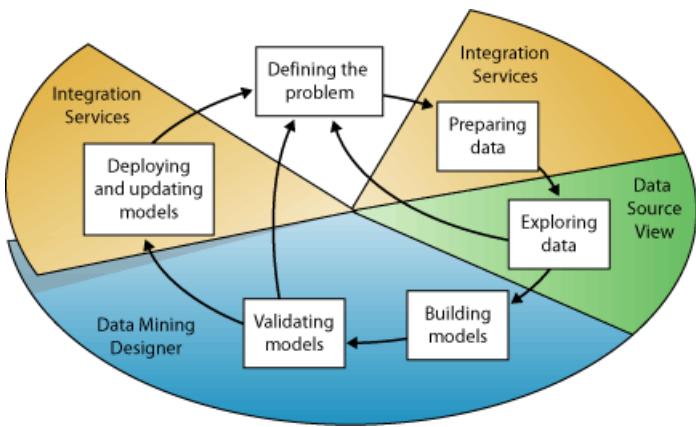

These patterns and trends can be collected and defined as a *data mining model*. Mining models can be applied to specific scenarios, such as:

- **Forecasting:** Estimating sales, predicting server loads or server downtime
- **Risk and probability:** Choosing the best customers for targeted mailings, determining the probable break-even point for risk scenarios, assigning probabilities to diagnoses or other outcomes
- **Recommendations:** Determining which products are likely to be sold together, generating recommendations
- **Finding sequences:** Analyzing customer selections in a shopping cart, predicting next likely events
- **Grouping:** Separating customers or events into cluster of related items, analyzing and predicting affinities

Building a mining model is part of a larger process that includes everything from asking questions about the data and creating a model to answer those questions, to deploying the model into a working environment. This process can be defined by using the following six basic steps:

1. [Defining the Problem](#)
2. [Preparing Data](#)
3. [Exploring Data](#)
4. [Building Models](#)
5. [Exploring and Validating Models](#)
6. [Deploying and Updating Models](#)

The following diagram describes the relationships between each step in the process, and the technologies in Microsoft SQL Server that you can use to complete each step.

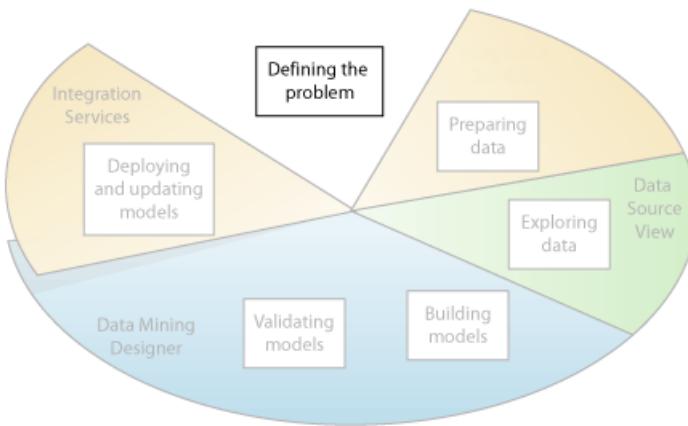

The process illustrated in the diagram is cyclical, meaning that creating a data mining model is a dynamic and iterative process. After you explore the data, you may find that the data is insufficient to create the appropriate mining models, and that you therefore have to look for more data. Alternatively, you may build several models and then realize that the models do not adequately answer the problem you defined, and that you therefore must redefine the problem. You may have to update the models after they have been deployed because more data has become available. Each step in the process might need to be repeated many times in order to create a good model.

Microsoft SQL Server Data Mining provides an integrated environment for creating and working with data mining models. This environment includes SQL Server Development Studio, which contains data mining algorithms and query tools that make it easy to build a comprehensive solution for a variety of projects, and SQL Server Management Studio, which contains tools for browsing models and managing data mining objects. For more information, see [Creating Multidimensional Models Using SQL Server Data Tools \(SSDT\)](#).

For an example of how the SQL Server tools can be applied to a business scenario, see the [Basic Data Mining Tutorial](#).

Defining the Problem

The first step in the data mining process, as highlighted in the following diagram, is to clearly define the problem, and consider ways that data can be utilized to provide an answer to the problem.

This step includes analyzing business requirements, defining the scope of the problem, defining the metrics by which the model will be evaluated, and defining specific objectives for the data mining project. These tasks translate into questions such as the following:

- What are you looking for? What types of relationships are you trying to find?
- Does the problem you are trying to solve reflect the policies or processes of the business?
- Do you want to make predictions from the data mining model, or just look for interesting patterns and associations?

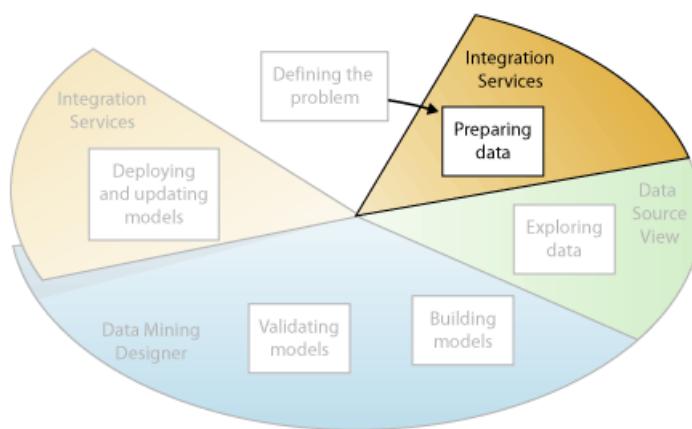

- Which outcome or attribute do you want to try to predict?
- What kind of data do you have and what kind of information is in each column? If there are multiple tables, how are the tables related? Do you need to perform any cleansing, aggregation, or processing to make the data usable?
- How is the data distributed? Is the data seasonal? Does the data accurately represent the processes of the business?

To answer these questions, you might have to conduct a data availability study, to investigate the needs of the business users with regard to the available data. If the data does not support the needs of the users, you might have to redefine the project.

You also need to consider the ways in which the results of the model can be incorporated in key performance indicators (KPI) that are used to measure business progress.

Preparing Data

The second step in the data mining process, as highlighted in the following diagram, is to consolidate and clean the data that was identified in the [Defining the Problem](#) step.

Data can be scattered across a company and stored in different formats, or may contain inconsistencies such as incorrect or missing entries. For example, the data might show that a customer bought a product before the product was offered on the market, or that the customer shops regularly at a store located 2,000 miles from her home.

Data cleaning is not just about removing bad data or interpolating missing values, but about finding hidden correlations in the data, identifying sources of data that are the most accurate, and determining which columns are the most appropriate for use in analysis. For example, should you use the shipping date or the order date? Is the best sales influencer the quantity, total price, or a discounted price? Incomplete data, wrong data, and inputs that appear separate but in fact are strongly correlated all can influence the results of the model in ways you do not expect.

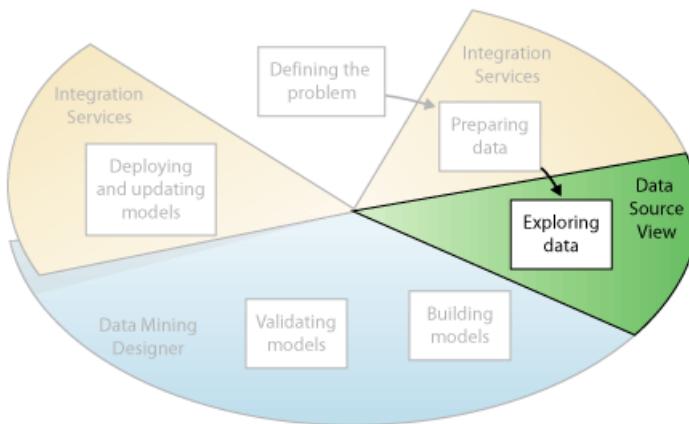

Therefore, before you start to build mining models, you should identify these problems and determine how you will fix them. For data mining typically you are working with a very large dataset and cannot examine every transaction for data quality; therefore, you might need to use some form of data profiling and automated data cleansing and filtering tools, such as those supplied in Integration Services, Microsoft SQL Server 2012 Master Data Services, or SQL Server Data Quality Services to explore the data and find the inconsistencies. For more information, see these resources:

- [Integration Services in Business Intelligence Development Studio](#)
- [Master Data Services Overview \(MDS\)](#)
- [Data Quality Services](#)

It is important to note that the data you use for data mining does not need to be stored in an Online Analytical Processing (OLAP) cube, or even in a relational database, although you can use both of these as data sources. You can conduct data mining using any source of data that has been defined as an Analysis Services data source. These can include text files, Excel workbooks, or data from other external providers. For more information, see [Supported Data Sources \(SSAS - Multidimensional\)](#).

Exploring Data

The third step in the data mining process, as highlighted in the following diagram, is to explore the prepared data.

You must understand the data in order to make appropriate decisions when you create the mining models. Exploration techniques include calculating the minimum and maximum values, calculating mean and standard deviations, and looking at the distribution of the data. For example, you might determine by reviewing the maximum, minimum, and mean values that the data is not representative of your customers or business processes, and that you therefore must obtain more balanced data or review the assumptions that are the basis for your expectations. Standard deviations and other distribution values can provide useful information about the stability and accuracy of the results. A large standard deviation can indicate that adding more data might help you improve the model. Data that strongly deviates from a standard distribution might be skewed, or might represent an accurate picture of a real-life problem, but make it difficult to fit a model to the data.

By exploring the data in light of your own understanding of the business problem, you can decide if the dataset contains flawed data, and then you can devise a strategy for fixing the problems or gain a deeper understanding of the behaviors that are typical of your business.

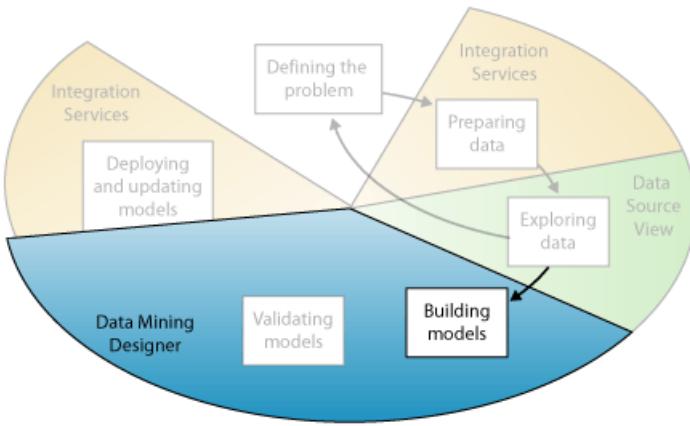

You can use tools such as Master Data Services to canvass available sources of data and determine their availability for data mining. You can use tools such as SQL Server Data Quality Services, or the Data Profiler in Integration Services, to analyze the distribution of your data and repair issues such as wrong or missing data.

After you have defined your sources, you combine them in a Data Source view by using the Data Source View Designer in Visual Studio with Analysis Services projects. For more information, see [Data Source Views in Multidimensional Models](#). This designer also contains some several tools that you can use to explore the data and verify that it will work for creating a model. For more information, see [Explore Data in a Data Source View \(Analysis Services\)](#).

Note that when you create a model, Analysis Services automatically creates statistical summaries of the data contained in the model, which you can query to use in reports or further analysis. For more information, see [Data Mining Queries](#).

Building Models

The fourth step in the data mining process, as highlighted in the following diagram, is to build the mining model or models. You will use the knowledge that you gained in the [Exploring Data](#) step to help define and create the models.

You define the columns of data that you want to use by creating a mining structure. The mining structure is linked to the source of data, but does not actually contain any data until you process it. When you process the mining structure, Analysis Services generates aggregates and other statistical information that can be used for analysis. This information can be used by any mining model that is based on the structure. For more information about how mining structures are related to mining models, see [Logical Architecture \(Analysis Services - Data Mining\)](#).

Before the structure and model is processed, a data mining model too is just a container that specifies the columns used for input, the attribute that you are predicting, and parameters that tell the algorithm how to process the data. Processing a model is often called *training*. Training refers to the process of applying a specific mathematical algorithm to the data in the structure in order to extract patterns. The patterns that you find in the training process depend on the selection of training data, the algorithm you chose, and how you have configured the algorithm. SQL Server 2017 contains many different algorithms, each suited to a different type of task, and each creating a different type of model. For a list of the algorithms provided in SQL Server 2017, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

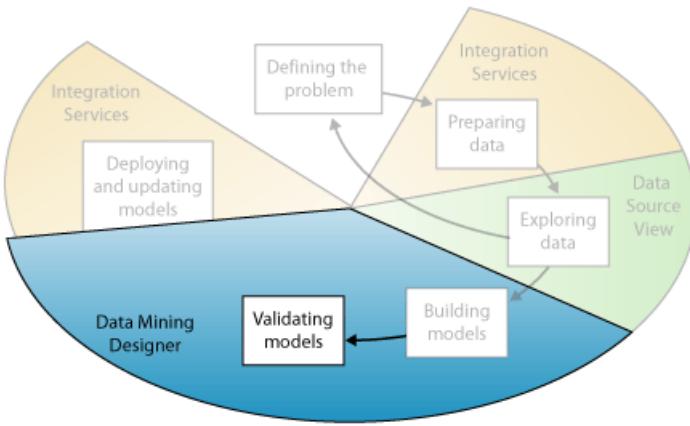

You can also use parameters to adjust each algorithm, and you can apply filters to the training data to use just a subset of the data, creating different results. After you pass data through the model, the mining model object contains summaries and patterns that can be queried or used for prediction.

You can define a new model by using the Data Mining Wizard in Visual Studio with Analysis Services projects, or by using the Data Mining Extensions (DMX) language. For more information about how to use the Data Mining Wizard, see [Data Mining Wizard \(Analysis Services - Data Mining\)](#). For more information about how to use DMX, see [Data Mining Extensions \(DMX\) Reference](#).

It is important to remember that whenever the data changes, you must update both the mining structure and the mining model. When you update a mining structure by reprocessing it, Analysis Services retrieves data from the source, including any new data if the source is dynamically updated, and repopulates the mining structure. If you have models that are based on the structure, you can choose to update the models that are based on the structure, which means they are retrained on the new data, or you can leave the models as is. For more information, see [Processing Requirements and Considerations \(Data Mining\)](#).

Exploring and Validating Models

The fifth step in the data mining process, as highlighted in the following diagram, is to explore the mining models that you have built and test their effectiveness.

Before you deploy a model into a production environment, you will want to test how well the model performs. Also, when you build a model, you typically create multiple models with different configurations and test all models to see which yields the best results for your problem and your data.

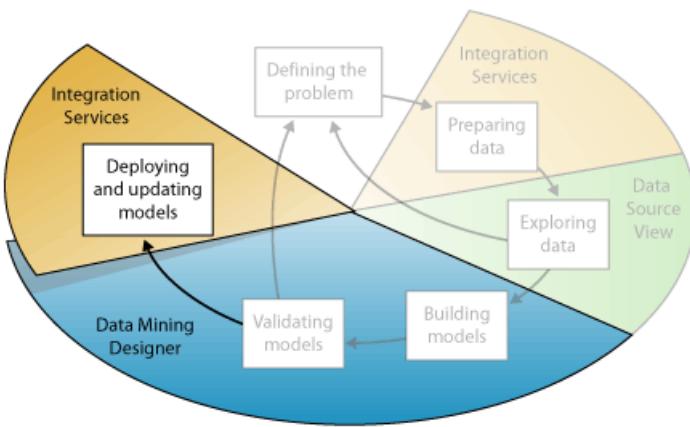

Analysis Services provides tools that help you separate your data into training and testing datasets so that you can accurately assess the performance of all models on the same data. You use the training dataset to build the model, and the testing dataset to test the accuracy of the model by creating prediction queries. This partitioning can be done automatically while building the mining model. For more information, see [Testing and Validation \(Data Mining\)](#).

You can explore the trends and patterns that the algorithms discover by using the viewers in Data Mining Designer in Visual Studio with Analysis Services projects. For more information, see [Data Mining Model Viewers](#). You can also test how well the models create predictions by using tools in the designer such as the lift chart and classification matrix. To verify whether the model is specific to your data, or may be used to make inferences on the general population, you can use the statistical technique called *cross-validation* to automatically create subsets of the data and test the model against each subset. For more information, see [Testing and Validation \(Data Mining\)](#).

If none of the models that you created in the **Building Models** step perform well, you might have to return to a previous step in the process and redefine the problem or reinvestigate the data in the original dataset.

Deploying and Updating Models

The last step in the data mining process, as highlighted in the following diagram, is to deploy the models that performed the best to a production environment.

After the mining models exist in a production environment, you can perform many tasks, depending on your needs. The following are some of the tasks you can perform:

- Use the models to create predictions, which you can then use to make business decisions. SQL Server provides the DMX language that you can use to create prediction queries, and Prediction Query Builder to help you build the queries. For more information, see [Data Mining Extensions \(DMX\) Reference](#).

- Create content queries to retrieve statistics, rules, or formulas from the model. For more information, see [Data Mining Queries](#).
- Embed data mining functionality directly into an application. You can include Analysis Management Objects (AMO), which contains a set of objects that your application can use to create, alter, process, and delete mining structures and mining models. Alternatively, you can send XML for Analysis (XMLA) messages directly to an instance of Analysis Services. For more information, see [Development \(Analysis Services - Data Mining\)](#).
- Use Integration Services to create a package in which a mining model is used to intelligently separate incoming data into multiple tables. For example, if a database is continually updated with potential customers, you could use a mining model together with Integration Services to split the incoming data into customers who are likely to purchase a product and customers who are likely to not purchase a product. For more information, see [Typical Uses of Integration Services](#).
- Create a report that lets users directly query against an existing mining model. For more information, see [Reporting Services in SQL Server Data Tools \(SSDT\)](#).
- Update the models after review and analysis. Any update requires that you reprocess the models. For more information, see [Processing Data Mining Objects](#).
- Update the models dynamically, as more data comes into the organization, and making constant changes to improve the effectiveness of the solution should be part of the deployment strategy. For more information, see [Management of Data Mining Solutions and Objects](#)

Data Mining Algorithms (Analysis Services - Data Mining)

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

An *algorithm* in data mining (or machine learning) is a set of heuristics and calculations that creates a model from data. To create a model, the algorithm first analyzes the data you provide, looking for specific types of patterns or trends. The algorithm uses the results of this analysis over many iterations to find the optimal parameters for creating the mining model. These parameters are then applied across the entire data set to extract actionable patterns and detailed statistics.

The mining model that an algorithm creates from your data can take various forms, including:

- A set of clusters that describe how the cases in a dataset are related.
- A decision tree that predicts an outcome, and describes how different criteria affect that outcome.
- A mathematical model that forecasts sales.
- A set of rules that describe how products are grouped together in a transaction, and the probabilities that products are purchased together.

The algorithms provided in SQL Server Data Mining are the most popular, well-researched methods of deriving patterns from data. To take one example, K-means clustering is one of the oldest clustering algorithms and is available widely in many different tools and with many different implementations and options. However, the particular implementation of K-means clustering used in SQL Server Data Mining was developed by Microsoft Research and then optimized for performance with Analysis Services. All of the Microsoft data mining algorithms can be extensively customized and are fully programmable, using the provided APIs. You can also automate the creation, training, and retraining of models by using the data mining components in Integration Services.

You can also use third-party algorithms that comply with the OLE DB for Data Mining specification, or develop custom algorithms that can be registered as services and then used within the SQL Server Data Mining framework.

Choosing the Right Algorithm

Choosing the best algorithm to use for a specific analytical task can be a challenge. While you can use different algorithms to perform the same business task, each algorithm produces a different result, and some algorithms can produce more than one type of result. For example, you can use the Microsoft Decision Trees algorithm not only for prediction, but also as a way to reduce the number of columns in a dataset, because the decision tree can identify columns that do not affect the final mining model.

Choosing an Algorithm by Type

SQL Server Data Mining includes the following algorithm types:

- **Classification algorithms** predict one or more discrete variables, based on the other attributes in the dataset.
- **Regression algorithms** predict one or more continuous numeric variables, such as profit or loss, based on other attributes in the dataset.

- **Segmentation algorithms** divide data into groups, or clusters, of items that have similar properties.
- **Association algorithms** find correlations between different attributes in a dataset. The most common application of this kind of algorithm is for creating association rules, which can be used in a market basket analysis.
- **Sequence analysis algorithms** summarize frequent sequences or episodes in data, such as a series of clicks in a web site, or a series of log events preceding machine maintenance.

However, there is no reason that you should be limited to one algorithm in your solutions. Experienced analysts will sometimes use one algorithm to determine the most effective inputs (that is, variables), and then apply a different algorithm to predict a specific outcome based on that data. SQL Server Data Mining lets you build multiple models on a single mining structure, so within a single data mining solution you could use a clustering algorithm, a decision trees model, and a Naïve Bayes model to get different views on your data. You might also use multiple algorithms within a single solution to perform separate tasks: for example, you could use regression to obtain financial forecasts, and use a neural network algorithm to perform an analysis of factors that influence forecasts.

Choosing an Algorithm by Task

To help you select an algorithm for use with a specific task, the following table provides suggestions for the types of tasks for which each algorithm is traditionally used.

EXAMPLES OF TASKS	MICROSOFT ALGORITHMS TO USE
<p>Predicting a discrete attribute:</p> <p>Flag the customers in a prospective buyers list as good or poor prospects.</p> <p>Calculate the probability that a server will fail within the next 6 months.</p> <p>Categorize patient outcomes and explore related factors.</p>	<p>Microsoft Decision Trees Algorithm</p> <p>Microsoft Naïve Bayes Algorithm</p> <p>Microsoft Clustering Algorithm</p> <p>Microsoft Neural Network Algorithm</p>

Microsoft Association Algorithm

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Association algorithm is an algorithm that is often used for recommendation engines. A recommendation engine recommends items to customers based on items they have already bought, or in which they have indicated an interest. The Microsoft Association algorithm is also useful for market basket analysis.

Association models are built on datasets that contain identifiers both for individual cases and for the items that the cases contain. A group of items in a case is called an *itemset*. An association model consists of a series of itemsets and the rules that describe how those items are grouped together within the cases. The rules that the algorithm identifies can be used to predict a customer's likely future purchases, based on the items that already exist in the customer's shopping cart. The following diagram shows a series of rules in an itemset.

Rule
Road Bottle Cage = Existing, Cycling Cap = Existing -> Water Bottle = Existing
Mountain-200 = Existing, Mountain Tire Tube = Existing -> HL Mountain Tire = Existing
Mountain-200 = Existing, Water Bottle = Existing -> Mountain Bottle Cage = Existing
Touring-1000 = Existing, Water Bottle = Existing -> Road Bottle Cage = Existing
Road-750 = Existing, Water Bottle = Existing -> Road Bottle Cage = Existing
Touring Tire = Existing, Sport-100 = Existing -> Touring Tire Tube = Existing

As the diagram illustrates, the Microsoft Association algorithm can potentially find many rules within a dataset. The algorithm uses two parameters, support and probability, to describe the itemsets and rules that it generates. For example, if X and Y represent two items that could be in a shopping cart, the support parameter is the number of cases in the dataset that contain the combination of items, X and Y. By using the support parameter in combination with the user-defined parameters, *MINIMUM_SUPPORT* and *MAXIMUM_SUPPORT*, the algorithm controls the number of itemsets that are generated. The probability parameter, also named *confidence*, represents the fraction of cases in the dataset that contain X and that also contain Y. By using the probability parameter in combination with the *MINIMUM_PROBABILITY* parameter, the algorithm controls the number of rules that are generated.

Example

The Adventure Works Cycle company is redesigning the functionality of its Web site. The goal of the redesign is to increase sell-through of products. Because the company records each sale in a transactional database, they can use the Microsoft Association algorithm to identify sets of products that tend to be purchased together. They can then predict additional items that a customer might be interested in, based on items that are already in the customer's shopping basket.

How the Algorithm Works

The Microsoft Association algorithm traverses a dataset to find items that appear together in a case. The algorithm then groups into itemsets any associated items that appear, at a minimum, in the number of cases that are specified by the *MINIMUM_SUPPORT* parameter. For example, an itemset could be "Mountain 200=Existing, Sport 100=Existing", and could have a support of 710. The algorithm then generates rules from the itemsets. These rules are used to predict the presence of an item in the database, based on the presence of other specific items that the algorithm identifies as important. For example, a rule could be "if Touring 1000=existing and Road bottle cage=existing, then Water bottle=existing", and could have a probability of 0.812. In this example, the algorithm identifies that the presence in the basket of the Touring 1000 tire and the water bottle cage predicts that a water bottle would also likely be in the basket.

For a more detailed explanation of the algorithm, together with a list of parameters for customizing the behavior of the algorithm and controlling the results in the mining model, see [Microsoft Association Algorithm Technical Reference](#).

Data Required for Association Models

When you prepare data for use in an association rules model, you should understand the requirements for the particular algorithm, including how much data is needed, and how the data is used.

The requirements for an association rules model are as follows:

- **A single key column** Each model must contain one numeric or text column that uniquely identifies each record. compound keys not permitted.
- **A single predictable column** An association model can have only one predictable column. Typically it is the key column of the nested table, such as the filed that lists the products that were purchased. The values must be discrete or discretized.
- **Input columns** . The input columns must be discrete. The input data for an association model often is contained in two tables. For example, one table might contain customer information while another table contains customer purchases. You can input this data into the model by using a nested table. For more information about nested tables, see [Nested Tables \(Analysis Services - Data Mining\)](#).

For more detailed information about the content types and data types supported for association models, see the Requirements section of [Microsoft Association Algorithm Technical Reference](#).

Viewing an Association Model

To explore the model, you can use the **Microsoft Association Viewer**. When you view an association model, Analysis Services presents the correlations from different angles so that you can better understand the relationships and rules that were found in the data. The **Itemset** pane in the viewer provides a detailed breakdown of the most common combinations, or itemsets. The **Rules** pane presents a list of rules that have been generalized from the data, adds calculations of probability, and ranks the rules by relative importance. the dependency network viewer lets you visually explore how individual different items are connected. For more information, see [Browse a Model Using the Microsoft Cluster Viewer](#).

If you want to find out more detail about any of the itemsets and rules, you can browse the model in the **Microsoft Generic Content Tree Viewer**. The content stored for the model includes the support for each itemset, a score for each rule, and other statistics. For more information, see [Mining Model Content for Association Models \(Analysis Services - Data Mining\)](#).

Creating Predictions

After the model has been processed, you can use the rules and itemsets to make predictions. In an association model, a prediction tells you what item is likely to occur given the presence of the specified item, and the prediction can include such information as the probability, the support, or the importance. For examples of how to create queries against an association model, see [Association Model Query Examples](#).

For general information about how to create a query against a data mining model, see [Data Mining Queries](#).

Performance

The process of creating itemsets and counting correlations can be time-consuming. Although the Microsoft Association Rules algorithm uses optimization techniques to save space and make processing faster, you should know that performance issues can occur under conditions such as the following:

- Data set is large with many individual items.
- Minimum itemset size is set too low.

To minimize processing time and reduce the complexity of the itemsets, you might try grouping related items by categories before you analyze the data.

Remarks

- Does not support the use of Predictive Model Markup Language (PMML) to create mining models.
- Supports drillthrough.
- Supports the use of OLAP mining models.
- Supports the creation of data mining dimensions.

[Association Model Query Examples](#)

Microsoft Association Algorithm Technical Reference

7/16/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Association Rules algorithm is a straightforward implementation of the well-known Apriori algorithm.

Both the Microsoft Decision Trees algorithm and the Microsoft Association Rules algorithm can be used to analyze associations, but the rules that are found by each algorithm can differ. In a decision trees model, the splits that lead to specific rules are based on information gain, whereas in an association model, rules are based completely on confidence. Therefore, in an association model, a strong rule, or one that has high confidence, might not necessarily be interesting because it does not provide new information.

Implementation of the Microsoft Association Algorithm

The Apriori algorithm does not analyze patterns, but rather generates and then counts *candidate itemsets*. An item can represent an event, a product, or the value of an attribute, depending on the type of data that is being analyzed.

In the most common type of association model Boolean variables, representing a Yes/No or Missing/Existing value, are assigned to each attribute, such as a product or event name. A market basket analysis is an example of an association rules model that uses Boolean variables to represent the presence or absence of particular products in a customer's shopping basket.

For each itemset, the algorithm then creates scores that represent support and confidence. These scores can be used to rank and derive interesting rules from the itemsets.

Association models can also be created for numerical attributes. If the attributes are continuous, the numbers can be *discretized*, or grouped in buckets. The discretized values can then be handled either as Booleans or as attribute-value pairs.

Support, Probability, and Importance

Support, which is sometimes referred to as *frequency*, means the number of cases that contain the targeted item or combination of items. Only items that have at least the specified amount of support can be included in the model.

A *frequent itemset* refers to a collection of items where the combination of items also has support above the threshold defined by the MINIMUM_SUPPORT parameter. For example, if the itemset is {A,B,C} and the MINIMUM_SUPPORT value is 10, each individual item A, B, and C must be found in at least 10 cases to be included in the model, and the combination of items {A,B,C} must also be found in at least 10 cases.

Note You can also control the number of itemsets in a mining model by specifying the maximum length of an itemset, where length means the number of items.

By default, the support for any particular item or itemset represents a count of the cases that contain that item or items. However, you can also express MINIMUM_SUPPORT as a percentage of the total cases in the data set, by typing the number as a decimal value less than 1. For example, if you specify a MINIMUM_SUPPORT value of 0.03, it means that at least 3% of the total cases in the data set must contain this item or itemset for inclusion in the model. You should experiment with your model to determine whether using a count or percentage makes more sense.

In contrast, the threshold for rules is expressed not as a count or percentage, but as a probability, sometimes

referred to as *confidence*. For example, if the itemset {A,B,C} occurs in 50 cases, but the itemset {A,B,D} also occurs in 50 cases, and the itemset {A,B} in another 50 cases, it is obvious that {A,B} is not a strong predictor of {C}. Therefore, to weight a particular outcomes against all known outcomes, Analysis Services calculates the probability of the individual rule (such as If {A,B} Then {C}) by dividing the support for the itemset {A,B,C} by the support for all related itemsets.

You can restrict the number of rules that a model produces by setting a value for MINIMUM_PROBABILITY.

For each rule that is created, Analysis Services outputs a score that indicates its *importance*, which is also referred to as *lift*. Lift Importance is calculated differently for itemsets and rules.

The importance of an itemset is calculated as the probability of the itemset divided by the compound probability of the individual items in the itemset. For example, if an itemset contains {A,B}, Analysis Services first counts all the cases that contain this combination A and B, and divides that by the total number of cases, and then normalizes the probability.

The importance of a rule is calculated by the log likelihood of the right-hand side of the rule, given the left-hand side of the rule. For example, in the rule `IF {A} Then {B}`, Analysis Services calculates the ratio of cases with A and B over cases with B but without A, and then normalizes that ratio by using a logarithmic scale.

Feature Selection

The Microsoft Association Rules algorithm does not perform any kind of automatic feature selection. Instead, the algorithm provides parameters that control the data that is used by the algorithm. This might include limits on the size of each itemset, or setting the maximum and minimum support required to add an itemset to the model.

- To filter out items and events that are too common and therefore uninteresting, decrease the value of MAXIMUM_SUPPORT to remove very frequent itemsets from the model.
- To filter out items and itemsets that are rare, increase the value of MINIMUM_SUPPORT.
- To filter out rules, increase the value of MINIMUM_PROBABILITY.

Customizing the Microsoft Association Rules Algorithm

The Microsoft Association Rules algorithm supports several parameters that affect the behavior, performance, and accuracy of the resulting mining model.

Setting Algorithm Parameters

You can change the parameters for a mining model at any time by using the Data Mining Designer in Visual Studio with Analysis Services projects. You can also change parameters programmatically by using the [AlgorithmParameters](#) collection in AMO, or by using the [MiningModels Element \(ASSL\)](#) in XMLA. The following table describes each parameter.

NOTE

You cannot change the parameters in an existing model by using a DMX statement; you must specify the parameters in the DMX CREATE MODEL or ALTER STRUCTURE... ADD MODEL when you create the model.

MAXIMUM_ITEMSET_COUNT

Specifies the maximum number of itemsets to produce. If no number is specified, the default value is used.

The default is 200000.

NOTE

Itemsets are ranked by support. Among itemsets that have the same support, ordering is arbitrary.

MAXIMUM_ITEMSET_SIZE

Specifies the maximum number of items that are allowed in an itemset. Setting this value to 0 specifies that there is no limit to the size of the itemset.

The default is 3.

NOTE

Decreasing this value can potentially reduce the time that is required for creating the model, because processing of the model stops when the limit is reached.

MAXIMUM_SUPPORT

Specifies the maximum number of cases that an itemset has for support. This parameter can be used to eliminate items that appear frequently and therefore potentially have little meaning.

If this value is less than 1, the value represents a percentage of the total cases. Values greater than 1 represent the absolute number of cases that can contain the itemset.

The default is 1.

MINIMUM_ITEMSET_SIZE

Specifies the minimum number of items that are allowed in an itemset. If you increase this number, the model might contain fewer itemsets. This can be useful if you want to ignore single-item itemsets, for example.

The default is 1.

NOTE

You cannot reduce model processing time by increasing the minimum value, because Analysis Services must calculate probabilities for single items anyway as part of processing. However, by setting this value higher you can filter out smaller itemsets.

MINIMUM_PROBABILITY

Specifies the minimum probability that a rule is true.

For example, if you set this value to 0.5, it means that no rule with less than fifty percent probability can be generated.

The default is 0.4.

MINIMUM_SUPPORT

Specifies the minimum number of cases that must contain the itemset before the algorithm generates a rule.

If you set this value to less than 1, the minimum number of cases is calculated as a percentage of the total cases.

If you set this value to a whole number greater than 1, specifies the minimum number of cases is calculated as a count of cases that must contain the itemset. The algorithm might automatically increase the value of this parameter if memory is limited.

The default is 0.03. This means that to be included in the model, an itemset must be found in at least 3% of cases.

OPTIMIZED_PREDICTION_COUNT

Defines the number of items to be cached for optimizing prediction.

The default value is 0. When the default is used, the algorithm will produce as many predictions as requested in the query.

If you specify a nonzero value for *OPTIMIZED_PREDICTION_COUNT*, prediction queries can return at most the

specified number of items, even if you request additional predictions. However, setting a value can improve prediction performance.

For example, if the value is set to 3, the algorithm caches only 3 items for prediction. You cannot see additional predictions that might be equally probable to the 3 items that are returned.

Modeling Flags

The following modeling flags are supported for use with the Microsoft Association Rules algorithm.

NOT NULL

Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training.

Applies to the mining structure column.

MODEL_EXISTENCE_ONLY

Means that the column will be treated as having two possible states: **Missing** and **Existing**. A null is a missing value.

Applies to the mining model column.

Requirements

An association model must contain a key column, input columns, and a single predictable column.

Input and Predictable Columns

The Microsoft Association Rules algorithm supports the specific input columns and predictable columns that are listed in the following table. For more information about the meaning of content types in a mining model, see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Cyclical, Discrete, Discretized, Key, Table, Ordered
Predictable attribute	Cyclical, Discrete, Discretized, Table, Ordered

NOTE

Cyclical and Ordered content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

Mining Model Content for Association Models (Analysis Services - Data Mining)

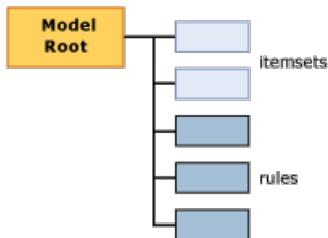

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes mining model content that is specific to models that use the Microsoft Association Rules algorithm. For an explanation of general and statistical terminology related to mining model content that applies to all model types, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Understanding the Structure of an Association Model

An association model has a simple structure. Each model has a single parent node that represents the model and its metadata, and each parent node has a flat list of itemsets and rules. The itemsets and rules are not organized in trees, they are ordered with itemsets first and rules next as shown in the following diagram.

Each itemset is contained in its own node (NODE_TYPE = 7). The *node* includes the definition of the itemset, the number of cases that contain this itemset, and other information.

Each rule is also contained in its own node (NODE_TYPE = 8). A *rule* describes a general pattern for how items are associated. A rule is like an IF-THEN statement. The left-hand side of the rule shows an existing condition or set of conditions. The right-hand side of the rule shows the item in your data set that is usually associated with the conditions on the left side.

Note If you want to extract either the rules or the itemsets, you can use a query to return only the node types that you want. For more information, see [Association Model Query Examples](#).

Model Content for an Association Model

This section provides detail and examples only for those columns in the mining model content that are relevant for association models.

For information about the general-purpose columns in the schema rowset, such as MODEL_CATALOG and MODEL_NAME, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

The names of the attributes that correspond to this node.

NODE_NAME

The name of the node. For an association model, this column contains the same value as NODE_UNIQUE_NAME.

NODE_UNIQUE_NAME

The unique name of the node.

NODE_TYPE

A association model outputs only the following node types:

NODE_TYPE_ID	TYPE
1 (Model)	Root or parent node.
7 (Itemset)	An itemset, or collection of attribute-value pairs. Examples: <div style="border: 1px solid black; padding: 5px; margin-top: 10px;">Product 1 = Existing, Product 2 = Existing</div> <p>or</p> <div style="border: 1px solid black; padding: 5px; margin-top: 10px;">Gender = Male .</div>
8 (Rule)	A rule defining how items relate to each other. <p>Example:</p> <div style="border: 1px solid black; padding: 5px; margin-top: 10px;">Product 1 = Existing, Product 2 = Existing -> Product 3 = Existing</div> <p>.</p>

NODE_CAPTION

A label or a caption associated with the node.

Itemset node A comma-separated list of items.

Rule node Contains the left and right-hand sides of the rule.

CHILDREN_CARDINALITY

Indicates the number of children of the current node.

Parent node Indicates the total number of itemsets plus rules.

NOTE

To get a breakdown of the count for itemsets and rules, see the NODE_DESCRIPTION for the root node of the model.

Itemset or rule node Always 0.

PARENT_UNIQUE_NAME

The unique name of the node's parent.

Parent node Always NULL.

Itemset or rule node Always 0.

NODE_DESCRIPTION

A user-friendly description of the contents of the node.

Parent node Includes a comma-separated list of the following information about the model:

ITEM	DESCRIPTION
ITEMSET_COUNT	Count of all itemsets in model.
RULE_COUNT	Count of all rules in model.
MIN_SUPPORT	<p>The minimum support found for any single itemset.</p> <p>Note This value might differ from the value that you set for the <i>MINIMUM_SUPPORT</i> parameter.</p>
MAX_SUPPORT	<p>The maximum support found for any single itemset.</p> <p>Note This value might differ from the value that you set for the <i>MAXIMUM_SUPPORT</i> parameter.</p>
MIN_ITEMSET_SIZE	<p>The size of the smallest itemset, represented as a count of items.</p> <p>A value of 0 indicates that the Missing state was treated as an independent item.</p> <p>Note The default value of the <i>MINIMUM_ITEMSET_SIZE</i> parameter is 1.</p>
MAX_ITEMSET_SIZE	<p>Indicates the size of the largest itemset that was found.</p> <p>Note This value is constrained by the value that you set for the <i>MAX_ITEMSET_SIZE</i> parameter when you created the model. This value can never exceed that value; however, it can be less. The default value is 3.</p>
MIN_PROBABILITY	<p>The minimum probability detected for any single itemset or rule in the model.</p> <p>Example: 0.400390625</p> <p>Note For itemsets, this value is always greater than the value that you set for the <i>MINIMUM_PROBABILITY</i> parameter when you created the model.</p>
MAX_PROBABILITY	<p>The maximum probability detected for any single itemset or rule in the model.</p> <p>Example: 1</p> <p>Note There is no parameter to constrain maximum probability of itemsets. If you want to eliminate items that are too frequent, use the <i>MAXIMUM_SUPPORT</i> parameter instead.</p>
MIN_LIFT	<p>The minimum amount of lift that is provided by the model for any itemset.</p> <p>Example: 0.14309369632511</p> <p>Note: Knowing the minimum lift can help you determine whether the lift for any one itemset is significant.</p>

ITEM	DESCRIPTION
MAX_LIFT	<p>The maximum amount of lift that is provided by the model for any itemset.</p> <p>Example: 1.95758227647523 Note Knowing the maximum lift can help you determine whether the lift for any one itemset is significant.</p>

Itemset node Itemset nodes contain a list of the items, displayed as a comma-separated text string.

Example:

Touring Tire = Existing, Water Bottle = Existing

This means touring tires and water bottles were purchased together.

Rule node Rule nodes contains a left-hand and right-hand side of the rule, separated by an arrow.

Example: Touring Tire = Existing, Water Bottle = Existing -> Cycling cap = Existing

This means that if someone bought a touring tire and a water bottle, they were also likely to buy a cycling cap.

NODE_RULE

An XML fragment that describes the rule or itemset that is embedded in the node.

Parent node Blank.

Itemset node Blank.

Rule node The XML fragment includes additional useful information about the rule, such as support, confidence, and the number of items, and the ID of the node that represents the left-hand side of the rule.

MARGINAL_RULE

Blank.

NODE_PROBABILITY

A probability or confidence score associated with the itemset or rule.

Parent node Always 0.

Itemset node Probability of the itemset.

Rule node Confidence value for the rule.

MARGINAL_PROBABILITY

Same as NODE_PROBABILITY.

NODE_DISTRIBUTION

The table contains very different information, depending on whether the node is an itemset or a rule.

Parent node Blank.

Itemset node Lists each item in the itemset together with a probability and support value. For example, if the itemset contains two products, the name of each product is listed, together with the count of cases that include each product.

Rule node Contains two rows. The first row shows the attribute from the right-hand side of the rule, which is the predicted item, together with a confidence score.

The second row is unique to association models; it contains a pointer to the itemset on the right-hand side of the rule. The pointer is represented in the ATTRIBUTE_VALUE column as the ID of the itemset that contains only the

right-hand item.

For example, if the rule is `If {A,B} Then {C}`, the table contains the name of the item `{C}`, and the ID of the node that contains the itemset for item C.

This pointer is useful because you can determine from the itemset node how many cases in all include the right-hand side product. The cases that are subject to the rule `If {A,B} Then {C}` are a subset of the cases listed in the itemset for `{C}`.

NODE_SUPPORT

The number of cases that support this node.

Parent node Number of cases in the model.

Itemset node Number of cases that contains all items in the itemset.

Rule node The number of cases that contain all items included in the rule.

MSOLAP_MODEL_COLUMN

Contains different information depending on whether the node is an itemset or rule.

Parent node Blank.

Itemset node Blank.

Rule node The ID of the itemset that contains the items in the left-hand side of the rule. For example, if the rule is `If {A,B} Then {C}`, this column contains the ID of the itemset that contains only `{A,B}`.

MSOLAP_NODE_SCORE

Parent node Blank.

Itemset node Importance score for the itemset.

Rule node Importance score for the rule.

NOTE

Importance is calculated differently for itemsets and rules. For more information, see [Microsoft Association Algorithm Technical Reference](#).

MSOLAP_NODE_SHORT_CAPTION

Blank.

[Association Model Query Examples](#)

Association Model Query Examples

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create either a content query, which provides details about the rules and itemsets discovered during analysis, or you can create a prediction query, which uses the associations discovered in the data to make predictions. For an association model, predictions typically are based on rules, and can be used to make recommendations, whereas queries on content typically explore the relationship among itemsets. You can also retrieve metadata about the model.

This section explains how to create these kinds of queries for models that are based on the Microsoft Association Rules algorithm.

Content Queries

[Getting model metadata data by using DMX](#)

[Getting metadata from the schema rowset](#)

[Retrieving the original parameters for the model](#)

[Retrieving a list of itemsets and products](#)

[Returning the top 10 itemsets](#)

Prediction Queries

[Predicting associated items](#)

[Determining confidence for related itemsets](#)

Finding Information about the Model

All mining models expose the content learned by the algorithm according to a standardized schema, which is named the mining model schema rowset. You can create queries against the mining model schema rowset either by using Data Mining Extensions (DMX) statements, or by using Analysis Services stored procedures. In SQL Server 2017, you can also query the schema rowsets directly as system tables, by using a SQL-like syntax.

Sample Query 1: Getting Model Metadata by Using DMX

The following query returns basic metadata about the association model, `Association`, such as the name of the model, the database where the model is stored, and the number of child nodes in the model. This query uses a DMX content query to retrieve the metadata from the parent node of the model:

```
SELECT MODEL_CATALOG, MODEL_NAME, NODE_CAPTION,  
NODE_SUPPORT, [CHILDREN_CARDINALITY], NODE_DESCRIPTION  
FROM Association.CONTENT  
WHERE NODE_TYPE = 1
```

NOTE

You must enclose the name of the column, CHILDREN_CARDINALITY, in brackets to distinguish it from the MDX reserved keyword of the same name.

Example results:

MODEL_CATALOG	Association Test
MODEL_NAME	Association
NODE_CAPTION	Association Rules Model
NODE_SUPPORT	14879
CHILDREN_CARDINALITY	942
NODE_DESCRIPTION	Association Rules Model; ITEMSET_COUNT=679; RULE_COUNT=263; MIN_SUPPORT=14; MAX_SUPPORT=4334; MIN_ITEMSET_SIZE=0; MAX_ITEMSET_SIZE=3; MIN_PROBABILITY=0.400390625; MAX_PROBABILITY=1; MIN_LIFT=0.14309369632511; MAX_LIFT=1.95758227647523

For a definition of what these columns mean in an association model, see [Mining Model Content for Association Models \(Analysis Services - Data Mining\)](#).

[Return to Top](#)

Sample Query 2: Getting Additional Metadata from the Schema Rowset

By querying the data mining schema rowset, you can find the same information that is returned in a DMX content query. However, the schema rowset provides some additional columns, such as the date the model was last processed, the mining structure, and the name of the column used as the predictable attribute.

```
SELECT MODEL_CATALOG, MODEL_NAME, SERVICE_NAME, PREDICTION_ENTITY,  
MINING_STRUCTURE, LAST_PROCESSED  
FROM $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'Association'
```

Example results:

MODEL_CATALOG	Adventure Works DW Multidimensional 2012
MODEL_NAME	Association
SERVICE_NAME	Association Rules Model
PREDICTION_ENTITY	v Assoc Seq Line Items
MINING_STRUCTURE	Association
LAST_PROCESSED	9/29/2007 10:21:24 PM

[Return to Top](#)

Sample Query 3: Retrieving Original Parameters for Model

The following query returns a single column that contains details about the parameter settings that were used

when the model was created.

```
SELECT MINING_PARAMETERS  
from $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'Association'
```

Example results:

```
MAXIMUM_ITEMSET_COUNT=200000,MAXIMUM_ITEMSET_SIZE=3,MAXIMUM_SUPPORT=1,MINIMUM_SUPPORT=9.40923449156529E-04,MINIMUM_IMPORTANCE=-  
999999999,MINIMUM_ITEMSET_SIZE=0,MINIMUM_PROBABILITY=0.4
```

[Return to Top](#)

Finding Information about Rules and Itemsets

There are two common uses of an association model: to discover information about frequent itemsets, and to extract details about particular rules and itemsets. For example, you might want to extract a list of rules that were scored as being especially interesting, or create a list of the most common itemsets. You retrieve such information by using a DMX content query. You can also browse this information by using the **Microsoft Association Viewer**.

Sample Query 4: Retrieving List of Itemsets and Products

The following query retrieves all of the itemsets, together with a nested table that lists the products included in each itemset. The NODE_NAME column contains the unique ID of the itemset within the model, whereas the NODE_CAPTION provides a text description of the items. In this example, the nested table is flattened, so that an itemset that contains two products generates two rows in the results. You can omit the FLATTENED keyword if your client supports hierarchical data.

```
SELECT FLATTENED NODE_NAME, NODE_CAPTION,  
NODE_PROBABILITY, NODE_SUPPORT,  
(SELECT ATTRIBUTE_NAME FROM NODE_DISTRIBUTION) as PurchasedProducts  
FROM Association.CONTENT  
WHERE NODE_TYPE = 7
```

Example results:

NODE_NAME	37
NODE_CAPTION	Sport-100 = Existing
NODE_PROBABILITY	0.291283016331743
NODE_SUPPORT	4334
PURCHASEDPRODUCTS.ATTRIBUTE_NAME	v Assoc Seq Line Items(Sport-100)

[Return to Top](#)

Sample Query 5: Returning Top 10 Itemsets

This example demonstrates how to use some of the grouping and ordering functions that DMX provides by default. The query returns the top 10 itemsets when ordered by the support for each node. Note that you do not need to explicitly group the results, as you would in Transact-SQL; however, you can use only one aggregate

function in each query.

```
SELECT TOP 10 (NODE_SUPPORT),NODE_NAME, NODE_CAPTION  
FROM Association.CONTENT  
WHERE NODE_TYPE = 7
```

Example results:

NODE_SUPPORT	4334
NODE_NAME	37
NODE_CAPTION	Sport-100 = Existing

[Return to Top](#)

Making Predictions using the Model

An association rules model is often used to generate recommendations, which are based on correlations discovered in the itemsets. Therefore, when you create a prediction query based on an association rules model, you are typically using the rules in the model to make guesses based on new data. [PredictAssociation \(DMX\)](#) is the function that returns recommendations, and has several arguments that you can use to customize the query results.

Another example of where queries on an association model might be useful is to return the confidence for various rules and itemsets so that you can compare the effectiveness of different cross-sell strategies. The following examples illustrate how to create such queries.

Sample Query 6: Predicting Associated Items

This example uses the Association model created in the [Intermediate Data Mining Tutorial \(Analysis Services - Data Mining\)](#). It demonstrates how to create a prediction query that tells you what products to recommend to a customer who has purchased a particular product. This type of query, where you provide values to the model in a **SELECT...UNION** statement, is called a singleton query. Because the predictable model column that corresponds to the new values is a nested table, you must use one **SELECT** clause to map the new value to the nested table column, `[Model]`, and another **SELECT** clause to map the nested table column to the case-level column, `[v Assoc Seq Line Items]`. Adding the keyword **INCLUDE-STATISTICS** to the query lets you see the probability and support for the recommendations.

```
SELECT PredictAssociation([Association].[vAssocSeqLineItems],INCLUDE_STATISTICS, 3)  
FROM [Association]  
NATURAL PREDICTION JOIN  
(SELECT  
(SELECT 'Classic Vest' as [Model])  
AS [v Assoc Seq Line Items])  
AS t
```

Example results:

MODEL	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY
Sport-100	4334	0.291283	0.252696
Water Bottle	2866	0.19262	0.175205

MODEL	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY
Patch kit	2113	0.142012	0.132389

[Return to Top](#)

Sample Query 7: Determining Confidence for Related Itemsets

Whereas rules are useful for generating recommendations, itemsets are more interesting for deeper analysis of the patterns in the data set. For example, if you were not satisfied with the recommendation that are returned by the previous sample query, you could examine other itemsets that contain Product A, to can get a better idea of whether Product A is an accessory that people tend to buy with all kinds of products, or whether A is strongly correlated with purchases of particular products. The easiest way to explore these relationships is by filtering the itemsets in the Microsoft Association Viewer; however, you can retrieve the same information with a query.

The following sample query returns all itemsets that include the Water Bottle item, including the single item Water bottle.

```
SELECT TOP 100 FROM
(
SELECT FLATTENED NODE_CAPTION, NODE_SUPPORT,
(SELECT ATTRIBUTE_NAME from NODE_DISTRIBUTION
WHERE ATTRIBUTE_NAME = 'v Assoc Seq Line Items(Water Bottle)' ) as D
FROM Association.CONTENT
WHERE NODE_TYPE = 7
) AS Items
WHERE [D.ATTRIBUTE_NAME] <> NULL
ORDER BY NODE_SUPPORT DESC
```

Example results:

NODE_CAPTION	NODE_SUPPORT	D.ATTRIBUTE_NAME
Water Bottle = Existing	2866	v Assoc Seq Line Items(Water Bottle)
Mountain Bottle Cage = Existing, Water Bottle = Existing	1136	v Assoc Seq Line Items(Water Bottle)
Road Bottle Cage = Existing, Water Bottle = Existing	1068	v Assoc Seq Line Items(Water Bottle)
Water Bottle = Existing, Sport-100 = Existing	734	v Assoc Seq Line Items(Water Bottle)

This query returns both the rows from the nested table that match the criteria, and all the rows from the outside or case table. Therefore, you must add a condition that eliminates the case table rows that have a null value for the target attribute name.

[Return to Top](#)

Function List

All Microsoft algorithms support a common set of functions. However, the Microsoft Association algorithm supports the additional functions listed in the following table.

Prediction Function	Usage
IsDescendant (DMX)	Determines whether one node is a child of another node in the neural network graph.
IsInNode (DMX)	Indicates whether the specified node contains the current case.
PredictAdjustedProbability (DMX)	Returns the weighted probability.
PredictAssociation (DMX)	Predicts membership in an associative dataset.
PredictHistogram (DMX)	Returns a table of values related to the current predicted value.
PredictNodeId (DMX)	Returns the Node_ID for each case.
PredictProbability (DMX)	Returns probability for the predicted value.
PredictSupport (DMX)	Returns the support value for a specified state.
PredictVariance (DMX)	Returns variance for the predicted value.

Microsoft Clustering Algorithm

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Clustering algorithm is a *segmentation* or *clustering* algorithm that iterates over cases in a dataset to group them into clusters that contain similar characteristics. These groupings are useful for exploring data, identifying anomalies in the data, and creating predictions.

Clustering models identify relationships in a dataset that you might not logically derive through casual observation. For example, you might easily guess that people who commute to their jobs by bicycle do not typically live a long distance from where they work. The algorithm, however, can find other characteristics about bicycle commuters that are not as obvious. In the following diagram, cluster A represents data about people who tend to drive to work, while cluster B represents data about people who tend to ride bicycles to work.

A = Commuters who drive to work
B = Commuters who bicycle to work

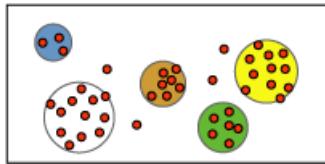

The clustering algorithm differs from other data mining algorithms, such as the Microsoft Decision Trees algorithm, in that you do not have to designate a predictable column to be able to build a clustering model. The clustering algorithm trains the model strictly from the relationships that exist in the data and from the clusters that the algorithm identifies.

Example

Consider a group of people who share similar demographic information and who buy similar products from the Adventure Works company. This group of people represents a cluster of data. Several such clusters may exist in a database. By observing the columns that make up a cluster, you can more clearly see how records in a dataset are related to one another.

How the Algorithm Works

The Microsoft Clustering algorithm first identifies relationships in a dataset and generates a series of clusters based on those relationships. A scatter plot is a useful way to visually represent how the algorithm groups data, as shown in the following diagram. The scatter plot represents all the cases in the dataset, and each case is a point on the graph. The clusters group points on the graph and illustrate the relationships that the algorithm identifies.

After first defining the clusters, the algorithm calculates how well the clusters represent groupings of the points, and then tries to redefine the groupings to create clusters that better represent the data. The algorithm iterates through this process until it cannot improve the results more by redefining the clusters.

You can customize the way the algorithm works by selecting a specifying a clustering technique, limiting the maximum number of clusters, or changing the amount of support required to create a cluster. For more

information, see [Microsoft Clustering Algorithm Technical Reference](#). This algorithm includes two popular clustering methods: K-means clustering and the Expectation Maximization method.

Data Required for Clustering Models

When you prepare data for use in training a clustering model, you should understand the requirements for the particular algorithm, including how much data is needed, and how the data is used.

The requirements for a clustering model are as follows:

- **A single key column** Each model must contain one numeric or text column that uniquely identifies each record. Compound keys are not allowed.
- **Input columns** Each model must contain at least one input column that contains the values that are used to build the clusters. You can have as many input columns as you want, but depending on the number of values in each column, the addition of extra columns can increase the time it takes to train the model.
- **Optional predictable column** The algorithm does not need a predictable column to build the model, but you can add a predictable column of almost any data type. The values of the predictable column can be treated as input to the clustering model, or you can specify that it be used for prediction only. For example, if you want to predict customer income by clustering on demographics such as region or age, you would specify income as **PredictOnly** and add all the other columns, such as region or age, as inputs.

For more detailed information about the content types and data types supported for clustering models, see the Requirements section of [Microsoft Clustering Algorithm Technical Reference](#).

Viewing a Clustering Model

To explore the model, you can use the **Microsoft Cluster Viewer**. When you view a clustering model, Analysis Services shows you the clusters in a diagram that depicts the relationships among clusters, and also provides a detailed profile of each cluster, a list of the attributes that distinguish each cluster from the others, and the characteristics of the entire training data set. For more information, see [Browse a Model Using the Microsoft Cluster Viewer](#).

If you want to know more detail, you can browse the model in the **Microsoft Generic Content Tree Viewer**. The content stored for the model includes the distribution for all values in each node, the probability of each cluster, and other information. For more information, see [Mining Model Content for Clustering Models \(Analysis Services - Data Mining\)](#).

Creating Predictions

After the model has been trained, the results are stored as a set of patterns, which you can explore or use to make predictions.

You can create queries to return predictions about whether new data fits into the clusters that were discovered, or to obtain descriptive statistics about the clusters.

For information about how to create queries against a data mining model, see [Data Mining Queries](#). For examples of how to use queries with a clustering model, see [Clustering Model Query Examples](#).

Remarks

- Supports the use of Predictive Model Markup Language (PMML) to create mining models.
- Supports drillthrough.
- Supports the use of OLAP mining models and the creation of data mining dimensions.

[Clustering Model Query Examples](#)

Microsoft Clustering Algorithm Technical Reference

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This section explains the implementation of the Microsoft Clustering algorithm, including the parameters that you can use to control the behavior of clustering models. It also provides guidance about how to improve performance when you create and process clustering models.

For additional information about how to use clustering models, see the following topics:

- [Mining Model Content for Clustering Models \(Analysis Services - Data Mining\)](#)
- [Clustering Model Query Examples](#)

Implementation of the Microsoft Clustering Algorithm

The Microsoft Clustering algorithm provides two methods for creating clusters and assigning data points to the clusters. The first, the *K-means* algorithm, is a hard clustering method. This means that a data point can belong to only one cluster, and that a single probability is calculated for the membership of each data point in that cluster. The second method, the *Expectation Maximization* (EM) method, is a *soft clustering* method. This means that a data point always belongs to multiple clusters, and that a probability is calculated for each combination of data point and cluster.

You can choose which algorithm to use by setting the *CLUSTERING_METHOD* parameter. The default method for clustering is scalable EM.

EM Clustering

In EM clustering, the algorithm iteratively refines an initial cluster model to fit the data and determines the probability that a data point exists in a cluster. The algorithm ends the process when the probabilistic model fits the data. The function used to determine the fit is the log-likelihood of the data given the model.

If empty clusters are generated during the process, or if the membership of one or more of the clusters falls below a given threshold, the clusters with low populations are reseeded at new points and the EM algorithm is rerun.

The results of the EM clustering method are probabilistic. This means that every data point belongs to all clusters, but each assignment of a data point to a cluster has a different probability. Because the method allows for clusters to overlap, the sum of items in all the clusters may exceed the total items in the training set. In the mining model results, scores that indicate support are adjusted to account for this.

The EM algorithm is the default algorithm used in Microsoft clustering models. This algorithm is used as the default because it offers multiple advantages in comparison to k-means clustering:

- Requires one database scan, at most.
- Will work despite limited memory (RAM).
- Has the ability to use a forward-only cursor.
- Outperforms sampling approaches.

The Microsoft implementation provides two options: scalable and non-scalable EM. By default, in scalable EM, the first 50,000 records are used to seed the initial scan. If this is successful, the model uses this data only. If the

model cannot be fit using 50,000 records, an additional 50,000 records are read. In non-scalable EM, the entire dataset is read regardless of its size. This method might create more accurate clusters, but the memory requirements can be significant. Because scalable EM operates on a local buffer, iterating through the data is much faster, and the algorithm makes much better use of the CPU memory cache than non-scalable EM. Moreover, scalable EM is three times faster than non-scalable EM, even if all the data can fit in main memory. In the majority of cases, the performance improvement does not lead to lower quality of the complete model.

For a technical report that describes the implementation of EM in the Microsoft Clustering algorithm, see [Scaling EM \(Expectation Maximization\) Clustering to Large Databases](#).

K-Means Clustering

K-means clustering is a well-known method of assigning cluster membership by minimizing the differences among items in a cluster while maximizing the distance between clusters. The "means" in k-means refers to the *centroid* of the cluster, which is a data point that is chosen arbitrarily and then refined iteratively until it represents the true mean of all data points in the cluster. The "k" refers to an arbitrary number of points that are used to seed the clustering process. The k-means algorithm calculates the squared Euclidean distances between data records in a cluster and the vector that represents the cluster mean, and converges on a final set of k clusters when that sum reaches its minimum value.

The k-means algorithm assigns each data point to exactly one cluster, and does not allow for uncertainty in membership. Membership in a cluster is expressed as a distance from the centroid.

Typically, the k-means algorithm is used for creating clusters of continuous attributes, where calculating distance to a mean is straightforward. However, the Microsoft implementation adapts the k-means method to cluster discrete attributes, by using probabilities. For discrete attributes, the distance of a data point from a particular cluster is calculated as follows:

$$1 - P(\text{data point}, \text{cluster})$$

NOTE

The Microsoft Clustering algorithm does not expose the distance function used in computing k-means, and measures of distance are not available in the completed model. However, you can use a prediction function to return a value that corresponds to distance, where distance is computed as the probability of a data point belonging to the cluster. For more information, see [ClusterProbability \(DMX\)](#).

The k-means algorithm provides two methods of sampling the data set: non-scalable K-means, which loads the entire data set and makes one clustering pass, or scalable k-means, where the algorithm uses the first 50,000 cases and reads more cases only if it needs more data to achieve a good fit of model to data.

Updates to the Microsoft Clustering Algorithm in SQL Server 2008

In SQL Server 2008, the default configuration of the Microsoft clustering algorithm was changed to use the internal parameter, NORMALIZATION = 1. Normalization is performed using z-score statistics, and assumes normal distribution. The intent of this change in the default behavior is to minimize the effect of attributes that might have large magnitudes and many outliers. However, z-score normalization may alter the clustering results on distributions that are not normal (such as uniform distributions). To prevent normalization and obtain the same behavior as the K-means clustering algorithm in SQL Server 2005, you can use the **Parameter Settings** dialog box to add the custom parameter, NORMALIZATION, and set its value to 0.

NOTE

The NORMALIZATION parameter is an internal property of the Microsoft Clustering algorithm and is not supported. In general, the use of normalization is recommended in clustering models to improve model results.

Customizing the Microsoft Clustering Algorithm

The Microsoft Clustering algorithm supports several parameters that affect the behavior, performance, and accuracy of the resulting mining model.

Setting Algorithm Parameters

The following table describes the parameters that can be used with the Microsoft Clustering algorithm. These parameters affect both the performance and accuracy of the resulting mining model.

CLUSTERING_METHOD

Specifies the clustering method for the algorithm to use. The following clustering methods are available:

ID	METHOD
1	Scalable EM
2	Non-scalable EM
3	Scalable K-Means
4	Non-scalable K-Means.

The default is 1 (scalable EM).

CLUSTER_COUNT

Specifies the approximate number of clusters to be built by the algorithm. If the approximate number of clusters cannot be built from the data, the algorithm builds as many clusters as possible. Setting the CLUSTER_COUNT to 0 causes the algorithm to use heuristics to best determine the number of clusters to build.

The default is 10.

CLUSTER_SEED

Specifies the seed number that is used to randomly generate clusters for the initial stage of model building.

By changing this number, you can change the way that the initial clusters are built, and then compare models that have been built using different seeds. If the seed is changed but the clusters that are found do not change greatly, the model can be considered relatively stable.

The default is 0.

MINIMUM_SUPPORT

Specifies the minimum number of cases that are required to build a cluster. If the number of cases in the cluster is lower than this number, the cluster is treated as empty and discarded.

If you set this number too high, you may miss valid clusters.

NOTE

If you use EM, which is the default clustering method, some clusters may have a support value that is lower than the specified value. This is because each case is evaluated for its membership in all possible clusters, and for some clusters there may be only minimal support.

The default is 1.

MODELLING_CARDINALITY

Specifies the number of sample models that are constructed during the clustering process.

Reducing the number of candidate models can improve performance at the risk of missing some good candidate models.

The default is 10.

STOPPING_TOLERANCE

Specifies the value that is used to determine when convergence is reached and the algorithm is finished building the model. Convergence is reached when the overall change in cluster probabilities is less than the ratio of the STOPPING_TOLERANCE parameter divided by the size of the model.

The default is 10.

SAMPLE_SIZE

Specifies the number of cases that the algorithm uses on each pass if the CLUSTERING_METHOD parameter is set to one of the scalable clustering methods. Setting the SAMPLE_SIZE parameter to 0 will cause the whole dataset to be clustered in a single pass. Loading the entire dataset in a single pass can cause memory and performance issues.

The default is 50000.

MAXIMUM_INPUT_ATTRIBUTES

Specifies the maximum number of input attributes that the algorithm can handle before it invokes feature selection. Setting this value to 0 specifies that there is no maximum number of attributes.

Increasing the number of attributes can significantly degrade performance.

The default is 255.

MAXIMUM_STATES

Specifies the maximum number of attribute states that the algorithm supports. If an attribute has more states than the maximum, the algorithm uses the most popular states and ignores the remaining states.

Increasing the number of states can significantly degrade performance.

The default is 100.

Modeling Flags

The algorithm supports the following modeling flags. You define modeling flags when you create the mining structure or mining model. The modeling flags specify how values in each column are handled during analysis.

MODELING FLAG	DESCRIPTION
MODEL_EXISTENCE_ONLY	<p>The column will be treated as having two possible states: Missing and Existing. A null is a missing value.</p> <p>Applies to mining model column.</p>
NOT NULL	<p>The column cannot contain a null. An error will result if Analysis Services encounters a null during model training.</p> <p>Applies to mining structure column.</p>

Requirements

A clustering model must contain a key column and input columns. You can also define input columns as being predictable. Columns set to **Predict Only** are not used to build clusters. The distribution of these values in the clusters are calculated after the clusters are built.

Input and Predictable Columns

The Microsoft Clustering algorithm supports the specific input columns and predictable columns that are listed in the following table. For more information about what the content types mean when used in a mining model, see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Continuous, Cyclical, Discrete, Discretized, Key, Table, Ordered
Predictable attribute	Continuous, Cyclical, Discrete, Discretized, Table, Ordered

NOTE

Cyclical and Ordered content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

Mining Model Content for Clustering Models (Analysis Services - Data Mining)

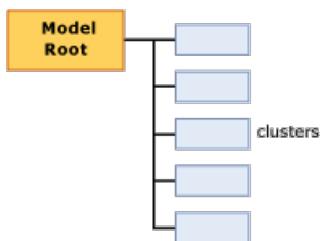

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes mining model content that is specific to models that use the Microsoft Clustering algorithm. For a general explanation of mining model content for all model types, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Understanding the Structure of a Clustering Model

A clustering model has a simple structure. Each model has a single parent node that represents the model and its metadata, and each parent node has a flat list of clusters (NODE_TYPE = 5). This organization is shown in the following image.

Each child node represents a single cluster and contains detailed statistics about the attributes of the cases in that cluster. This includes a count of the number of cases in the cluster, and the distribution of values that distinguish the cluster from other clusters.

NOTE

You do not need to iterate through the nodes to get a count or description of the clusters; the model parent node also counts and lists the clusters.

The parent node contains useful statistics that describe the actual distribution of all the training cases. These statistics are found in the nested table column, NODE DISTRIBUTION. For example, the following table shows several rows from the NODE DISTRIBUTION table that describe the distribution of customer demographics for the clustering model, `TM_Clustering`, that you create in the [Basic Data Mining Tutorial](#):

ATTRIBUTE_NAME	ATTRIBUTE_VALUE	SUPPORT	PROBABILITY	VARIANCE	VALUE_TYPE
Age	Missing	0	0	0	1 (Missing)
Age	44.9016152716593	12939	1	125.663453102554	3 (Continuous)
Gender	Missing	0	0	0	1 (Missing)
Gender	F	6350	0.490764355823479	0	4 (Discrete)

ATTRIBUTE_NAME	ATTRIBUTE_VALUE	SUPPORT	PROBABILITY	VARIANCE	VALUE_TYPE
Gender	M	6589	0.509235644176 521	0	4 (Discrete)

From these results, you can see that there were 12939 cases used to build the model, that the ratio of males to females was about 50-50, and that the mean age was 44. The descriptive statistics vary depending on whether the attribute being reported is a continuous numeric data type, such as age, or a discrete value type, such as gender. The statistical measures *mean* and *variance* are computed for continuous data types, whereas *probability* and *support* are computed for discrete data types.

NOTE

The variance represents the total variance for the cluster. When the value for variance is small, it indicates that most values in the column were fairly close to the mean. To obtain the standard deviation, calculate the square root of the variance.

Note that for each of the attributes there is a **Missing** value type that tells you how many cases had no data for that attribute. Missing data can be significant and affects calculations in different ways, depending on the data type. For more information, see [Missing Values \(Analysis Services - Data Mining\)](#).

Model Content for a Clustering Model

This section provides detail and examples only for those columns in the mining model content that are relevant for clustering models.

For information about the general-purpose columns in the schema rowset, such as MODEL_CATALOG and MODEL_NAME, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

Always blank in clustering models because there is no predictable attribute in the mode.

NODE_NAME

Always same as NODE_UNIQUE_NAME.

NODE_UNIQUE_NAME

A unique identifier for the node within the model. This value cannot be changed.

NODE_TYPE

A clustering model outputs the following node types:

NODE ID AND NAME	DESCRIPTION
1 (Model)	Root node for model.
5 (Cluster)	Contains a count of cases in the cluster, the characteristics of cases in the cluster, and statistics that describe the values in the cluster.

NODE_CAPTION

A friendly name for display purposes. When you create a model, the value of NODE_UNIQUE_NAME is

automatically used as the caption. However, you can change the value for NODE_CAPTION to update the display name for the cluster, either programmatically or by using the viewer.

NOTE

When you reprocess the model, all name changes will be overwritten by the new values. You cannot persist names in the model, or track changes in cluster membership between different versions of a model.

CHILDREN_CARDINALITY

An estimate of the number of children that the node has.

Parent node Indicates the number of clusters in the model.

Cluster nodes Always 0.

PARENT_UNIQUE_NAME

The unique name of the node's parent.

Parent node Always NULL

Cluster nodes Usually 000.

NODE_DESCRIPTION

A description of the node.

Parent node Always **(All)**.

Cluster nodes A comma-separated list of the primary attributes that distinguish the cluster from other clusters.

NODE_RULE

Not used for clustering models.

MARGINAL_RULE

Not used for clustering models.

NODE_PROBABILITY

The probability associated with this node. **Parent node** Always 1.

Cluster nodes The probability represents the compound probability of the attributes, with some adjustments depending on the algorithm used to create the clustering model.

MARGINAL_PROBABILITY

The probability of reaching the node from the parent node. In a clustering model, the marginal probability is always the same as the node probability.

NODE DISTRIBUTION

A table that contains the probability histogram of the node.

Parent node See the Introduction to this topic.

Cluster nodes Represents the distribution of attributes and values for cases that are included in this cluster.

NODE_SUPPORT

The number of cases that support this node. **Parent node** Indicates the number of training cases for the entire model.

Cluster nodes Indicates the size of the cluster as a number of cases.

Note If the model uses K-Means clustering, each case can belong to only one cluster. However, if the model uses EM clustering, each case can belong to different cluster, and the case is assigned a weighted distance for each

cluster to which it belongs. Therefore, for EM models the sum of support for an individual cluster is greater than support for the overall model.

MSOLAP_MODEL_COLUMN

Not used for clustering models.

MSOLAP_NODE_SCORE

Displays a score associated with the node.

Parent node The Bayesian Information Criterion (BIC) score for the clustering model.

Cluster nodes Always 0.

MSOLAP_NODE_SHORT_CAPTION

A label used for display purposes. You cannot change this caption.

Parent node The type of model: Cluster model

Cluster nodes The name of the cluster. Example: Cluster 1.

Remarks

Analysis Services provides multiple methods for creating a clustering model. If you do not know which method was used to create the model that you are working with, you can retrieve the model metadata programmatically, by using an ADOMD client or AMO, or by querying the data mining schema rowset. For more information, see [Query the Parameters Used to Create a Mining Model](#).

NOTE

The structure and content of the model stay the same, regardless of which clustering method or parameters you use.

[Data Mining Queries](#)

Clustering Model Query Examples

7/16/2019 • 14 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can retrieve metadata about the model, or create a content query that provides details about the patterns discovered in analysis. Alternatively, you can create a prediction query, which uses the patterns in the model to make predictions for new data. Each type of query will provide different information. For example, a content query might provide additional details about the clusters that were found, whereas a prediction query might tell you in which cluster a new data point is most likely to belong.

This section explains how to create queries for models that are based on the Microsoft Clustering algorithm.

Content Queries

[Getting Model Metadata by Using DMX](#)

[Returning All Possible Clusters with Probability and Distance](#)

Finding Information about the Model

All mining models expose the content learned by the algorithm according to a standardized schema, the mining model schema rowset. You can create queries against the mining model schema rowset by using Data Mining Extension (DMX) statements. In SQL Server 2017, you can also query the schema rowsets directly as system tables.

[Return to Top](#)

Sample Query 1: Getting Model Metadata by Using DMX

The following query returns basic metadata about the clustering model, `TM_Clustering`, that you created in the Basic Data Mining Tutorial. The metadata available in the parent node of a clustering model includes the name of the model, the database where the model is stored, and the number of child nodes in the model. This query uses a DMX content query to retrieve the metadata from the parent node of the model:

```

SELECT MODEL_CATALOG, MODEL_NAME, NODE_CAPTION,
NODE_SUPPORT, [CHILDREN_CARDINALITY], NODE_DESCRIPTION
FROM TM_Clustering.CONTENT
WHERE NODE_TYPE = 1

```

NOTE

You must enclose the name of the column, CHILDREN_CARDINALITY, in brackets to distinguish it from the Multidimensional Expressions (MDX) reserved keyword of the same name.

Example results:

MODEL_CATALOG	TM_Clustering
MODEL_NAME	Adventure Works DW
NODE_CAPTION	Cluster Model
NODE_SUPPORT	12939
CHILDREN_CARDINALITY	10
NODE_DESCRIPTION	All

For a definition of what these columns mean in a clustering model, see [Mining Model Content for Clustering Models \(Analysis Services - Data Mining\)](#).

[Return to Top](#)

Sample Query 2: Retrieving Model Metadata from the Schema Rowset

By querying the data mining schema rowset, you can find the same information that is returned in a DMX content query. However, the schema rowset provides some additional columns. These include the parameters that were used when the model was created, the date and time that the model was last processed, and the owner of the model.

The following example returns the date the model was created, modified, and last processed, together with the clustering parameters that were used to build the model, and the size of the training set. This information can be useful for documenting the model, or for determining which of the clustering options were used to create an existing model.

```

SELECT MODEL_NAME, DATE_CREATED, LAST_PROCESSED, PREDICTION_ENTITY, MINING_PARAMETERS
from $system.DMSCHEMA_MINING_MODELS
WHERE MODEL_NAME = 'TM_Clustering'

```

Example results:

MODEL_NAME	TM_Clustering
DATE_CREATED	10/12/2007 7:42:51 PM

LAST_PROCESSED	10/12/2007 8:09:54 PM
PREDICTION_ENTITY	Bike Buyer
MINING_PARAMETERS	CLUSTER_COUNT=10, CLUSTER_SEED=0, CLUSTERING_METHOD=1, MAXIMUM_INPUT_ATTRIBUTES=255, MAXIMUM_STATES=100, MINIMUM_SUPPORT=1, MODELLING_CARDINALITY=10, SAMPLE_SIZE=50000, STOPPING_TOLERANCE=10

[Return to Top](#)

Finding Information about Clusters

The most useful content queries on clustering models generally return the same type of information that you can browse by using the **Cluster Viewer**. This includes cluster profiles, cluster characteristics, and cluster discrimination. This section provides examples of queries that retrieve this information.

Sample Query 3: Returning a Cluster or List of Clusters

Because all clusters have a node type of 5, you can easily retrieve a list of the clusters by querying the model content for only the nodes of that type. You can also filter the nodes that are returned by probability or by support, as shown in this example.

```
SELECT NODE_NAME, NODE_CAPTION ,NODE_SUPPORT, NODE_DESCRIPTION
FROM TM_Clustering.CONTENT
WHERE NODE_TYPE = 5 AND NODE_SUPPORT > 1000
```

Example results:

NODE_NAME	002
NODE_CAPTION	Cluster 2
NODE_SUPPORT	1649

NODE_DESCRIPTION	English Education=Graduate Degree , 32 <=Age <=48 , Number Cars Owned=0 , 35964.0771121808 <=Yearly Income <=97407.7163393957 , English Occupation=Professional , Commute Distance=2-5 Miles , Region=North America , Bike Buyer=1 , Number Children At Home=0 , Number Cars Owned=1 , Commute Distance=0-1 Miles , English Education=Bachelors , Total Children=1 , Number Children At Home=2 , English Occupation=Skilled Manual , Marital Status=S , Total Children=0 , House Owner Flag=0 , Gender=F , Total Children=2 , Region=Pacific
------------------	--

The attributes that define the cluster can be found in two columns in the data mining schema rowset.

- The NODE_DESCRIPTION column contains a comma-separated list of attributes. Note that the list of attributes might be abbreviated for display purposes.
- The nested table in the NODE DISTRIBUTION column contains the full list of attributes for the cluster. If your client does not support hierarchical rowsets, you can return the nested table by adding the FLATTENED keyword before the SELECT column list. For more information about the use of the FLATTENED keyword, see [SELECT FROM <model>.CONTENT \(DMX\)](#).

[Return to Top](#)

Sample Query 4: Returning Attributes for a Cluster

For every cluster, the **Cluster Viewer** displays a profile that lists the attributes and their values. The viewer also displays a histogram that shows the distribution of values for the whole population of cases in the model. If you are browsing the model in the viewer, you can easily copy the histogram from the Mining Legend and then paste it to Excel or a Word document. You can also use the Cluster Characteristics pane of the viewer to graphically compare the attributes of different clusters.

However, if you must obtain values for more than one cluster at a time, it is easier to query the model. For example, when you browse the model, you might notice that the top two clusters differ with regard to one attribute, `Number Cars Owned`. Therefore, you want to extract the values for each cluster.

```
SELECT TOP 2 NODE_NAME,
(SELECT ATTRIBUTE_VALUE, [PROBABILITY] FROM NODE DISTRIBUTION WHERE ATTRIBUTE_NAME = 'Number Cars Owned')
AS t
FROM [TM_Clustering].CONTENT
WHERE NODE_TYPE = 5
```

The first line of the code specifies that you want only the top two clusters.

NOTE

By default, the clusters are ordered by support. Therefore, the NODE_SUPPORT column can be omitted.

The second line of the code adds a sub-select statement that returns only certain columns from the nested table column. Furthermore, it restricts the rows from the nested table to those related to the target attribute, `Number Cars Owned`. To simplify the display, the nested table is aliased.

NOTE

The nested table column, `PROBABILITY`, must be enclosed in brackets because it is also the name of a reserved MDX keyword.

Example results:

NODE_NAME	T.ATTRIBUTE_VALUE	T.PROBABILITY
001	2	0.829207754
001	1	0.109354156
001	3	0.034481552
001	4	0.013503302
001	0	0.013453236
001	Missing	0
002	0	0.576980023
002	1	0.406623939
002	2	0.016380082
002	3	1.60E-05
002	4	0
002	Missing	0

[Return to Top](#)

Sample Query 5: Return a Cluster Profile Using System Stored Procedures

As a shortcut, rather than writing your own queries by using DMX, you can also call the system stored procedures that Analysis Services uses to work with clusters. The following example illustrates how to use the internal stored procedures to return the profile for a cluster with the ID of 002.

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterProfiles('TM_Clustering',
'002',0.0005
```

Similarly, you can use a system stored procedure to return the characteristics of a specific cluster, as shown in the following example:

```
CALL
System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterCharacteristics('TM_Clustering',
'009',0.0005
```

Example results:

ATTRIBUTES	VALUES	FREQUENCY	SUPPORT
Number Children at Home	0	0.999999829076798	899
Region	North America	0.999852875241508	899
Total Children	0	0.993860958572323	893

NOTE

The data mining system stored procedures are for internal use and Microsoft reserves the right to change them as needed. For production use, we recommend that you create queries by using DMX, AMO, or XMLA.

[Return to Top](#)

Sample Query 6: Find Discriminating Factors for a Cluster

The **Cluster Discrimination** tab of the **Cluster Viewer** enables you to easily compare a cluster with another cluster, or compare a cluster with all remaining cases (the complement of the cluster).

However, creating queries to return this information can be complex, and you might need some additional processing on the client to store the temporary results and compare the results of two or more queries. As a shortcut, you can use the system stored procedures.

The following query returns a single table that indicates the primary discriminating factors between the two clusters that have the node IDs of 009 and 007. Attributes with positive values favor cluster 009, whereas attributes with negative values favor cluster 007.

```
CALL
System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterDiscrimination('TM_Clustering','009',
,'007',0.0005,true)
```

Example results:

ATTRIBUTES	VALUES	SCORE
Region	North America	100
English Occupation	Skilled Manual	94.9003803898654
Region	Europe	-72.5041051379789
English Occupation	Manual	-69.6503163202722

This is the same information that is presented in the chart of the **Cluster Discrimination** viewer if you select Cluster 9 from the first drop-down list and Cluster 7 from the second drop-down list. To compare cluster 9 with its complement, you use the empty string in the second parameter, as shown in the following example:

```
CALL
System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterDiscrimination('TM_Clustering','009',
,'',0.0005,true)
```

NOTE

The data mining system stored procedures are for internal use and Microsoft reserves the right to change them as needed. For production use, we recommend that you create queries by using DMX, AMO, or XMLA.

[Return to Top](#)

Sample Query 7: Returning Cases that Belong to a Cluster

If drillthrough has been enabled on the mining model, you can create queries that return detailed information about the cases used in the model. Moreover, if drillthrough has been enabled on the mining structure, you can include columns from the underlying structure by using the [StructureColumn \(DMX\)](#) function.

The following example returns two columns that were used in the model, Age and Region, and one more column, First Name, that was not used in the model. The query returns only cases that were classified into Cluster 1.

```
SELECT [Age], [Region], StructureColumn('First Name')
FROM [TM_Clustering].CASES
WHERE IsInNode('001')
```

To return the cases that belong to a cluster, you must know the ID of the cluster. You can obtain the ID of the cluster by browsing the model in one of the viewers. Or, you can rename a cluster for easier reference, after which you could use the name in place of an ID number. However, know that the names that you assign to a cluster will be lost if the model is reprocessed.

[Return to Top](#)

Making Predictions using the Model

Although clustering is typically used for describing and understanding data, the Microsoft implementation also lets you make prediction about cluster membership, and return probabilities associated with the prediction. This section provides examples of how to create prediction queries on clustering models. You can make predictions for multiple cases, by specifying a tabular data source, or you can provide new values on at a time by creating a singleton query. For clarity the examples in this section are all singleton queries.

For more information about how to create prediction queries using DMX, see [Data Mining Query Tools](#).

[Return to Top](#)

Sample Query 8: Predicting Outcomes from a Clustering Model

If the clustering model you create contains a predictable attribute, you can use the model to make predictions about outcomes. However, the model handles the predictable attribute differently depending on whether you set the predictable column to **Predict** or **PredictOnly**. If you set the usage of the column to **Predict**, the values for that attribute are added to the clustering model and appear as attributes in the finished model. However, if you set the usage of the column to **PredictOnly**, the values are not used to create clusters. Instead, after the mode is completed, the clustering algorithm creates new values for the **PredictOnly** attribute based on the clusters to which each case belongs.

The following query provides a single new case to the model, where the only information about the case is the age and gender. The SELECT statement specifies the predictable attribute/value pair that you are interested in, and the [PredictProbability \(DMX\)](#) function tells you the probability that a case with those attributes will have the targeted outcome.

```

SELECT
    [TM_Clustering].[Bike Buyer], PredictProbability([Bike Buyer],1)
FROM
    [TM_Clustering]
NATURAL PREDICTION JOIN
(SELECT 40 AS [Age],
    'F' AS [Gender]) AS t

```

Example of results when usage is set to **Predict**:

BIKE BUYER	EXPRESSION
1	0.592924735740338

Example of results when the usage is set to **PredictOnly** and the model is reprocessed:

BIKE BUYER	EXPRESSION
1	0.55843544003102

In this example, the difference in the model is not significant. However, sometimes it can be important to detect differences between the actual distribution of values and what the model predicts. The [PredictCaseLikelihood \(DMX\)](#) function is useful in this scenario, because it tells you how likely a case is, given the model.

The number that is returned by the [PredictCaseLikelihood](#) function is a probability, and therefore is always between 0 and 1, with a value of .5 representing random outcome. Therefore, a score less than .5 means that the predicted case is unlikely, given the model, and a score over .5 indicates that the predicted case is more likely than not to fit the model.

For example, the following query returns two values that characterize the likelihood of a new sample case. The non-normalized value represents the probability given the current model. When you use the **NORMALIZED** keyword, the likelihood score that is returned by the function is adjusted by dividing "probability with the model" by "probability without the model".

```

SELECT
    PredictCaseLikelihood(NORMALIZED) AS [NormalizedValue], PredictCaseLikelihood(NONNORMALIZED) AS
    [NonNormalizedValue]
FROM
    [TM_Clustering_PredictOnly]
NATURAL PREDICTION JOIN
(SELECT 40 AS [Age],
    'F' AS [Gender]) AS t

```

Example results:

NORMALIZEDVALUE	NONNORMALIZEDVALUE
5.56438372679893E-11	8.65459953145182E-68

Note that the numbers in these results are expressed in scientific notation.

[Return to Top](#)

Sample Query 9: Determining Cluster Membership

This example uses the [Cluster \(DMX\)](#) function to return the cluster to which the new case is most likely to belong, and uses the [ClusterProbability \(DMX\)](#) function to return the probability for membership in that cluster.

```

SELECT Cluster(), ClusterProbability()
FROM
    [TM_Clustering]
NATURAL PREDICTION JOIN
(SELECT 40 AS [Age],
    'F' AS [Gender],
    'S' AS [Marital Status]) AS t

```

Example results:

\$CLUSTER	EXPRESSION
Cluster 2	0.397918596951617

Note By default, the **ClusterProbability** function returns the probability of the most likely cluster. However, you can specify a different cluster by using the syntax `ClusterProbability('cluster name')`. If you do this, be aware that the results from each prediction function are independent of the other results. Therefore, the probability score in the second column could refer to a different cluster than the cluster named in the first column.

[Return to Top](#)

Sample Query 10: Returning All Possible Clusters with Probability and Distance

In the previous example, the probability score was not very high. To determine if there is a better cluster, you can use the [PredictHistogram \(DMX\)](#) function together with the [Cluster \(DMX\)](#) function to return a nested table that includes all possible clusters, together with the probability that the new case that belongs to each cluster. The FLATTENED keyword is used to change the hierarchical rowset into a flat table for easier viewing.

```

SELECT FLATTENED PredictHistogram(Cluster())
From
    [TM_Clustering]
NATURAL PREDICTION JOIN
(SELECT 40 AS [Age],
    'F' AS [Gender],
    'S' AS [Marital Status])

```

EXPRESSION.\$CLUSTER	EXPRESSION.\$DISTANCE	EXPRESSION.\$PROBABILITY
Cluster 2	0.602081403048383	0.397918596951617
Cluster 10	0.719691686785675	0.280308313214325
Cluster 4	0.867772590378791	0.132227409621209
Cluster 5	0.931039872200985	0.0689601277990149
Cluster 3	0.942359230072167	0.0576407699278328
Cluster 6	0.958973668972756	0.0410263310272437
Cluster 7	0.979081275926724	0.0209187240732763
Cluster 1	0.999169044818624	0.000830955181376364
Cluster 9	0.999831227795894	0.000168772204105754

EXPRESSION.\$CLUSTER	EXPRESSION.\$DISTANCE	EXPRESSION.\$PROBABILITY
Cluster 8	1	0

By default, the results are ranked by probability. The results tell you that, even though the probability for Cluster 2 is fairly low, Cluster 2 is still the best fit for the new data point.

Note The additional column, `$DISTANCE`, represents the distance from the data point to the cluster. By default, the Microsoft Clustering Algorithm uses scalable EM clustering, which assigns multiple clusters to each data point and ranks the possible clusters. However, if you create your clustering model using the K-means algorithm, only one cluster can be assigned to each data point, and this query would return only one row. Understanding these differences is necessary to interpret the results of the [PredictCaseLikelihood \(DMX\)](#) function. For more information about the differences between EM and K-means clustering, see [Microsoft Clustering Algorithm Technical Reference](#).

[Return to Top](#)

Function List

All Microsoft algorithms support a common set of functions. However, models that are built by using the Microsoft Clustering algorithm support the additional functions that are listed in the following table.

Prediction Function	Usage
Cluster (DMX)	Returns the cluster that is most likely to contain the input case.
ClusterDistance (DMX)	Returns the distance of the input case from the specified cluster, or if no cluster is specified, the distance of the input case from the most likely cluster. Returns the probability that the input case belongs to the specified cluster.
ClusterProbability (DMX)	Returns the probability that the input case belongs to the specified cluster.
IsDescendant (DMX)	Determines whether one node is a child of another node in the model.
IsInNode (DMX)	Indicates whether the specified node contains the current case.
PredictAdjustedProbability (DMX)	Returns the weighted probability.
PredictAssociation (DMX)	Predicts membership in an associative dataset.
PredictCaseLikelihood (DMX)	Returns the likelihood that an input case will fit in the existing model.
PredictHistogram (DMX)	Returns a table of values related to the current predicted value.
PredictNodeId (DMX)	Returns the Node_ID for each case.

PredictProbability (DMX)	Returns probability for the predicted value.
PredictStdev (DMX)	Returns the predicted standard deviation for the specified column.
PredictSupport (DMX)	Returns the support value for a specified state.
PredictVariance (DMX)	Returns the variance of a specified column.

For the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

[Microsoft Clustering Algorithm](#)

Microsoft Decision Trees Algorithm

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Decision Trees algorithm is a classification and regression algorithm for use in predictive modeling of both discrete and continuous attributes.

For discrete attributes, the algorithm makes predictions based on the relationships between input columns in a dataset. It uses the values, known as states, of those columns to predict the states of a column that you designate as predictable. Specifically, the algorithm identifies the input columns that are correlated with the predictable column. For example, in a scenario to predict which customers are likely to purchase a bicycle, if nine out of ten younger customers buy a bicycle, but only two out of ten older customers do so, the algorithm infers that age is a good predictor of bicycle purchase. The decision tree makes predictions based on this tendency toward a particular outcome.

For continuous attributes, the algorithm uses linear regression to determine where a decision tree splits.

If more than one column is set to predictable, or if the input data contains a nested table that is set to predictable, the algorithm builds a separate decision tree for each predictable column

Example

The marketing department of the Adventure Works Cycles company wants to identify the characteristics of previous customers that might indicate whether those customers are likely to buy a product in the future. The AdventureWorks2012 database stores demographic information that describes previous customers. By using the Microsoft Decision Trees algorithm to analyze this information, the marketing department can build a model that predicts whether a particular customer will purchase products, based on the states of known columns about that customer, such as demographics or past buying patterns.

How the Algorithm Works

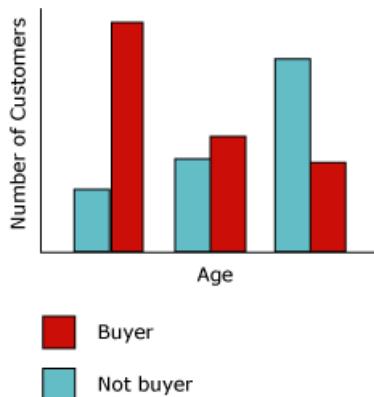

The Microsoft Decision Trees algorithm builds a data mining model by creating a series of splits in the tree. These splits are represented as *nodes*. The algorithm adds a node to the model every time that an input column is found to be significantly correlated with the predictable column. The way that the algorithm determines a split is different depending on whether it is predicting a continuous column or a discrete column.

The Microsoft Decision Trees algorithm uses *feature selection* to guide the selection of the most useful attributes. Feature selection is used by all SQL Server Data Mining algorithms to improve performance and the quality of analysis. Feature selection is important to prevent unimportant attributes from using processor time. If you use too many input or predictable attributes when you design a data mining model, the model can take a very long time to process, or even run out of memory. Methods used to determine whether to split the tree include industry-standard metrics for *entropy* and *Bayesian networks**.* For more information about the methods used to select meaningful attributes and then score and rank the attributes, see [Feature Selection \(Data Mining\)](#).

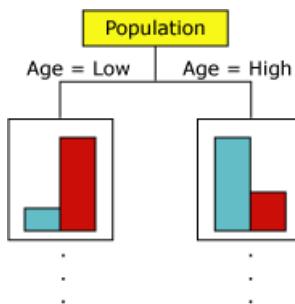

A common problem in data mining models is that the model becomes too sensitive to small differences in the training data, in which case it said to be *overfitted* or *over-trained*. An overfitted model cannot be generalized to other data sets. To avoid overfitting on any particular set of data, the Microsoft Decision Trees algorithm uses techniques for controlling the growth of the tree. For a more in-depth explanation of how the Microsoft Decision Trees algorithm works, see [Microsoft Decision Trees Algorithm Technical Reference](#).

Predicting Discrete Columns

The way that the Microsoft Decision Trees algorithm builds a tree for a discrete predictable column can be demonstrated by using a histogram. The following diagram shows a histogram that plots a predictable column, Bike Buyers, against an input column, Age. The histogram shows that the age of a person helps distinguish whether that person will purchase a bicycle.

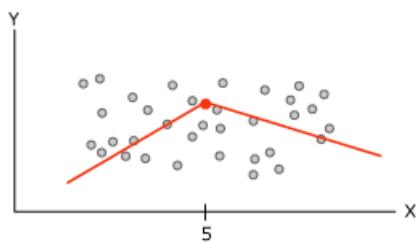

The correlation that is shown in the diagram would cause the Microsoft Decision Trees algorithm to create a new node in the model.

As the algorithm adds new nodes to a model, a tree structure is formed. The top node of the tree describes the breakdown of the predictable column for the overall population of customers. As the model continues to grow, the algorithm considers all columns.

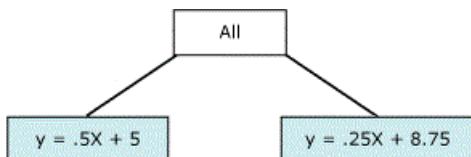

Predicting Continuous Columns

When the Microsoft Decision Trees algorithm builds a tree based on a continuous predictable column, each node contains a regression formula. A split occurs at a point of non-linearity in the regression formula. For example, consider the following diagram.

In a standard regression model, you would attempt to derive a single formula that represents the trend and relationships for the data as a whole. However, a single formula might do a poor job of capturing the discontinuity in complex data. Instead, the Microsoft Decision Trees algorithm looks for segments of the tree that are largely linear and creates separate formulas for these segments. By breaking up the data into different segments, the model can do a much better job of approximating the data.

The following diagram represents the tree diagram for the model in the scatterplot above. To predict the outcome, the model provides two different formulas: one for the left branch, with the formula $y = .5x + 5$, and one for the right branch, with the formula $y = .25x + 8.75$. The point where the two lines come together in the scatterplot is the point of non-linearity, and is the point where a node in a decision tree model would split.

This is a simple model with only two linear equations; therefore, the split in the tree is immediately after the **All** node. However, a split can occur at any level of the tree. That means that in a tree containing multiple levels and nodes, where each node is characterized by a different collection of attributes, a formula might be shared across multiple nodes, or apply only to a single node. For example, you might get one formula for a node defined as "customers over a certain age and income", and another in a node that represents "customers who commute long distances". To see the formula for an individual node or segment, just click the node.

Data Required for Decision Tree Models

When you prepare data for use in a decision trees model, you should understand the requirements for the particular algorithm, including how much data is needed, and how the data is used.

The requirements for a decision tree model are as follows:

- **A single key column** Each model must contain one numeric or text column that uniquely identifies each record. Compound keys are not permitted.
- **A predictable column** Requires at least one predictable column. You can include multiple predictable attributes in a model, and the predictable attributes can be of different types, either numeric or discrete. However, increasing the number of predictable attributes can increase processing time.
- **Input columns** Requires input columns, which can be discrete or continuous. Increasing the number of input attributes affects processing time.

For more detailed information about the content types and data types supported for decision tree models, see the Requirements section of [Microsoft Decision Trees Algorithm Technical Reference](#).

Viewing a Decision Trees Model

To explore the model, you can use the **Microsoft Tree Viewer**. If your model generates multiple trees, you can select a tree and the viewer shows you a breakdown of how the cases are categorized for each predictable attribute. You can also view the interaction of the trees by using the dependency network viewer. For more information, see [Browse a Model Using the Microsoft Tree Viewer](#).

If you want to know more detail about any branch or node in the tree, you can also browse the model by using the **Microsoft Generic Content Tree Viewer**. The content stored for the model includes the distribution for all values in each node, probabilities at each level of the tree, and regression formulas for continuous attributes. For more information, see [Mining Model Content for Decision Tree Models \(Analysis Services - Data Mining\)](#).

Creating Predictions

After the model has been processed, the results are stored as a set of patterns and statistics, which you can use to explore relationships or make predictions.

For examples of queries to use with a decision trees model, see [Decision Trees Model Query Examples](#).

For general information about how to create queries against mining models, see [Data Mining Queries](#).

Remarks

- Supports the use of Predictive Model Markup Language (PMML) to create mining models.

- Supports drillthrough.
- Supports the use of OLAP mining models and the creation of data mining dimensions.

Microsoft Decision Trees Algorithm Technical Reference

7/16/2019 • 11 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The Microsoft Decision Trees algorithm is a hybrid algorithm that incorporates different methods for creating a tree, and supports multiple analytic tasks, including regression, classification, and association. The Microsoft Decision Trees algorithm supports modeling of both discrete and continuous attributes.

This topic explains the implementation of the algorithm, describes how to customize the behavior of the algorithm for different tasks, and provides links to additional information about querying decision tree models.

Implementation of the Decision Trees Algorithm

The Microsoft Decision Trees algorithm applies the Bayesian approach to learning causal interaction models by obtaining approximate posterior distributions for the models. For a detailed explanation of this approach, see the paper on the Microsoft Research site, by [Structure and Parameter Learning](#).

The methodology for assessing the information value of the *priors* needed for learning is based on the assumption of *likelihood equivalence*. This assumption says that data should not help to discriminate network structures that otherwise represent the same assertions of conditional independence. Each case is assumed to have a single Bayesian prior network and a single measure of confidence for that network.

Using these prior networks, the algorithm then computes the relative *posterior probabilities* of network structures given the current training data, and identifies the network structures that have the highest posterior probabilities.

The Microsoft Decision Trees algorithm uses different methods to compute the best tree. The method used depends on the task, which can be linear regression, classification, or association analysis. A single model can contain multiple trees for different predictable attributes. Moreover, each tree can contain multiple branches, depending on how many attributes and values there are in the data. The shape and depth of the tree built in a particular model depends on the scoring method and other parameters that were used. Changes in the parameters can also affect where the nodes split.

Building the Tree

When the Microsoft Decision Trees algorithm creates the set of possible input values, it performs *feature selection* to identify the attributes and values that provide the most information, and removes from consideration the values that are very rare. The algorithm also groups values into *bins*, to create groupings of values that can be processed as a unit to optimize performance.

A tree is built by determining the correlations between an input and the targeted outcome. After all the attributes have been correlated, the algorithm identifies the single attribute that most cleanly separates the outcomes. This point of the best separation is measured by using an equation that calculates information gain. The attribute that has the best score for information gain is used to divide the cases into subsets, which are then recursively analyzed by the same process, until the tree cannot be split any more.

The exact equation used to evaluate information gain depends on the parameters set when you created the algorithm, the data type of the predictable column, and the data type of the input.

Discrete and Continuous Inputs

When the predictable attribute is discrete and the inputs are discrete, counting the outcomes per input is a matter of creating a matrix and generating scores for each cell in the matrix.

However, when the predictable attribute is discrete and the inputs are continuous, the input of the continuous columns are automatically discretized. You can accept the default and have Analysis Services find the optimum number of bins, or you can control the manner in which continuous inputs are discretized by setting the [DiscretizationMethod](#) and [DiscretizationBucketCount](#) properties. For more information, see [Change the Discretization of a Column in a Mining Model](#).

For continuous attributes, the algorithm uses linear regression to determine where a decision tree splits.

When the predictable attribute is a continuous numeric data type, feature selection is applied to the outputs as well, to reduce the possible number of outcomes and build the model faster. You can change the threshold for feature selection and thereby increase or decrease the number of possible values by setting the MAXIMUM_OUTPUT_ATTRIBUTES parameter.

For a more detailed explanation about how the Microsoft Decision Trees algorithm works with discrete predictable columns, see [Learning Bayesian Networks: The Combination of Knowledge and Statistical Data](#). For more information about how the Microsoft Decision Trees algorithm works with a continuous predictable column, see the appendix of [Autoregressive Tree Models for Time-Series Analysis](#).

Scoring Methods and Feature Selection

The Microsoft Decision Trees algorithm offers three formulas for scoring information gain: Shannon's entropy, Bayesian network with K2 prior, and Bayesian network with a uniform Dirichlet distribution of priors. All three methods are well established in the data mining field. We recommend that you experiment with different parameters and scoring methods to determine which provides the best results. For more information about these scoring methods, see [Feature Selection](#).

All Analysis Services data mining algorithms automatically use feature selection to improve analysis and reduce processing load. The method used for feature selection depends on the algorithm that is used to build the model. The algorithm parameters that control feature selection for a decision trees model are MAXIMUM_INPUT_ATTRIBUTES and MAXIMUM_OUTPUT.

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Decision Trees	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	If any columns contain non-binary continuous values, the interestingness score is used for all columns, to ensure consistency. Otherwise, the default or specified method is used.
Linear Regression	Interestingness score	Linear Regression only uses interestingness, because it only supports continuous columns.

Scalability and Performance

Classification is an important data mining strategy. Generally, the amount of information that is needed to classify the cases grows in direct proportion to the number of input records. This limits the size of the data that can be classified. The Microsoft Decision Trees algorithm uses the following methods to resolve these problems, improve performance, and eliminate memory restrictions:

- Feature selection to optimize the selection of attributes.
- Bayesian scoring to control tree growth.

- Optimization of binning for continuous attributes.
- Dynamic grouping of input values to determine the most important values.

The Microsoft Decision Trees algorithm is fast and scalable, and has been designed to be easily parallelized, meaning that all processors work together to build a single, consistent model. The combination of these characteristics makes the decision-tree classifier an ideal tool for data mining.

If performance constraints are severe, you might be able to improve processing time during the training of a decision tree model by using the following methods. However, if you do so, be aware that eliminating attributes to improve processing performance will change the results of the model, and possibly make it less representative of the total population.

- Increase the value of the COMPLEXITY_PENALTY parameter to limit tree growth.
- Limit the number of items in association models to limit the number of trees that are built.
- Increase the value of the MINIMUM_SUPPORT parameter to avoid overfitting.
- Restrict the number of discrete values for any attribute to 10 or less. You might try grouping values in different ways in different models.

NOTE

You can use the data exploration tools available in SQL Server 2017 Integration Services (SSIS) to visualize the distribution of values in your data and group your values appropriately before beginning data mining. For more information, see [Data Profiling Task and Viewer](#). You can also use the [Data Mining Add-ins for Excel 2007](#), to explore, group and relabel data in Microsoft Excel.

Customizing the Decision Trees Algorithm

The Microsoft Decision Trees algorithm supports parameters that affect the performance and accuracy of the resulting mining model. You can also set modeling flags on the mining model columns or mining structure columns to control the way that data is processed.

NOTE

The Microsoft Decision Trees algorithm is available in all editions of SQL Server; however, some advanced parameters for customizing the behavior of the Microsoft Decision Trees algorithm are available for use only in specific editions of SQL Server. For a list of features that are supported by the editions of SQL Server, see [Features Supported by the Editions of SQL Server 2012](#) (<https://go.microsoft.com/fwlink/?LinkId=232473>).

Setting Algorithm Parameters

The following table describes the parameters that you can use with the Microsoft Decision Trees algorithm.

COMPLEXITY_PENALTY

Controls the growth of the decision tree. A low value increases the number of splits, and a high value decreases the number of splits. The default value is based on the number of attributes for a particular model, as described in the following list:

- For 1 through 9 attributes, the default is 0.5.
- For 10 through 99 attributes, the default is 0.9.
- For 100 or more attributes, the default is 0.99.

FORCE_REGRESSOR

Forces the algorithm to use the specified columns as regressors, regardless of the importance of the columns as calculated by the algorithm. This parameter is only used for decision trees that are predicting a continuous attribute.

NOTE

By setting this parameter, you force the algorithm to try to use the attribute as a regressor. However, whether the attribute is actually used as a regressor in the final model depends on the results of analysis. You can find out which columns were used as regressors by querying the model content.

[Available only in some editions of SQL Server]

MAXIMUM_INPUT_ATTRIBUTES

Defines the number of input attributes that the algorithm can handle before it invokes feature selection.

The default is 255.

Set this value to 0 to turn off feature selection.

[Available only in some editions of SQL Server]

MAXIMUM_OUTPUT_ATTRIBUTES

Defines the number of output attributes that the algorithm can handle before it invokes feature selection.

The default is 255.

Set this value to 0 to turn off feature selection.

[Available only in some editions of SQL Server]

MINIMUM_SUPPORT

Determines the minimum number of leaf cases that is required to generate a split in the decision tree.

The default is 10.

You may need to increase this value if the dataset is very large, to avoid overtraining.

SCORE_METHOD

Determines the method that is used to calculate the split score. The following options are available:

ID	NAME
1	Entropy
3	Bayesian with K2 Prior
4	Bayesian Dirichlet Equivalent (BDE) with uniform prior (default)

The default is 4, or BDE.

For an explanation of these scoring methods, see [Feature Selection](#).

SPLIT_METHOD

Determines the method that is used to split the node. The following options are available:

ID	NAME
1	Binary: Indicates that regardless of the actual number of values for the attribute, the tree should be split into two branches.
2	Complete: Indicates that the tree can create as many splits as there are attribute values.
3	Both: Specifies that Analysis Services can determine whether a binary or complete split should be used to produce the best results.

The default is 3.

Modeling Flags

The Microsoft Decision Trees algorithm supports the following modeling flags. When you create the mining structure or mining model, you define modeling flags to specify how values in each column are handled during analysis. For more information, see [Modeling Flags \(Data Mining\)](#).

MODELING FLAG	DESCRIPTION
MODEL_EXISTENCE_ONLY	Means that the column will be treated as having two possible states: Missing and Existing . A null is a missing value. Applies to mining model columns.
NOT NULL	Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training. Applies to mining structure columns.

Regressors in Decision Tree Models

Even if you do not use the Microsoft Linear Regression algorithm, any decision tree model that has continuous numeric inputs and outputs can potentially include nodes that represent a regression on a continuous attribute.

You do not need to specify that a column of continuous numeric data represents a regressor. The Microsoft Decision Trees algorithm will automatically use the column as a potential regressor and partition the dataset into regions with meaningful patterns even if you do not set the REGRESSOR flag on the column.

However, you can use the FORCE_REGRESSOR parameter to guarantee that the algorithm will use a particular regressor. This parameter can be used only with the Microsoft Decision Trees and Microsoft Linear Regression algorithms. When you set the modeling flag, the algorithm will try to find regression equations of the form $a*c1 + b*c2 + \dots$ to fit the patterns in the nodes of the tree. The sum of the residuals is calculated, and if the deviation is too great, a split is forced in the tree.

For example, if you are predicting customer purchasing behavior using **Income** as an attribute, and set the REGRESSOR modeling flag on the column, the algorithm will first try to fit the **Income** values by using a standard regression formula. If the deviation is too great, the regression formula is abandoned and the tree will be split on another attribute. The decision tree algorithm will then try to fit a regressor for income in each of the branches after the split.

Requirements

A decision tree model must contain a key column, input columns, and at least one predictable column.

Input and Predictable Columns

The Microsoft Decision Trees algorithm supports the specific input columns and predictable columns that are listed in the following table. For more information about what the content types mean when used in a mining model, see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Continuous, Cyclical, Discrete, Discretized, Key, Ordered, Table
Predictable attribute	Continuous, Cyclical, Discrete, Discretized, Ordered, Table

NOTE

Cyclical and Ordered content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

Mining Model Content for Decision Tree Models (Analysis Services - Data Mining)

7/16/2019 • 18 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes mining model content that is specific to models that use the Microsoft Decision Trees algorithm. For a general explanation of mining model content for all model types, see [Mining Model Content \(Analysis Services - Data Mining\)](#). It is important to remember that The Microsoft Decision Trees algorithm is a hybrid algorithm that can create models with very different functions: a decision tree can represent associations, rules, or even linear regression. The structure of the tree is essentially the same, but how you interpret the information will depend on the purpose for which you created the model.

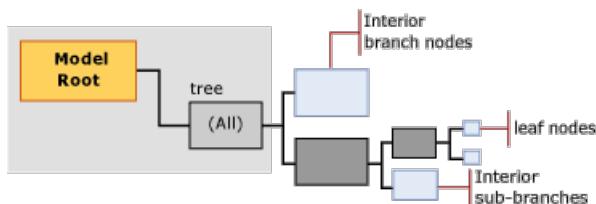

Understanding the Structure of a Decision Trees Model

A decision trees model has a single parent node that represents the model and its metadata. Underneath the parent node are independent trees that represent the predictable attributes that you select. For example, if you set up your decision tree model to predict whether customers will purchase something, and provide inputs for gender and income, the model would create a single tree for the purchasing attribute, with many branches that divide on conditions related to gender and income.

However, if you then add a separate predictable attribute for participation in a customer rewards program, the algorithm will create two separate trees under the parent node. One tree contains the analysis for purchasing, and another tree contains the analysis for the customer rewards program. If you use the Decision Trees algorithm to create an association model, the algorithm creates a separate tree for each product that is being predicted, and the tree contains all the other product combinations that contribute towards selection of the target attribute.

NOTE

If your model includes multiple trees, you can view only one tree at a time in the **Microsoft Tree Viewer**. However, in the **Generic Content Tree Viewer**, all trees in the same model are displayed at the same time.

The tree for each predictable attribute contains information that describes how the input columns that you choose affect the outcome of that particular predictable attribute. Each tree is headed by a node (NODE_TYPE = 9) that contains the predictable attribute, followed by a series of nodes (NODE_TYPE = 10) that represent the input attributes. An attribute corresponds to either a case-level column or values of nested table columns, which are generally the values in the **Key** column of the nested table.

Interior and leaf nodes represent split conditions. A tree can split on the same attribute multiple times. For example, the **TM_DecisionTree** model might split on [Yearly Income] and [Number of Children], and then split again on [Yearly Income] further down the tree.

The Microsoft Decision Trees algorithm can also contain linear regressions in all or part of the tree. If the attribute that you are modeling is a continuous numeric data type, the model can create a regression tree node

(NODE_TYPE = 25) wherever the relationship between the attributes can be modeled linearly. In this case, the node contains a regression formula.

However, if the predictable attribute has discrete values, or if numeric values have been bucketed or discretized, the model always creates a classification tree (NODE_TYPE =2). A classification tree can have multiple branches or interior tree nodes (NODE_TYPE =3) for each value of the attribute. However, the split is not necessarily on each value of the attribute.

The Microsoft Decision Trees algorithm does not allow continuous data types as inputs; therefore, if any columns have a continuous numeric data type, the values are discretized. The algorithm performs its own discretization at the point of a split for all continuous attributes.

NOTE

Analysis Services automatically chooses a method for bucketing continuous attributes; however, you can control how continuous values in the inputs are discretized by setting the content type of the mining structure column to **Discretized** and then setting the [DiscretizationBucketCount](#) or [DiscretizationMethod](#) property.

[Top](#)

Model Content for a Decision Trees Model

This section provides details and examples only for those columns in the mining model content that have particular relevance for decision trees models. For information about general-purpose columns in the schema rowset, and explanations of mining model terminology, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

Name of the attribute that corresponds to this node.

NODE_NAME

Always same as NODE_UNIQUE_NAME.

NODE_UNIQUE_NAME

A unique identifier for the node within the model. This value cannot be changed.

For decision tree models, the unique names follow the following convention, which does not apply to all algorithms:

The child nodes of any particular node will all have the same hexadecimal prefix, followed by another hexadecimal number that represents the sequence of the child node within the parent. You can use the prefixes to infer a path.

NODE_TYPE

In decision tree models, the following types of nodes are created:

NODE_TYPE	DESCRIPTION
1 (Model)	Root node for model.

NODE_TYPE	DESCRIPTION
2 (Tree)	Parent node for classification trees in the model. Labeled "All".
3 (Interior)	Head of interior branch, found within a classification tree or regression tree.
4 (Distribution)	Leaf node, found within a classification tree or regression tree.
25 (Regression tree)	Parent node for regression tree within the model. Labeled as "All".

NODE_CAPTION

A friendly name for display purposes.

When you create a model, the value of NODE_UNIQUE_NAME is automatically used as the caption. However, you can change the value for NODE_CAPTION to update the display name for the cluster, either programmatically or by using the viewer. The caption is automatically generated by the model. The content of the caption depends on the type of model, and the node type.

In a decision trees model, the NODE_CAPTION and the NODE_DESCRIPTION have different information, depending on the level in the tree. For more information and examples, see [Node Caption and Node Description](#).

CHILDREN_CARDINALITY

An estimate of the number of children that the node has.

Parent node Indicates the number of predictable attributes that were modeled. A tree is created for each predictable attribute.

Tree node The All node for each tree tells you how many values were used for the target attribute.

- If the target attribute is discrete, the value equals the number of distinct values plus 1 for the **Missing** state.
- If the predictable attribute is continuous, the value tells you how many buckets were used to model the continuous attribute.

Leaf nodes Always 0.

PARENT_UNIQUE_NAME

The unique name of the node's parent. NULL is returned for any nodes at the root level.

NODE_DESCRIPTION

A description of the node.

In a decision trees model, the NODE_CAPTION and the NODE_DESCRIPTION have different information, depending on the level in the tree.

For more information and examples, see [Node Caption and Node Description](#).

NODE_RULE

An XML description of the rule that describes the path to the current node from its immediate parent node.

For more information and examples, see [Node Rule and Marginal Rule](#).

MARGINAL_RULE

An XML description of the rule that describes the path from the model parent node to the current node.

For more information, see [Node Rule and Marginal Rule](#).

NODE_PROBABILITY

The probability associated with this node.

For more information, see [Probability](#).

MARGINAL_PROBABILITY

The probability of reaching the node from the parent node.

For more information, see [Probability](#).

NODE_DISTRIBUTION

A table that contains the probability histogram of the node. The information in this table differs depending on whether the predictable attribute is a continuous or discrete variable.

Model root node This table is empty.

(All) node Contains a summary for the model as a whole.

Interior node Contains aggregated statistics for its leaf nodes.

Leaf node Contains support and probability for the predicted outcomes given all the conditions in the path leading to the current leaf node.

Regression node Contains regression formula that represents the relationship between the inputs and the predictable attribute.

For more information, see [Node Distribution for Discrete Attributes](#) and [Node Distribution for Continuous Attributes](#).

NODE_SUPPORT

The number of cases that support this node.

MSOLAP_MODEL_COLUMN

Indicates the column that contains the predictable attribute.

MSOLAP_NODE_SCORE

Displays a score associated with the node. For more information, see [Node Score](#).

MSOLAP_NODE_SHORT_CAPTION

A label used for display purposes.

Remarks

A decision trees model does not have a separate node that stores statistics for the entire model, unlike the marginal statistics node found in a Naive Bayes or neural network model. Instead, the model creates a separate tree for each predictable attribute, with an (All) node at the top of the tree. Each tree is independent of the others. If your model contains only one predictable attribute, there is only one tree, and therefore only one (All) node.

Each tree that represents an output attribute is additionally subdivided into interior branches (NODE_TYPE = 3) that represent splits. Each of these trees contains statistics about the distribution of the target attribute. In addition, each leaf node (NODE_TYPE = 4) contains statistics that describe input attributes and their values, together with the number of cases in support of each attribute-value pair. Therefore, in any branch of a decision tree, you can view the probabilities or the distribution of data easily without having to query the source data. Each level of the tree necessarily represents the sum of its immediate child nodes.

For examples of how to retrieve these statistics, see [Decision Trees Model Query Examples](#).

[Top](#)

Example of Decision Tree Structure

To understand how a decision tree works, consider an example, such as the AdventureWorks bike buyer scenario. Assuming that the predictable attribute is customer purchases, the decision trees algorithm tries to find one column of data, among all the inputs that you provided, that most effectively detects the customers that are likely to purchase a bike and those who are unlikely to buy a bike. For example, the model might find that Age is the best indicator of purchasing behavior. Specifically, that the customers over the age of 30 are very likely to purchase a bike, and all other customers are unlikely to make a purchase. In this scenario, the model creates a *split* on the Age attribute. That means that the tree divides into two branches, one containing customers over the age of 30, and the other containing customers under 30. The new branches are represented in the model structure as two new interior trees (NODE_TYPE = 3).

For each branch, the model continues to look for additional attributes to use in differentiating customers. If there is insufficient evidence in the data to continue creating subgroups of customers, the model stops building the tree. The model will also stop building the tree whenever the number of cases in the node is too small to continue, regardless of how good the split is, or if the value is null or missing. By stopping the growth of the tree early, you prevent the model from training too closely to one particular set of data.

Each interior tree node contains leaf nodes that provide a breakdown of the outcomes given the current classification results. For example, you might have an interior node that represents Age ≥ 30 and Gender = Male. The node for this group shows you how many customers in this category purchased or did not purchase something. For example, the classification might contain the following tree splits:

INTERIOR TREE	SPLIT
Age ≥ 30	Age ≥ 30 and Gender = Male
	Age ≥ 30 and Gender = Female
Age < 30	Age < 30 and Gender = Male
	Age < 30 and Gender = Female

When you use a decision tree model for prediction, the model takes the attributes that you provide to it as arguments and follows the path of the attributes down through the tree. In general, all predictions go to a leaf, and the interior nodes are used only for classification.

A leaf node always has a NODE_TYPE of 4 (Distribution) and contains a histogram that tells the probability of each outcome (purchase or not purchase) given the attributes you provide. For example, if you ask for a prediction for a new customer who is a male over 60, the model will look up the corresponding node (Age > 30 and Gender = Male) and then return the probability for the outcome that you specify. These probabilities are stored in the [NODE DISTRIBUTION](#) table for the node.

If the predictable attribute is a continuous number, the algorithm tries to create a regression formula that models the relationship between the predictable attribute and the inputs.

[Top](#)

Node Caption and Node Description

In a decision tree model, the node caption and node description contain similar information. However, the node description is more complete and contains more information as you move closer to the leaf nodes. Both the node caption and node description are localized strings.

NODE_CAPTION	Displays the attribute that distinguishes that particular node relative to the parent node. The node caption defines a sub-segment of the population based the split condition. For example, if the split was on [Age] and it was a three-way split, the node captions for the three child nodes might be "[Age] < 40", "40 <= [Age] < 50", "[Age] >= 50".
NODE_DESCRIPTION	Contains a full list of the attributes that distinguish that node from other nodes, starting from the model parent node. For example, Product name = Apple and Color = Red.

[Top](#)

Node Rule and Marginal Rule

The NODE_RULE and MARGINAL_RULE columns contain the same information as the NODE_CAPTION and NODE_DESCRIPTION columns, but represent the information as XML fragments. The node rule is an XML version of the full path, whereas the marginal rule indicates the most recent split.

The attribute represented by the XML fragment can be either simple or complex. A simple attribute contains the name of the model column, and the value of the attribute. If the model column contains a nested table, the nested table attribute is represented as a concatenation of the table name, the key value, and the attribute.

NOTE

SQL Server Analysis Services supports version 2.0 of the PMML standard, with extensions to support the use of nested table. If your data contains nested tables and you generate a PMML version of the model, all elements in the model that include the predicates are marked as an extension.

[Top](#)

Node Distribution for Discrete Attributes

In a decision trees model, the NODE DISTRIBUTION table contains useful statistics. However, the type of statistics depends on whether the tree predicts a discrete or continuous attribute. This section describes the meaning of the node distribution statistics for discrete attributes.

Attribute Name and Attribute Value

In a classification tree, the attribute name always contains the name of the predictable column. This value tells you what the tree predicts. Because a single tree always represents a single predictable attribute, this value is repeated throughout the tree.

For a discrete data type, the attribute value field lists the possible values of the predictable column, plus the **Missing** value.

Support

The support value for each node tells you how many cases are included in this node. At the (All) level, you should see the complete count of cases that were used to train the model. For each split in the tree, the support value is the count of cases that were grouped into that node of the tree. The sum of cases in the leaf nodes necessarily equals the count of cases in the parent node of the tree.

For nodes that represent continuous attributes, the presence of nulls in the data might lead to some counterintuitive results. For example, if there are m cases, a mean value would be calculated as sum(all cases)/n, where n is a number less than m, and m-n indicates the count of cases with missing values. Support is also represented as n.

Probability

The probability associated with each node tells you the probability that any case in the whole data set would end up in this particular node. Probability scores are computed both for the tree as a whole, and for the immediate split.

For example, the following table shows a very simple model, with 100 cases.

INTERIOR TREE	CASES	LEAF NODE	CASES	PROBABILITY RELATIVE TO PARENT NODE	PROBABILITY RELATIVE TO TOP NODE
Age >= 30	60	Age >= 30 and Gender = Male	50	50/60 = .83	50/100 = .5
		Age >= 30 and Gender = Female	10	10/60 = .16	10/100 = .10
Age < 30	40	Age < 30 and Gender = Male	30	30/40 = .75	30/100 = .30
		Age < 30 and Gender = Female	10	10/40 = .25	10/100 = .10

A small adjustment is made in all models to account for possible missing values. For continuous attributes, each value or range of values is represented as a state (for example, Age <30, Age = 30, and Age >30) and the probabilities are calculated as follows: state exists (value = 1), some other state exists (value = 0), state is **Missing**. For more information about how probabilities are adjusted to represent missing values, see [Missing Values \(Analysis Services - Data Mining\)](#).

The probabilities for each node are calculated almost directly from the distribution, as follows:

Probability = (support for state + support for prior state) / (node support plus the prior node support)

Analysis Services uses probabilities for each node to compare the stored probability with the prior probability to determine whether the path from the parent to the child node indicates a strong inference.

When making predictions, the probability of the distribution must be balanced with the probability of the node, to smoothen the probabilities. For example, if a split in the tree separates cases by a ratio of 9000/1000, the tree is very unbalanced. As a result, a prediction coming from the small branch should not carry the same weight as a prediction coming from a branch with many cases.

Variance

Variance is a measure of how scattered values in a sample are, given an expected distribution. For discrete values, the variance is 0 by definition.

For information about how variance is calculated for continuous values, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

Value Type

The value type column provides information about the meaning of the numeric value provided in the other columns in the NODE DISTRIBUTION table. You can use the value type in queries to retrieve specific rows from the nested tables. For examples, see [Decision Trees Model Query Examples](#).

Of the types in the [MiningValueType](#) enumeration, the following are used in classification trees.

VALUE TYPE	DESCRIPTION
1 (Missing)	Indicates a count, probability, or other statistic related to missing values.

Value Type	Description
4 (Discrete)	Indicates a count, probability, or other statistic related to a discrete or discretized value.

If the model includes a continuous predictable attribute, the tree might also contain value types that are unique to regression formulas. For a list of the value types that are used in regression trees, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

Node Score

The node score represents slightly different information at each level of the tree. In general, the score is a numeric value that tells you how good a split was achieved by splitting on the condition. The value is represented as a double, where a higher value is better.

By definition, the model node and all leaf nodes have a node score of 0.

For the (All) node that represents the top of each tree, the MSOLAP_NODE_SCORE column contains the best split score in the whole tree.

For all other nodes in the tree (except leaf nodes), the score for each node represents the best split score for the current node, minus the split score for the parent node. Typically, the split score for a parent node should always be better than the split score on any one of its child nodes. That is because a decision trees model ideally splits on the most important attributes first.

There are many ways of calculating a score for a split, depending on the algorithm parameter you choose. A discussion of how the scores are calculated for each of the scoring methods is beyond the scope of this topic. For more information, see "[Learning Bayesian Networks: The Combination of Knowledge and Statistical Data](#)", on the Microsoft Research Web site.

NOTE

If you create a decision trees model that has both continuous and discrete predictable attributes, you will see completely different scores in the (All) nodes that represent each tree type. Each model should be considered independently, and the methods used for scoring regression are completely different from those used for scoring classification. The node score values cannot be compared.

[Top](#)

Regression Nodes within a Decision Tree Model

If a decision trees model contains a predictable attribute with continuous numeric data, the Microsoft Decision Trees algorithm seeks to find areas in the data where the relationship between the predicted state and the input variables is linear. If the algorithm is successful in finding a linear relationship, it creates a special tree (NODE_TYPE = 25) that represents a linear regression. These regression tree nodes are more complex than nodes that represent discrete values.

In general, a regression maps the changes in the continuous dependent (predictable variable) as a function of changes in the inputs. If the dependent variable has any continuous inputs, and the relationship between the input and predicted value is stable enough to be computed as a line graph, the node for the regression contains a formula.

However, if the relationship between the input and predicted value is *nonlinear*, a split is created instead, just like a standard decision tree. For example, assume that A is the predictable attribute, and B and C are the inputs, where C is a continuous value type. If the relationship between A and C is fairly stable in parts of the data, but unstable in others, the algorithm will create splits to represent the different areas of the data.

SPLIT CONDITION	RESULT IN NODE
if $n < 5$	Relationship can be expressed as equation 1
if n between 5 and 10	No equation
if $n > 10$	Relationship can be expressed as equation 2

For more information about regression nodes, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

[Microsoft Decision Trees Algorithm](#)

Decision Trees Model Query Examples

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create a content query, which provides details about the patterns discovered in analysis, or you can create a prediction query, which uses the patterns in the model to make predictions for new data. For example, a content query for a decision trees model might provide statistics about the number of cases at each level of the tree, or the rules that differentiate between cases. Alternatively, a prediction query maps the model to new data in order to generate recommendations, classifications, and so forth. You can also retrieve metadata about the model by using a query.

This section explains how to create queries for models that are based on the Microsoft Decision Trees algorithm.

Content Queries

[Getting Details about Trees in the Model by Using DMX](#)

[Retrieving Subtrees from the Model](#)

Prediction Queries

[Returning Predictions with Probabilities](#)

[Predicting Associations from a Decision Trees Model](#)

[Retrieving a Regression Formula from a Decision Trees Model](#)

Finding Information about a Decision Trees Model

To create meaningful queries on the content of a decision trees model, you should understand the structure of the model content, and which node types store what kind of information. For more information, see [Mining Model Content for Decision Tree Models \(Analysis Services - Data Mining\)](#).

Sample Query 1: Retrieving Model Parameters from the Data Mining Schema Rowset

By querying the data mining schema rowset, you can find metadata about the model, such as when it was created, when the model was last processed, the name of the mining structure that the model is based on, and the name of the column used as the predictable attribute. You can also return the parameters that were used when the model was first created.

```
select MINING_PARAMETERS  
from $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'TM_Decision Tree'
```

Sample results:

MINING_PARAMETERS

COMPLEXITY_PENALTY=0.5,
MAXIMUM_INPUT_ATTRIBUTES=255,MAXIMUM_OUTPUT_ATTRIBUTES=255,MINIMUM_SUPPORT=10,S
CORE_METHOD=4,SPLIT_METHOD=3,FORCE_REGRESSOR=

Sample Query 2: Returning Details about the Model Content by Using DMX

The following query returns some basic information about the decision trees that were created when you built the model in the [Basic Data Mining Tutorial](#). Each tree structure is stored in its own node. Because this model contains a single predictable attribute, there is only one tree node. However, if you create an association model by using the Decision Trees algorithm, there might be hundreds of trees, one for each product.

This query returns all the nodes of type 2, which are the top level nodes of a tree that represents a particular predictable attribute.

NOTE

The column, CHILDREN_CARDINALITY, must be enclosed in brackets to distinguish it from the MDX reserved keyword of the same name.

```
SELECT MODEL_NAME, NODE_NAME, NODE_CAPTION,  
NODE_SUPPORT, [CHILDREN_CARDINALITY]  
FROM TM_DecisionTrees.CONTENT  
WHERE NODE_TYPE = 2
```

Example results:

MODEL_NAME	NODE_NAME	NODE_CAPTION	NODE_SUPPORT	CHILDREN_CARDINALITY
TM_DecisionTree	000000001	All	12939	5

What do these results tell you? In a decision trees model, the cardinality of a particular node tells you how many immediate children that node has. The cardinality for this node is 5, meaning that the model divided the target population of potential bike buyers into 5 subgroups.

The following related query returns the children for these five subgroups, together with the distribution of attributes and values in the child nodes. Because statistics such as support, probability, and variance are stored in the nested table, NODE DISTRIBUTION, this example uses the `FLATTENED` keyword to output the nested table columns.

NOTE

The nested table column, SUPPORT, must be enclosed in brackets to distinguish it from the reserved keyword of the same name.

```
SELECT FLATTENED NODE_NAME, NODE_CAPTION,  
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE, [SUPPORT]  
FROM NODE_DISTRIBUTION) AS t  
FROM TM_DecisionTree.CONTENT  
WHERE [PARENT_UNIQUE_NAME] = '000000001'
```

Example results:

NODE_NAME	NODE_CAPTION	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	SUPPORT
00000000100	Number Cars Owned = 0	Bike Buyer	Missing	0

NODE_NAME	NODE_CAPTION	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	SUPPORT
00000000100	Number Cars Owned = 0	Bike Buyer	0	1067
00000000100	Number Cars Owned = 0	Bike Buyer	1	1875
00000000101	Number Cars Owned = 3	Bike Buyer	Missing	0
00000000101	Number Cars Owned = 3	Bike Buyer	0	678
00000000101	Number Cars Owned = 3	Bike Buyer	1	473

From these results, you can tell that of the customers who bought a bike ([Bike Buyer] = 1), 1067 customers had 0 cars and 473 customers had 3 cars.

Sample Query 3: Retrieving Subtrees from the Model

Suppose you wanted to discover more about the customers who did buy a bike. You can view additional detail for any of the sub-trees by using the [IsDescendant \(DMX\)](#) function in the query, as shown in the following example. The query returns the count of bike purchasers by retrieving leaf nodes (NODE_TYPE = 4) from the tree that contains customers who are over 42 years of age. The query restricts rows from the nested table to those where Bike Buyer = 1.

```
SELECT FLATTENED NODE_NAME, NODE_CAPTION, NODE_TYPE,
(
  SELECT [SUPPORT] FROM NODE_DISTRIBUTION WHERE ATTRIBUTE_NAME = 'Bike Buyer' AND ATTRIBUTE_VALUE = '1'
) AS t
FROM TM_DecisionTree.CONTENT
WHERE ISDESCENDANT('0000000010001')
AND NODE_TYPE = 4
```

Example results:

NODE_NAME	NODE_CAPTION	T.SUPPORT
000000001000100	Yearly Income >= 26000 and < 42000	266
00000000100010100	Total Children = 3	75
0000000010001010100	Number Children At Home = 1	75

Making Predictions using a Decision Trees Model

Because decision trees can be used for various tasks, including classification, regression, and even association, when you create a prediction query on a decision tree model you have many options available to you. You must understand the purpose for which the model was created to understand the results of prediction. The following query samples illustrate three different scenarios:

- Returning a prediction for a classification model, together with the probability of the prediction being correct, and then filtering the results by the probability;

- Creating a singleton query to predict associations;
- Retrieving the regression formula for a part of a decision tree where the relationship between the input and output is linear.

Sample Query 4: Returning Predictions with Probabilities

The following sample query uses the decision tree model that was created in the [Basic Data Mining Tutorial](#). The query passes in a new set of sample data, from the table dbo.ProspectiveBuyers in AdventureWorks2012 DW, to predict which of the customers in the new data set will purchase a bike.

The query uses the prediction function [PredictHistogram \(DMX\)](#), which returns a nested table that contains useful information about the probabilities discovered by the model. The final WHERE clause of the query filters the results to return only those customers who are predicted as likely to buy a bike, with a probability greater than 0%.

```

SELECT
    [TM_DecisionTree].[Bike Buyer],
    PredictHistogram([Bike Buyer]) as Results
From
    [TM_DecisionTree]
PREDICTION JOIN
    OPENQUERY([Adventure Works DW Multidimensional 2012],
        'SELECT
            [FirstName],
            [LastName],
            [MaritalStatus],
            [Gender],
            [YearlyIncome],
            [TotalChildren],
            [NumberChildrenAtHome],
            [HouseOwnerFlag],
            [NumberCarsOwned]
        FROM
            [dbo].[ProspectiveBuyer]
        ') AS t
ON
    [TM_DecisionTree].[First Name] = t.[FirstName] AND
    [TM_DecisionTree].[Last Name] = t.[LastName] AND
    [TM_DecisionTree].[Marital Status] = t.[MaritalStatus] AND
    [TM_DecisionTree].[Gender] = t.[Gender] AND
    [TM_DecisionTree].[Yearly Income] = t.[YearlyIncome] AND
    [TM_DecisionTree].[Total Children] = t.[TotalChildren] AND
    [TM_DecisionTree].[Number Children At Home] = t.[NumberChildrenAtHome] AND
    [TM_DecisionTree].[House Owner Flag] = t.[HouseOwnerFlag] AND
    [TM_DecisionTree].[Number Cars Owned] = t.[NumberCarsOwned]
WHERE [Bike Buyer] = 1
AND PredictProbability([Bike Buyer]) > '.05'

```

By default, Analysis Services returns nested tables with the column label, **Expression**. You can change this label by aliasing the column that is returned. If you do this, the alias (in this case, **Results**) is used as both the column heading and as the value in the nested table. You must expand the nested table to see the results.

Example results with **Bike Buyer** = 1:

BIKE BUYER	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY	\$VARIANCE	\$STDEV
1	2540	0.634849242045 644	0.013562168281 562	0	0

BIKE BUYER	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY	\$VARIANCE	\$STDEV
0	1460	0.364984174579 377	0.006613369325 50915	0	0
	0	0.000166583374 979177	0.000166583374 979177	0	0

If your provider does not support hierarchical rowsets, such as those shown here, you can use the FLATTENED keyword in the query to return the results as a table that contains nulls in place of the repeated column values. For more information, see [Nested Tables \(Analysis Services - Data Mining\)](#) or [Understanding the DMX Select Statement](#).

Sample Query 5: Predicting Associations from a Decision Trees Model

The following sample query is based on the Association mining structure. To follow along with this example, you can add a new model to this mining structure, and select Microsoft Decision Trees as the algorithm. For more information on how to create the Association mining structure, see [Lesson 3: Building a Market Basket Scenario \(Intermediate Data Mining Tutorial\)](#).

The following sample query is a singleton query, which you can create easily in Visual Studio with Analysis Services projects by choosing fields and then selecting values for those fields from a drop-down list.

```
SELECT PredictAssociation([DT_Association].[v Assoc Seq Line Items],3)
FROM
    [DT_Association]
NATURAL PREDICTION JOIN
(SELECT (SELECT 'Patch kit' AS [Model]) AS [v Assoc Seq Line Items]) AS t
```

Expected results:

MODEL
Mountain-200
Mountain Tire Tube
Touring Tire Tube

The results tell you the three best products to recommend to customers who have purchased the Patch Kit product. You can also provide multiple products as input when you make recommendations, either by typing in values, or by using the **Singleton Query Input** dialog box and adding or removing values. The following sample query shows how the multiple values are provided, upon which to make a prediction. Values are connected by a UNION clause in the SELECT statement that defines the input values.

```
SELECT PredictAssociation([DT_Association].[v Assoc Seq Line Items],3)
From
    [DT_Association]
NATURAL PREDICTION JOIN
(SELECT (SELECT 'Racing Socks' AS [Model]
UNION SELECT 'Women''s Mountain Shorts' AS [Model]) AS [v Assoc Seq Line Items]) AS t
```

Expected results:

MODEL

Long-Sleeve Logo Jersey

Mountain-400-W

Classic Vest

Sample Query 6: Retrieving a Regression Formula from a Decision Trees Model

When you create a decision tree model that contains a regression on a continuous attribute, you can use the regression formula to make predictions, or you can extract information about the regression formula. For more information about queries on regression models, see [Linear Regression Model Query Examples](#).

If a decision trees model contains a mixture of regression nodes and nodes that split on discrete attributes or ranges, you can create a query that returns only the regression node. The NODE DISTRIBUTION table contains the details of the regression formula. In this example, the columns are flattened and the NODE DISTRIBUTION table is aliased for easier viewing. However, in this model, no regressors were found to relate Income with other continuous attributes. In such cases, Analysis Services returns the mean value of the attribute and the total variance in the model for that attribute.

```
SELECT FLATTENED NODE DISTRIBUTION AS t
FROM DT_Predict. CONTENT
WHERE NODE_TYPE = 25
```

Example results:

T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VARIANCE	T.VALUETYPE
Yearly Income	Missing	0	0.000457142857 142857	0	1
Yearly Income	57220.8876687 257	17484	0.999542857142 857	1041275619.527 76	3
	57220.8876687 257	0	0	1041216662.543 87	11

For more information about the value types and the statistics used in regression models, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

List of Prediction Functions

All Microsoft algorithms support a common set of functions. However, the Microsoft Decision Trees algorithm supports the additional functions listed in the following table.

Prediction Function	Usage
IsDescendant (DMX)	Determines whether one node is a child of another node in the model.

IsInNode (DMX)	Indicates whether the specified node contains the current case.
PredictAdjustedProbability (DMX)	Returns the weighted probability.
PredictAssociation (DMX)	Predicts membership in an associative dataset.
PredictHistogram (DMX)	Returns a table of values related to the current predicted value.
PredictNodeId (DMX)	Returns the Node_ID for each case.
PredictProbability (DMX)	Returns probability for the predicted value.
PredictStdev (DMX)	Returns the predicted standard deviation for the specified column.
PredictSupport (DMX)	Returns the support value for a specified state.
PredictVariance (DMX)	Returns the variance of a specified column.

For a list of the functions that are common to all Microsoft algorithms, see [General Prediction Functions \(DMX\)](#).
 For the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

Microsoft Linear Regression Algorithm

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Linear Regression algorithm is a variation of the Microsoft Decision Trees algorithm that helps you calculate a linear relationship between a dependent and independent variable, and then use that relationship for prediction.

The relationship takes the form of an equation for a line that best represents a series of data. For example, the line in the following diagram is the best possible linear representation of the data.

Each data point in the diagram has an error associated with its distance from the regression line. The coefficients a and b in the regression equation adjust the angle and location of the regression line. You can obtain the regression equation by adjusting a and b until the sum of the errors that are associated with all the points reaches its minimum.

There are other kinds of regression that use multiple variables, and also nonlinear methods of regression. However, linear regression is a useful and well-known method for modeling a response to a change in some underlying factor.

Example

You can use linear regression to determine a relationship between two continuous columns. For example, you can use linear regression to compute a trend line from manufacturing or sales data. You could also use the linear regression as a precursor to development of more complex data mining models, to assess the relationships among data columns.

Although there are many ways to compute linear regression that do not require data mining tools, the advantage of using the Microsoft Linear Regression algorithm for this task is that all the possible relationships among the variables are automatically computed and tested. You do not have to select a computation method, such as solving for least squares. However, linear regression might oversimplify the relationships in scenarios where multiple factors affect the outcome.

How the Algorithm Works

The Microsoft Linear Regression algorithm is a variation of the Microsoft Decision Trees algorithm. When you select the Microsoft Linear Regression algorithm, a special case of the Microsoft Decision Trees algorithm is invoked, with parameters that constrain the behavior of the algorithm and require certain input data types. Moreover, in a linear regression model, the whole data set is used for computing relationships in the initial pass, whereas a standard decision trees model splits the data repeatedly into smaller subsets or trees.

Data Required for Linear Regression Models

When you prepare data for use in a linear regression model, you should understand the requirements for the particular algorithm. This includes how much data is needed, and how the data is used. The requirements for this model type are as follows:

- **A single key column** Each model must contain one numeric or text column that uniquely identifies each record. Compound keys are not permitted.
- **A predictable column** Requires at least one predictable column. You can include multiple predictable attributes in a model, but the predictable attributes must be continuous numeric data types. You cannot use a datetime data type as a predictable attribute even if the native storage for the data is numeric.
- **Input columns** Input columns must contain continuous numeric data and be assigned the appropriate data type.

For more information, see the Requirements section of [Microsoft Linear Regression Algorithm Technical Reference](#).

Viewing a Linear Regression Model

To explore the model, you use the **Microsoft Tree Viewer**. The tree structure for a linear regression model is very simple, with all the information about the regression equation contained in a single node. For more information, see [Browse a Model Using the Microsoft Tree Viewer](#).

If you want to know more detail about the equation, you can also view the coefficients and other details by using the [Microsoft Generic Content Tree Viewer](#).

For a linear regression model, the model content includes metadata, the regression formula, and statistics about the distribution of input values. For more information, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

Creating Predictions

After the model has been processed, the results are stored as a set of statistics together with the linear regression formula, which you can use to compute future trends. For examples of queries to use with a linear regression model, see [Linear Regression Model Query Examples](#).

For general information about how to create queries against mining models, see [Data Mining Queries](#).

In addition to creating a linear regression model by selecting the Microsoft Linear Regression algorithm, if the predictable attribute is a continuous numeric data type, you can create a decision tree model that contains regressions. In this case, the algorithm will split the data when it finds appropriate separation points, but for some regions of data, will create a regression formula instead. For more information about regression trees within a decision trees model, see [Mining Model Content for Decision Tree Models \(Analysis Services - Data Mining\)](#).

Remarks

- Does not support the use of Predictive Model Markup Language (PMML) to create mining models.
- Does not support the creation of data mining dimensions.
- Supports drillthrough.
- Supports the use of OLAP mining models.

Microsoft Linear Regression Algorithm Technical Reference

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Linear Regression algorithm is a special version of the Microsoft Decision Trees algorithm that is optimized for modeling pairs of continuous attributes. This topic explains the implementation of the algorithm, describes how to customize the behavior of the algorithm, and provides links to additional information about querying models.

Implementation of the Linear Regression Algorithm

The Microsoft Decision Trees algorithm can be used for many tasks: linear regression, classification, or association analysis. To implement this algorithm for the purpose of linear regression, the parameters of the algorithm are controlled to restrict the growth of the tree and keep all data in the model in a single node. In other words, although linear regression is based on a decision tree, the tree contains only a single root and no branches: all data resides in the root node.

To accomplish this, the algorithm's *MINIMUM_LEAF_CASES* parameter is set to be greater than or equal to the total number of cases that the algorithm uses to train the mining model. With the parameter set in this way, the algorithm will never create a split, and therefore performs a linear regression.

The equation that represents the regression line takes the general form of $y = ax + b$, and is known as the regression equation. The variable Y represents the output variable, X represents the input variable, and a and b are adjustable coefficients. You can retrieve the coefficients, intercepts, and other information about the regression formula by querying the completed mining model. For more information, see [Linear Regression Model Query Examples](#).

Scoring Methods and Feature Selection

All Analysis Services data mining algorithms automatically use feature selection to improve analysis and reduce processing load. The method used for feature selection in linear regression is the interestingness score, because the model supports only continuous columns. For reference, the following table shows the difference in feature selection for the Linear Regression algorithm and the Decision Trees algorithm.

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Linear Regression	Interestingness score	<p>Default.</p> <p>Other feature selection methods that are available with the Decision Trees algorithm apply to discrete variables only and therefore are not applicable to linear regression models.</p>

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Decision Trees	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	If any columns contain non-binary continuous values, the interestingness score is used for all columns, to ensure consistency. Otherwise, the default or specified method is used.

The algorithm parameters that control feature selection for a decision trees model are MAXIMUM_INPUT_ATTRIBUTES and MAXIMUM_OUTPUT.

Customizing the Linear Regression Algorithm

The Microsoft Linear Regression algorithm supports parameters that affect the behavior, performance, and accuracy of the resulting mining model. You can also set modeling flags on the mining model columns or mining structure columns to control the way that data is processed.

Setting Algorithm Parameters

The following table lists the parameters that are provided for the Microsoft Linear Regression algorithm.

PARAMETER	DESCRIPTION
<i>MAXIMUM_INPUT_ATTRIBUTES</i>	Defines the number of input attributes that the algorithm can handle before it invokes feature selection. Set this value to 0 to turn off feature selection. The default is 255.
<i>MAXIMUM_OUTPUT_ATTRIBUTES</i>	Defines the number of output attributes that the algorithm can handle before it invokes feature selection. Set this value to 0 to turn off feature selection. The default is 255.
<i>FORCE_REGRESSOR</i>	Forces the algorithm to use the indicated columns as regressors, regardless of the importance of the columns as calculated by the algorithm.

Modeling Flags

The Microsoft Linear Regression algorithm supports the following modeling flags. When you create the mining structure or mining model, you define modeling flags to specify how values in each column are handled during analysis. For more information, see [Modeling Flags \(Data Mining\)](#).

MODELING FLAG	DESCRIPTION
NOT NULL	Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training. Applies to mining structure columns.

MODELING FLAG	DESCRIPTION
REGRESSOR	<p>Indicates that the column contains continuous numeric values that should be treated as potential independent variables during analysis. Applies to mining model columns.</p> <p>Note: Flagging a column as a regressor does not ensure that the column will be used as a regressor in the final model.</p>

Regressors in Linear Regression Models

Linear regression models are based on the Microsoft Decision Trees algorithm. However, even if you do not use the Microsoft Linear Regression algorithm, any decision tree model can contain a tree or nodes that represent a regression on a continuous attribute.

You do not need to specify that a continuous column represents a regressor. The Microsoft Decision Trees algorithm will partition the dataset into regions with meaningful patterns even if you do not set the REGRESSOR flag on the column. The difference is that when you set the modeling flag, the algorithm will try to find regression equations of the form $a*c1 + b*c2 + \dots$ to fit the patterns in the nodes of the tree. The sum of the residuals is calculated, and if the deviation is too great, a split is forced in the tree.

For example, if you are predicting customer purchasing behavior using income as an attribute, and set the REGRESSOR modeling flag on the [Income] column, the algorithm would first try to fit the values by using a standard regression formula. If the deviation is too great, the regression formula is abandoned and the tree would be split on some other attribute. The decision tree algorithm would then try to fit a regressor for income in each of the branches after the split.

You can use the FORCED_REGRESSOR parameter to guarantee that the algorithm will use a particular regressor. This parameter can be used with the Microsoft Decision Trees and Microsoft Linear Regression algorithms.

Requirements

A linear regression model must contain a key column, input columns, and at least one predictable column.

Input and Predictable Columns

The Microsoft Linear Regression algorithm supports the specific input columns and predictable columns that are listed in the following table. For more information about what the content types mean when used in a mining model, see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Continuous, Cyclical, Key, Table, and Ordered
Predictable attribute	Continuous, Cyclical, and Ordered

NOTE

Cyclical and **Ordered** content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

Mining Model Content for Linear Regression Models (Analysis Services - Data Mining)

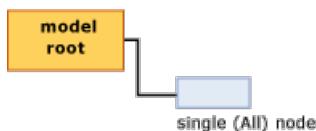

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes mining model content that is specific to models that use the Microsoft Linear Regression algorithm. For a general explanation of mining model content for all model types, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Understanding the Structure of a Linear Regression Model

A linear regression model has an extremely simple structure. Each model has a single parent node that represents the model and its metadata, and a regression tree node (NODE_TYPE = 25) that contains the regression formula for each predictable attribute.

Linear regression models use the same algorithm as Microsoft Decision Trees, but different parameters are used to constrain the tree, and only continuous attributes are accepted as inputs. However, because linear regression models are based on the Microsoft Decision Trees algorithm, linear regression models are displayed by using the Microsoft Decision Tree Viewer. For information, see [Browse a Model Using the Microsoft Tree Viewer](#).

The next section explains how to interpret information in the regression formula node. This information applies not only to linear regression models, but also to decision trees models that contain regressions in a portion of the tree.

Model Content for a Linear Regression Model

This section provides detail and examples only for those columns in the mining model content that have particular relevance for linear regression.

For information about general-purpose columns in the schema rowset, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

Root node: Blank

Regression node: The name of the predictable attribute.

NODE_NAME

Always same as NODE_UNIQUE_NAME.

NODE_UNIQUE_NAME

A unique identifier for the node within the model. This value cannot be changed.

NODE_TYPE

A linear regression model outputs the following node types:

NODE_TYPE_ID	TYPE	DESCRIPTION
25	Regression tree root	Contains the formula that describes the relationship between the input and output variable.

NODE_CAPTION

A label or a caption associated with the node. This property is primarily for display purposes.

Root node: Blank

Regression node: All.

CHILDREN_CARDINALITY

An estimate of the number of children that the node has.

Root node: Indicates the number of regression nodes. One regression node is created for each predictable attribute in the model.

Regression node: Always 0.

PARENT_UNIQUE_NAME

The unique name of the node's parent. NULL is returned for any nodes at the root level.

NODE_DESCRIPTION

A description of the node.

Root node: Blank

Regression node: All.

NODE_RULE

Not used for linear regression models.

MARGINAL_RULE

Not used for linear regression models.

NODE_PROBABILITY

The probability associated with this node.

Root node: 0

Regression node: 1

MARGINAL_PROBABILITY

The probability of reaching the node from the parent node.

Root node: 0

Regression node: 1

NODE DISTRIBUTION

A nested table that provides statistics about the values in the node.

Root node: 0

Regression node: A table that contains the elements used to build the regression formula. A regression node contains the following value types:

VALUETYPE
1 (Missing)
3 (Continuous)
7 (Coefficient)
8 (Score Gain)
9 (Statistics)
11 (Intercept)

NODE_SUPPORT

The number of cases that support this node.

Root node: 0

Regression node: Count of training cases.

MSOLAP_MODEL_COLUMN

Name of predictable attribute.

MSOLAP_NODE_SCORE

Same as NODE_PROBABILITY

MSOLAP_NODE_SHORT_CAPTION

Label used for display purposes.

Remarks

When you create a model by using the Microsoft Linear Regression algorithm, the data mining engine creates a special instance of a decision trees model and supplies parameters that constrain the tree to contain all the training data in a single node. All continuous inputs are flagged and evaluated as potential regressors, but only those regressors that fit the data are retained as regressors in the final model. The analysis produces either a single regression formula for each regressor or no regression formula at all.

You can view the complete regression formula in the **Mining Legend**, by clicking the **(All)** node in the [Microsoft Tree Viewer](#).

Also, when you create a decision trees model that includes a continuous predictable attribute, sometimes the tree has regression nodes that share the properties of regression tree nodes.

Node Distribution for Continuous Attributes

Most of the important information in a regression node is contained in the NODE DISTRIBUTION table. The following example illustrates the layout of the NODE DISTRIBUTION table. In this example, the Targeted Mailing mining structure has been used to create a linear regression model that predicts customer income based on age. The model is for the purpose of illustration only, because it can be built easily using the existing AdventureWorks2012 sample data and mining structure.

ATTRIBUTE_NAME	ATTRIBUTE_VALUE	SUPPORT	PROBABILITY	VARIANCE	VALUETYPE

ATTRIBUTE_NAME	ATTRIBUTE_VALUE	SUPPORT	PROBABILITY	VARIANCE	VALUETYPE
Yearly Income	Missing	0	0.00045714285 7142857	0	1
Yearly Income	57220.8876687 257	17484	0.99954285714 2857	1041275619.52 776	3
Age	471.687717702 463	0	0	126.969442359 327	7
Age	234.680904692 439	0	0	0	8
Age	45.4269617936 399	0	0	126.969442359 327	9
	35793.5477381 267	0	0	1012968919.28 372	11

The NODE_DISTRIBUTION table contains multiple rows, each grouped by a variable. The first two rows are always value types 1 and 3, and describe the target attribute. The succeeding rows provide details about the formula for a particular *regressor*. A regressor is an input variable that has a linear relationship with the output variable. You can have multiple regressors, and each regressor will have a separate row for the coefficient (VALUETYPE = 7), score gain (VALUETYPE = 8), and statistics (VALUETYPE = 9). Finally, the table has a row that contains the intercept of the equation (VALUETYPE = 11).

Elements of the Regression Formula

The nested NODE_DISTRIBUTION table contains each element of the regression formula in a separate row. The first two rows of data in the example results contain information about the predictable attribute, **Yearly Income**, which models the dependent variable. The SUPPORT column shows the count of cases in support of the two states of this attribute: either a **Yearly Income** value was available, or the **Yearly Income** value was missing.

The VARIANCE column tells you the computed variance of the predictable attribute. *Variance* is a measure of how scattered the values are in a sample, given an expected distribution. Variance here is calculated by taking the average of the squared deviation from the mean. The square root of the variance is also known as standard deviation. Analysis Services does not provide the standard deviation but you can easily calculate it.

For each regressor, three rows are output. They contain the coefficient, score gain, and regressor statistics.

Finally, the table contains a row that provides the intercept for the equation.

Coefficient

For each regressor, a coefficient (VALUETYPE = 7) is calculated. The coefficient itself appears in the ATTRIBUTE_VALUE column, whereas the VARIANCE column tells you the variance for the coefficient. The coefficients are calculated so as to maximize linearity.

Score Gain

The score gain (VALUETYPE = 8) for each regressor represents the interestingness score of the attribute. You can use this value to estimate the usefulness of multiple regressors.

Statistics

The regressor statistic (VALUETYPE = 9) is the mean for the attribute for cases that have a value. The ATTRIBUTE_VALUE column contains the mean itself, whereas the VARIANCE column contains the sum of deviations from the mean.

Intercept

Normally, the *intercept* (VALUETYPE = 11) or *residual* in a regression equation tells you the value of the predictable attribute, at the point where the input attribute, is 0. In many cases, this might not happen, and could lead to counterintuitive results.

For example, in a model that predicts income based on age, it is useless to learn the income at age 0. In real-life, it is typically more useful to know about the behavior of the line with respect to average values. Therefore, SQL Server Analysis Services modifies the intercept to express each regressor in a relationship with the mean.

This adjustment is difficult to see in the mining model content, but is apparent if you view the completed equation in the **Mining Legend** of the **Microsoft Tree Viewer**. The regression formula is shifted away from the 0 point to the point that represents the mean. This presents a view that is more intuitive given the current data.

Therefore, assuming that the mean age is around 45, the intercept (VALUETYPE = 11) for the regression formula tells you the mean income.

Linear Regression Model Query Examples

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create a content query, which provides details about the patterns discovered in analysis, or you can create a prediction query, which uses the patterns in the model to make predictions for new data. For example, a content query might provide additional details about the regression formula, while a prediction query might tell you if a new data point fits the model. You can also retrieve metadata about the model by using a query.

This section explains how to create queries for models that are based on the Microsoft Linear Regression algorithm.

NOTE

Because linear regression is based on a special case of the Microsoft Decision Trees algorithm, there are many similarities, and some decision tree models that use continuous predictable attributes can contain regression formulas. For more information, see [Microsoft Decision Trees Algorithm Technical Reference](#).

Content queries

[Using the Data Mining Schema Rowset to determine parameters used for a model](#)

[Using DMX to return the regression formula for the model](#)

[Returning only the coefficient for the model](#)

Prediction queries

[Predicting income using a singleton query](#)

[Using prediction functions with a regression model](#)

Finding Information about the Linear Regression Model

The structure of a linear regression model is extremely simple: the mining model represents the data as a single node, which defines the regression formula. For more information, see [Mining Model Content for Logistic Regression Models \(Analysis Services - Data Mining\)](#).

[Return to Top](#)

Sample Query 1: Using the Data Mining Schema Rowset to Determine Parameters Used for a Model

By querying the data mining schema rowset, you can find metadata about the model. This might include when the model was created, when the model was last processed, the name of the mining structure that the model is based on, and the name of the column designated as the predictable attribute. You can also return the parameters that were used when the model was first created.

```
SELECT MINING_PARAMETERS  
FROM $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'TM_PredictIncome'
```

Sample results:

MINING_PARAMETERS

```
COMPLEXITY_PENALTY=0.9,  
MAXIMUM_INPUT_ATTRIBUTES=255,  
MAXIMUM_OUTPUT_ATTRIBUTES=255,  
MINIMUM_SUPPORT=10,  
SCORE_METHOD=4,  
SPLIT_METHOD=3,  
FORCE_REGRESSOR=
```

NOTE

The parameter setting, "`FORCE_REGRESSOR =` ", indicates that the current value for the `FORCE_REGRESSOR` parameter is null.

[Return to Top](#)

Sample Query 2: Retrieving the Regression Formula for the Model

The following query returns the mining model content for a linear regression model that was built by using the same Targeted Mailing data source that was used in the [Basic Data Mining Tutorial](#). This model predicts customer income based on age.

The query returns the contents of the node that contains the regression formula. Each variable and coefficient is stored in a separate row of the nested `NODE_DISTRIBUTION` table. If you want to view the complete regression formula, use the [Microsoft Tree Viewer](#), click the **(All)** node, and open the **Mining Legend**.

```
SELECT FLATTENED NODE_DISTRIBUTION as t  
FROM LR_PredictIncome.CONTENT
```

NOTE

If you reference individual columns of the nested table by using a query such as

```
SELECT <column name> from NODE_DISTRIBUTION
```

, some columns, such as **SUPPORT** or **PROBABILITY**, must be enclosed in brackets to distinguish them from reserved keywords of the same name.

Expected results:

T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VARIANCE	T.VALUETYPE
Yearly Income	Missing	0	0.00045714285 7142857	0	1
Yearly Income	57220.8876687 257	17484	0.99954285714 2857	1041275619.52 776	3
Age	471.687717702 463	0	0	126.969442359 327	7

T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VARIANCE	T.VALUETYPE
Age	234.680904692 439	0	0	0	8
Age	45.4269617936 399	0	0	126.969442359 327	9
	35793.5477381 267	0	0	1012968919.28 372	11

In comparison, in the **Mining Legend**, the regression formula appears as follows:

```
Yearly Income = 57,220.919 + 471.688 * (Age - 45.427)
```

You can see that in the **Mining Legend**, some numbers are rounded; however, the NODE DISTRIBUTION table and the **Mining Legend** essentially contain the same values.

The values in the VALUETYPE column tell you what kind of information is contained in each row, which is useful if you are processing the results programmatically. The following table shows the value types that are output for a linear regression formula.

VALUETYPE
1 (Missing)
3 (Continuous)
7 (Coefficient)
8 (Score Gain)
9 (Statistics)
7 (Coefficient)
8 (Score Gain)
9 (Statistics)
11 (Intercept)

For more information about the meaning of each value type for regression models, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

[Return to Top](#)

Sample Query 3: Returning Only the Coefficient for the Model

By using the VALUETYPE enumeration, you can return only the coefficient for the regression equation, as shown in the following query:

```

SELECT FLATTENED MODEL_NAME,
       (SELECT ATTRIBUTE_VALUE, VALUETYPE
        FROM NODE DISTRIBUTION
        WHERE VALUETYPE = 11)
  AS t
FROM LR_PredictIncome.CONTENT

```

This query returns two rows, one from the mining model content, and the row from the nested table that contains the coefficient. The ATTRIBUTE_NAME column is not included here because it is always blank for the coefficient.

MODEL_NAME	T.ATTRIBUTE_VALUE	T.VALUETYPE
LR_PredictIncome		
LR_PredictIncome	35793.5477381267	11

[Return to Top](#)

Making Predictions from a Linear Regression Model

You can build prediction queries on linear regression models by using the Mining Model Prediction tab in Data Mining Designer. The prediction query builder is available in both SQL Server Management Studio and Visual Studio with Analysis Services projects.

NOTE

You can also create queries on regression models by using the SQL Server 2005 (9.x) Data Mining Add-ins for Excel or the SQL Server 2008 Data Mining Add-ins for Excel. Even though the Data Mining Add-ins for Excel do not create regression models, you can browse and query any mining model that is stored on an instance of Analysis Services.

[Return to Top](#)

Sample Query 4: Predicting Income using a Singleton Query

The easiest way to create a single query on a regression model is by using the **Singleton Query Input** dialog box. For example, you can build the following DMX query by selecting the appropriate regression model, choosing **Singleton Query**, and then typing **20** as the value for **Age**.

```

SELECT [LR_PredictIncome].[Yearly Income]
  From [LR_PredictIncome]
  NATURAL PREDICTION JOIN
  (SELECT 20 AS [Age]) AS t

```

Sample results:

YEARLY INCOME
45227.302092176

[Return to Top](#)

Sample Query 5: Using Prediction Functions with a Regression Model

You can use many of the standard prediction functions with linear regression models. The following example illustrates how to add some descriptive statistics to the prediction query results. From these results, you can see

that there is considerable deviation from the mean for this model.

```
SELECT
    ([LR_PredictIncome].[Yearly Income]) as [PredIncome],
    (PredictStdev([LR_PredictIncome].[Yearly Income])) as [StDev1]
From
    [LR_PredictIncome]
NATURAL PREDICTION JOIN
    (SELECT 20 AS [Age]) AS t
```

Sample results:

YEARLY INCOME	STDEV1
45227.302092176	31827.1726561396

[Return to Top](#)

List of Prediction Functions

All Microsoft algorithms support a common set of functions. However, the Microsoft Linear Regression algorithm supports the additional functions listed in the following table.

Prediction Function	Usage
IsDescendant (DMX)	Determines whether one node is a child of another node in the model.
IsInNode (DMX)	Indicates whether the specified node contains the current case.
PredictHistogram (DMX)	Returns a predicted value, or set of values, for a specified column.
PredictNodId (DMX)	Returns the Node_ID for each case.
PredictStdev (DMX)	Returns standard deviation for the predicted value.
PredictSupport (DMX)	Returns the support value for a specified state.
PredictVariance (DMX)	Returns the variance of a specified column.

For a list of the functions that are common to all Microsoft algorithms, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#). For more information about how to use these functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

Microsoft Logistic Regression Algorithm

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Logistic regression is a well-known statistical technique that is used for modeling binary outcomes.

There are various implementations of logistic regression in statistics research, using different learning techniques. The Microsoft Logistic Regression algorithm has been implemented by using a variation of the Microsoft Neural Network algorithm. This algorithm shares many of the qualities of neural networks but is easier to train.

One advantage of logistic regression is that the algorithm is highly flexible, taking any kind of input, and supports several different analytical tasks:

- Use demographics to make predictions about outcomes, such as risk for a certain disease.
- Explore and weight the factors that contribute to a result. For example, find the factors that influence customers to make a repeat visit to a store.
- Classify documents, e-mail, or other objects that have many attributes.

Example

Consider a group of people who share similar demographic information and who buy products from the Adventure Works company. By modeling the data to relate to a specific outcome, such as purchase of a target product, you can see how the demographic information contributes to someone's likelihood of buying the target product.

How the Algorithm Works

Logistic regression is a well-known statistical method for determining the contribution of multiple factors to a pair of outcomes. The Microsoft implementation uses a modified neural network to model the relationships between inputs and outputs. The effect of each input on the output is measured, and the various inputs are weighted in the finished model. The name logistic regression comes from the fact that the data curve is compressed by using a logistic transformation, to minimize the effect of extreme values. For more information about the implementation, and how to customize the algorithm, see [Microsoft Logistic Regression Algorithm Technical Reference](#).

Data Required for Logistic Regression Models

When you prepare data for use in training a logistic regression model, you should understand the requirements for the particular algorithm, including how much data is needed, and how the data is used.

The requirements for a logistic regression model are as follows:

A single key column Each model must contain one numeric or text column that uniquely identifies each record. Compound keys are not allowed.

Input columns Each model must contain at least one input column that contains the values that are used as factors in analysis. You can have as many input columns as you want, but depending on the number of values in each column, the addition of extra columns can increase the time it takes to train the model.

At least one predictable column The model must contain at least one predictable column of any data type, including continuous numeric data. The values of the predictable column can also be treated as inputs to the

model, or you can specify that it be used for prediction only. Nested tables are not allowed for predictable columns, but can be used as inputs.

For more detailed information about the content types and data types supported for logistic regression models, see the Requirements section of [Microsoft Logistic Regression Algorithm Technical Reference](#).

Viewing a Logistic Regression Model

To explore the model, you can use the Microsoft Neural Network Viewer, or the Microsoft Generic Content Tree Viewer.

When you view the model by using the Microsoft Neural Network Viewer, Analysis Services shows you the factors that contribute to a particular outcome, ranked by their importance. You can choose an attribute and values to compare. For more information, see [Browse a Model Using the Microsoft Neural Network Viewer](#).

If you want to know more, you can browse the model details by using the Microsoft Generic Content Tree Viewer. The model content for a logistic regression model includes a marginal node that shows you all the inputs used for the model, and subnetworks for the predictable attributes. For more information, see [Mining Model Content for Logistic Regression Models \(Analysis Services - Data Mining\)](#).

Creating Predictions

After the model has been trained, you can create queries against the model content to get the regression coefficients and other details, or you can use the model to make predictions.

- For general information about how to create queries against a data mining model, see [Data Mining Queries](#).
- For examples of queries on a logistic regression model, see [Clustering Model Query Examples](#).

Remarks

- Does not support drillthrough. This is because the structure of nodes in the mining model does not necessarily correspond directly to the underlying data.
- Does not support the creation of data mining dimensions.
- Supports the use of OLAP mining models.
- Does not support the use of Predictive Model Markup Language (PMML) to create mining models.

[Logistic Regression Model Query Examples](#)

Microsoft Logistic Regression Algorithm Technical Reference

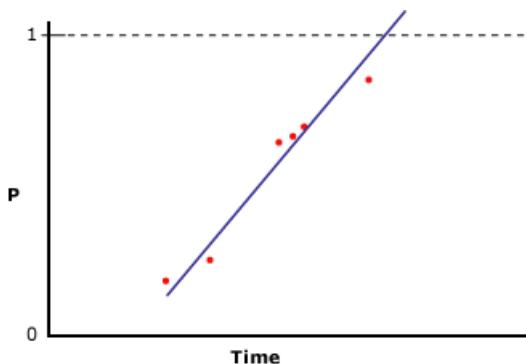

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

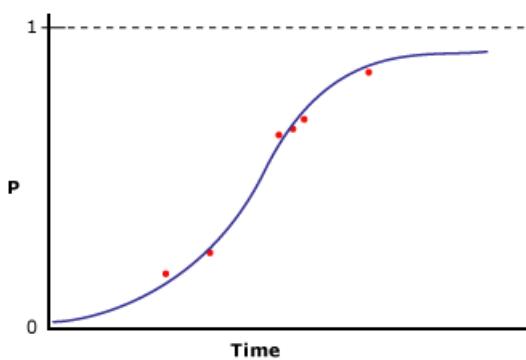

The Microsoft Logistic Regression algorithm is a variation of the Microsoft Neural Network algorithm, where the *HIDDEN_NODE_RATIO* parameter is set to 0. This setting will create a neural network model that does not contain a hidden layer, and that therefore is equivalent to logistic regression.

Implementation of the Microsoft Logistic Regression Algorithm

Suppose the predictable column contains only two states, yet you still want to perform a regression analysis, relating input columns to the probability that the predictable column will contain a specific state. The following diagram illustrates the results you will obtain if you assign 1 and 0 to the states of the predictable column, calculate the probability that the column will contain a specific state, and perform a linear regression against an input variable.

The x-axis contains values of an input column. The y-axis contains the probabilities that the predictable column will be one state or the other. The problem with this is that the linear regression does not constrain the column to be between 0 and 1, even though those are the maximum and minimum values of the column. A way to solve this problem is to perform logistic regression. Instead of creating a straight line, logistic regression analysis creates an "S" shaped curve that contains maximum and minimum constraints. For example, the following diagram illustrates the results you will achieve if you perform a logistic regression against the same data as used for the previous example.

Notice how the curve never goes above 1 or below 0. You can use logistic regression to describe which input columns are important in determining the state of the predictable column.

Feature Selection

Feature selection is used automatically by all Analysis Services data mining algorithms to improve analysis and reduce processing load. The method used for feature selection in a logistic regression model depends on the data type of the attribute. Because logistic regression is based on the Microsoft Neural Network algorithm, it uses a subset of the feature selection methods that apply to neural networks. For more information, see [Feature Selection \(Data Mining\)](#).

Scoring Inputs

Scoring in the context of a neural network model or logistic regression model means the process of converting the values that are present in the data into a set of values that use the same scale and therefore can be compared to each other. For example, suppose the inputs for Income range from 0 to 100,000 whereas the inputs for [Number of Children] range from 0 to 5. This conversion process allows you to compare the importance of each input regardless of the difference in values.

For each state that appears in the training set, the model generates an input. For discrete or discretized inputs, an additional input is created to represent the Missing state, if the missing state appears at least once in the training set. For continuous inputs, at most two input nodes are created: one for Missing values, if present in the training data, and one input for all existing, or non-null, values. Each input is scaled to a numeric format using the z-score normalization method, $(x - \mu)/\sigma$.

During z-score normalization, the mean (μ) and standard deviation are obtained over the complete training set.

Continuous values

Value is present: $(x - \mu)/\sigma$ (X is the actual value being encoded)

Value is absent: $-\mu/\sigma$ (negative mu divided by sigma)

Discrete values

$\mu = p$ (the prior probability of a state)

$\text{StdDev} = \sqrt{p(1-p)}$

Value is present: $\sqrt{(1 - \mu)/\sigma}$ (One minus mu divided by sigma)

Value is absent: $(-\mu)/\sigma$ (negative mu divided by sigma)

Understanding Logistic Regression Coefficients

There are various methods in the statistical literature for performing logistic regression, but an important part of all methods is assessing the fit of the model. A variety of goodness-to-fit statistics have been proposed, among them odds ratios and covariate patterns. A discussion of how to measure the fit of a model is beyond the scope of this topic; however, you can retrieve the value of the coefficients in the model and use them to design your own measures of fit.

NOTE

The coefficients that are created as part of a logistic regression model do not represent odds ratios and should not be interpreted as such.

The coefficients for each node in the model graph represent a weighted sum of the inputs to that node. In a logistic regression model, the hidden layer is empty; therefore, there is only one set of coefficients, which is stored in the output nodes. You can retrieve the values of the coefficients by using the following query:

```

SELECT FLATTENED [NODE_UNIQUE_NAME],
(SELECT ATTRIBUTE_NAME< ATTRIBUTE_VALUE
FROM NODE DISTRIBUTION) AS t
FROM <model name>.CONTENT
WHERE NODE_TYPE = 23

```

For each output value, this query returns the coefficients and an ID that points back to the related input node. It also returns a row that contains the value of the output and the intercept. Each input X has its own coefficient (Ci), but the nested table also contains a "free" coefficient (Co), calculated according to the following formula:

$$F(X) = X_1 * C_1 + X_2 * C_2 + \dots + X_n * C_n + X_0$$

Activation: $\exp(F(X)) / (1 + \exp(F(X)))$

For more information, see [Logistic Regression Model Query Examples](#).

Customizing the Logistic Regression Algorithm

The Microsoft logistic regression algorithm supports several parameters that affect the behavior, performance, and accuracy of the resulting mining model. You can also modify the behavior of the model by setting modeling flags on the columns used as input.

Setting Algorithm Parameters

The following table describes the parameters that can be used with the Microsoft Logistic Regression algorithm.

HOLDOUT_PERCENTAGE

Specifies the percentage of cases within the training data used to calculate the holdout error.

HOLDOUT_PERCENTAGE is used as part of the stopping criteria while training the mining model.

The default is 30.

HOLDOUT_SEED

Specifies a number to use to seed the pseudo-random generator when randomly determining the holdout data.

If HOLDOUT_SEED is set to 0, the algorithm generates the seed based on the name of the mining model, to guarantee that the model content remains the same during reprocessing.

The default is 0.

MAXIMUM_INPUT_ATTRIBUTES

Defines the number of input attributes that the algorithm can handle before it invokes feature selection. Set this value to 0 to turn off feature selection.

The default is 255.

MAXIMUM_OUTPUT_ATTRIBUTES

Defines the number of output attributes that the algorithm can handle before it invokes feature selection. Set this value to 0 to turn off feature selection.

The default is 255.

MAXIMUM_STATES

Specifies the maximum number of attribute states that the algorithm supports. If the number of states that an attribute has is larger than the maximum number of states, the algorithm uses the most popular states of the attribute and ignores the remaining states.

The default is 100.

SAMPLE_SIZE

Specifies the number of cases to be used to train the model. The algorithm provider uses either this number or

the percentage of total of cases that are not included in the holdout percentage as specified by the HOLDOUT_PERCENTAGE parameter, whichever value is smaller.

In other words, if HOLDOUT_PERCENTAGE is set to 30, the algorithm will use either the value of this parameter, or a value that is equal to 70 percent of the total number of cases, whichever is smaller.

The default is 10000.

Modeling Flags

The following modeling flags are supported for use with the Microsoft Logistic Regression algorithm.

NOT NULL

Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training.

Applies to mining structure columns.

MODEL_EXISTENCE_ONLY

Means that the column will be treated as having two possible states: **Missing** and **Existing**. A null is a missing value.

Applies to mining model column.

Requirements

A logistic regression model must contain a key column, input columns, and at least one predictable column.

Input and Predictable Columns

The Microsoft Logistic Regression algorithm supports the specific input column content types, predictable column content types, and modeling flags that are listed in the following table. For more information about what the content types mean when used in a mining model, see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Continuous, Discrete, Discretized, Key, Table
Predictable attribute	Continuous, Discrete, Discretized

Mining Model Content for Logistic Regression Models

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

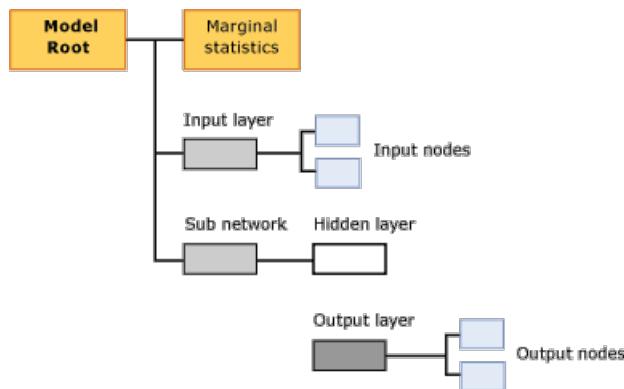

This topic describes mining model content that is specific to models that use the Microsoft Logistic Regression algorithm. For an explanation of how to interpret statistics and structure shared by all model types, and general definitions of terms related to mining model content, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Understanding the Structure of a Logistic Regression Model

A logistic regression model is created by using the Microsoft Neural Network algorithm with parameters that constrain the model to eliminate the hidden node. Therefore, the overall structure of a logistic regression model is almost identical to that of a neural network: each model has a single parent node that represents the model and its metadata, and a special marginal statistics node (NODE_TYPE = 24) that provides descriptive statistics about the inputs used in the model.

Additionally, the model contains a subnetwork (NODE_TYPE = 17) for each predictable attribute. Just like in a neural network model, each subnetwork always contains two branches: one for the input layer, and another branch that contains the hidden layer (NODE_TYPE = 19) and the output layer (NODE_TYPE = 20) for the network. The same subnetwork may be used for multiple attributes if they are specified as predict-only. Predictable attributes that are also inputs may not appear in the same subnetwork.

However, in a logistic regression model, the node that represents the hidden layer is empty, and has no children. Therefore the model contains nodes that represent individual outputs (NODE_TYPE = 23) and individual inputs (NODE_TYPE = 21) but no individual hidden nodes.

By default, a logistic regression model is displayed in the **Microsoft Neural Network Viewer**. With this custom viewer, you can filter on input attributes and their values, and graphically see how they affect the outputs. The tooltips in the viewer show you the probability and lift associated with each pair of inputs and output values. For more information, see [Browse a Model Using the Microsoft Neural Network Viewer](#).

To explore the structure of the inputs and subnetworks, and to see detailed statistics, you can use the Microsoft Generic Content Tree viewer. You can click on any node to expand it and see the child nodes, or view the weights and other statistics contained in the node.

Model Content for a Logistic Regression Model

This section provides detail and examples only for those columns in the mining model content that have particular relevance for logistic regression. The model content is almost identical to that of a neural network model, but descriptions that apply to neural network models may be repeated in this table for convenience.

For information about general-purpose columns in the schema rowset, such as MODEL_CATALOG and MODEL_NAME, that are not described here, or for explanations of mining model terminology, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

The names of the attribute that corresponds to this node.

NODE	CONTENT
Model root	Blank
Marginal statistics	Blank
Input layer	Blank
Input node	Input attribute name
Hidden layer	Blank
Output layer	Blank
Output node	Output attribute name

NODE_NAME

The name of the node. Currently, this column contains the same value as NODE_UNIQUE_NAME, though this may change in future releases.

NODE_UNIQUE_NAME

The unique name of the node.

For more information about how the names and IDs provide structural information about the model, see the section, [Using Node Names and IDs](#).

NODE_TYPE

A logistic regression model outputs the following node types:

NODE_TYPE_ID	DESCRIPTION
1	Model.
17	Organizer node for the subnetwork.
18	Organizer node for the input layer.

NODE_TYPE_ID	DESCRIPTION
19	Organizer node for the hidden layer. The hidden layer is empty.
20	Organizer node for the output layer.
21	Input attribute node.
23	Output attribute node.
24	Marginal statistics node.

NODE_CAPTION

A label or a caption associated with the node. In logistic regression models, always blank.

CHILDREN_CARDINALITY

An estimate of the number of children that the node has.

NODE	CONTENT
Model root	Indicates the count of child nodes, which includes at least 1 network, 1 required marginal node, and 1 required input layer. For example, if the value is 5, there are 3 subnetworks.
Marginal statistics	Always 0.
Input layer	Indicates the number of input attribute-values pairs that were used by the model.
Input node	Always 0.
Hidden layer	In a logistic regression model, always 0.
Output layer	Indicates the number of output values.
Output node	Always 0.

PARENT_UNIQUE_NAME

The unique name of the node's parent. NULL is returned for any nodes at the root level.

For more information about how the names and IDs provide structural information about the model, see the section, [Using Node Names and IDs](#).

NODE_DESCRIPTION

A user-friendly description of the node.

NODE	CONTENT
Model root	Blank
Marginal statistics	Blank
Input layer	Blank

NODE	CONTENT
Input node	Input attribute name
Hidden layer	Blank
Output layer	Blank
Output node	If the output attribute is continuous, contains the name of the output attribute. If the output attribute is discrete or discretized, contains the name of the attribute and the value.

NODE_RULE

An XML description of the rule that is embedded in the node.

NODE	CONTENT
Model root	Blank
Marginal statistics	Blank
Input layer	Blank
Input node	An XML fragment containing the same information as the NODE_DESCRIPTION column.
Hidden layer	Blank
Output layer	Blank
Output node	An XML fragment containing the same information as the NODE_DESCRIPTION column.

MARGINAL_RULE

For logistic regression models, always blank.

NODE_PROBABILITY

The probability associated with this node. For logistic regression models, always 0.

MARGINAL_PROBABILITY

The probability of reaching the node from the parent node. For logistic regression models, always 0.

NODE_DISTRIBUTION

A nested table that contains statistical information for the node. For detailed information about the contents of this table for each node type, see the section, Understanding the NODE_DISTRIBUTION Table, in [Mining Model Content for Neural Network Models \(Analysis Services - Data Mining\)](#).

NODE_SUPPORT

For logistic regression models, always 0.

NOTE

Support probabilities are always 0 because the output of this model type is not probabilistic. The only thing that is meaningful for the algorithm is the weights; therefore, the algorithm does not compute probability, support, or variance.

To get information about the support in the training cases for specific values, see the marginal statistics node.

MSOLAP_MODEL_COLUMN

|Node|Content|

|-----|-----|

|Model root|Blank|

|Marginal statistics|Blank|

|Input layer|Blank|

|Input node|Input attribute name.|

|Hidden layer|Blank|

|Output layer|Blank|

|Output node|Input attribute name.|

MSOLAP_NODE_SCORE

In logistic regression models, always 0.

MSOLAP_NODE_SHORT_CAPTION

In logistic regression models, always blank.

Using Node Names and IDs

The naming of the nodes in a logistic regression model provides additional information about the relationships between nodes in the model. The following table shows the conventions for the IDs that are assigned to nodes in each layer.

NODE TYPE	CONVENTION FOR NODE ID
Model root (1)	00000000000000000000.
Marginal statistics node (24)	10000000000000000000
Input layer (18)	30000000000000000000
Input node (21)	Starts at 60000000000000000000
Subnetwork (17)	20000000000000000000
Hidden layer (19)	40000000000000000000
Output layer (20)	50000000000000000000
Output node (23)	Starts at 80000000000000000000

You can use these IDs to determine how output attributes are related to specific input layer attributes, by viewing the NODE DISTRIBUTION table of the output node. Each row in that table contains an ID that points back to a specific input attribute node. The NODE DISTRIBUTION table also contains the coefficient for that input-output pair.

Logistic Regression Model Query Examples

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create a content query, which provides details about the patterns discovered in analysis, or you can create a prediction query, which uses the patterns in the model to make predictions using new data.

This section explains how to create queries for models that are based on the Microsoft Logistic Regression algorithm.

Content Queries

[Retrieving Model Parameters by Using the Data Mining Schema Rowset](#)

[Finding Additional Detail about the Model by Using DMX](#)

Prediction Queries

[Making Predictions for a Continuous Value](#)

[Making Predictions for a Discrete Value](#)

Getting Information about the Logistic Regression Model

Logistic regression models are created by using the Microsoft Neural Network algorithm with a special set of parameters; therefore, a logistic regression model has some of the same information as a neural networks model, but is less complex. To understand the structure of the model content, and which node types store what kind of information, see [Mining Model Content for Logistic Regression Models \(Analysis Services - Data Mining\)](#).

To follow along in the query scenarios, you can create a logistic regression model as described in the following section of the Intermediate Data Mining Tutorial: [Lesson 5: Building Neural Network and Logistic Regression Models \(Intermediate Data Mining Tutorial\)](#).

You can also use the mining structure, Targeted Mailing, from the [Basic Data Mining Tutorial](#).

```
ALTER MINING STRUCTURE [Targeted Mailing]
ADD MINING MODEL [TM_Logistic Regression]
([Customer Key],
[Age],
[Bike Buyer] PREDICT,
[Yearly Income] PREDICT,
[Commute Distance],
[English Education],
Gender,
[House Owner Flag],
[Marital Status],
[Number Cars Owned],
[Number Children At Home],
[Region],
[Total Children]
)
USING Microsoft_Logistic_Regression
```

Sample Query 1: Retrieving Model Parameters by Using the Data Mining Schema Rowset

By querying the data mining schema rowset, you can find metadata about the model, such as when it was created, when the model was last processed, the name of the mining structure that the model is based on, and the name of the column used as the predictable attribute. The following example returns the parameters that were used when the model was first created, together with the name and type of the model, and the date that it was created.

```
SELECT MODEL_NAME, SERVICE_NAME, DATE_CREATED, MINING_PARAMETERS
FROM $system.DMSCHEMA_MINING_MODELS
WHERE MODEL_NAME = 'Call Center_LR'
```

Sample results:

MODEL_NAME	SERVICE_NAME	DATE_CREATED	MINING_PARAMETERS
Call Center_LR	Microsoft_Logistic_Regression	04/07/2009 20:38:33	HOLDOUT_PERCENTAGE=30, HOLDOUT_SEED=1, MAXIMUM_INPUT_ATTRIBUTES=255, MAXIMUM_OUTPUT_ATTRIBUTES=255, MAXIMUM_STATES=100, SAMPLE_SIZE=10000

Sample Query 2: Finding Additional Detail about the Model by Using DMX

The following query returns some basic information about the logistic regression model. A logistic regression model is similar to a neural network model in many ways, including the presence of a marginal statistic node (NODE_TYPE = 24) that describes the values used as inputs. This example query uses the Targeted Mailing model, and gets the values of all the inputs by retrieving them from the nested table, NODE DISTRIBUTION.

```
SELECT FLATTENED NODE DISTRIBUTION AS t
FROM [TM_Logistic Regression].CONTENT
```

Partial results:

T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VARIANCE	T.VALUETYPE
Age	Missing	0	0	0	1
Age	45.43491192	17484	1	126.9544114	3
Bike Buyer	Missing	0	0	0	1
Bike Buyer	0	8869	0.507263784	0	4
Bike Buyer	1	8615	0.492736216	0	4
Commute Distance	Missing	0	0	0	1
Commute Distance	5-10 Miles	3033	0.173472889	0	4

The actual query returns many more rows; however, this sample illustrates the type of information that is provided about the inputs. For discrete inputs, each possible value is listed in the table. For continuous-value

inputs such as Age, a complete listing is impossible, so the input is discretized as a mean. For more information about how to use the information in the marginal statistics node, see [Mining Model Content for Logistic Regression Models \(Analysis Services - Data Mining\)](#).

NOTE

The results have been flattened for easier viewing, but you can return the nested table in a single column if your provider supports hierarchical rowsets.

Prediction Queries on a Logistic Regression Model

You can use the [Predict \(DMX\)](#) function with every kind of mining model to provide new data to the model and make predictions based on the new values. You can also use functions to return additional information about the prediction, such as the probability that a prediction is correct. This section provides some examples of prediction queries on a logistic regression model.

Sample Query 3: Making Predictions for a Continuous Value

Because logistic regression supports the use of continuous attributes for both input and prediction, it is easy to create models that correlate various factors in your data. You can use prediction queries to explore the relationship among these factors.

The following query sample is based on the Call Center model, from the Intermediate Tutorial, and creates a singleton query that predicts service grade for the Friday AM shift. The [PredictHistogram \(DMX\)](#) function returns a nested table that provides statistics relevant to understanding the validity of the predicted value.

```
SELECT
    Predict([Call Center_LR].[Service Grade]) as Predicted ServiceGrade,
    PredictHistogram([Call Center_LR].[Service Grade]) as [Results],
FROM
    [Call Center_LR]
NATURAL PREDICTION JOIN
(SELECT 'Friday' AS [Day Of Week],
    'AM' AS [Shift]) AS t
```

Sample results:

PREDICTED SERVICE GRADE	SERVICE GRADE	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY	\$VARIANCE	\$STDEV
0.102601830 123659	0.102601830 123659	83.02325581 39535	0.988372093 023256	0	0.001205526 60600087	0.034720694 203902
		0.976744186 046512	0.011627906 9767442	0.011627906 9767442	0	0

For more information about the probability, support, and standard deviation values in the nested NODE_DISTRIBUTION table, see [Mining Model Content for Logistic Regression Models \(Analysis Services - Data Mining\)](#).

Sample Query 4: Making Predictions for a Discrete Value

Logistic regression is typically used in scenarios where you want to analyze the factors that contribute to a binary outcome. Although the model used in the tutorial predicts a continuous value, **ServiceGrade**, in a real-life scenario you might want to set up the model to predict whether service grade met some discretized target value. Alternatively, you could output the predictions using a continuous value but later group the predicted outcomes

into **Good**, **Fair**, or **Poor**.

The following sample illustrates how to change the way that the predictable attribute is grouped. To do this, you create a copy of the mining structure and then change the discretization method of the target column so that the values are grouped rather than continuous.

The following procedure describes how to change the grouping of Service Grade values in the Call Center data.

To create a discretized version of the Call Center mining structure and models

1. In Visual Studio with Analysis Services projects, in Solution Explorer, expand **Mining Structures**.
2. Right-click Call Center.dmm and select **Copy**.
3. Right click **Mining Structures** and select **Paste**. A new mining structure is added, named Call Center 1.
4. Right-click the new mining structure and select **Rename**. Type the new name, **Call Center Discretized**.
5. Double-click the new mining structure to open it in the designer. Notice that the mining models have all been copied as well, and all have the extension 1. Leave the names as is for now.
6. In the **Mining Structure** tab, right-click the column for Service Grade, and select **Properties**.
7. Change the **Content** property from **Continuous** to **Discretized**. Change the **DiscretizationMethod** property to **Clusters**. For Discretization BucketCount, type **3**.

NOTE

These parameters are just used for illustrating the process, and do not necessarily produce a valid model,

8. From the **Mining Model** menu, select **Process structure and all models**.

The following sample query is based on this discretized model, and predicts the service grade for the specified day of the week, together with the probabilities for each predicted outcome.

```
SELECT
  (PredictHistogram([Call Center_LR 1].[Service Grade])) as [Predictions]
FROM
  [Call Center_LR 1]
NATURAL PREDICTION JOIN
  (SELECT 'Saturday' AS [Day Of Week]) AS t
```

Expected results:

Predictions:

SERVICE GRADE	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY	\$VARIANCE	\$STDEV
0.108727183831 25	35.72465047706 41	0.425293458060 287	0.017016836003 0293	0	0
0.058557692306 25	31.70988808007 03	0.377498667619 885	0.020882020060 454	0	0
0.170169491525	15.61091598832 02	0.185844237956 192	0.066138657138 6049	0	0
	0.954545454545 455	0.011363636363 6364	0.011363636363 6364	0	0

Note that the predicted outcomes have been grouped into three categories as specified; however, these groupings are based on the clustering of actual values in the data, not arbitrary values that you might set as business goals.

List of Prediction Functions

All Microsoft algorithms support a common set of functions. However, the Microsoft Logistic Regression algorithm supports the additional functions listed in the following table.

Prediction Function	Usage
IsDescendant (DMX)	Determines whether one node is a child of another node in the model.
PredictAdjustedProbability (DMX)	Returns the adjusted probability of a specified state.
PredictHistogram (DMX)	Returns a predicted value, or set of values, for a specified column.
PredictProbability (DMX)	Returns the probability for a specified state.
PredictStdev (DMX)	Returns standard deviation for the predicted value.
PredictSupport (DMX)	Returns the support value for a specified state.
PredictVariance (DMX)	Returns the variance of a specified column.

For a list of the functions that are common to all Microsoft algorithms, see [General Prediction Functions \(DMX\)](#). For the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

NOTE

For neural network and logistic regression models, the [PredictSupport \(DMX\)](#) function returns a single value that represents the size of the training set for the entire model.

Microsoft Naïve Bayes Algorithm

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Naïve Bayes algorithm is a classification algorithm based on Bayes' theorems, and can be used for both exploratory and predictive modeling. The word naïve in the name Naïve Bayes derives from the fact that the algorithm uses Bayesian techniques but does not take into account dependencies that may exist.

This algorithm is less computationally intense than other Microsoft algorithms, and therefore is useful for quickly generating mining models to discover relationships between input columns and predictable columns. You can use this algorithm to do initial exploration of data, and then later you can apply the results to create additional mining models with other algorithms that are more computationally intense and more accurate.

Example

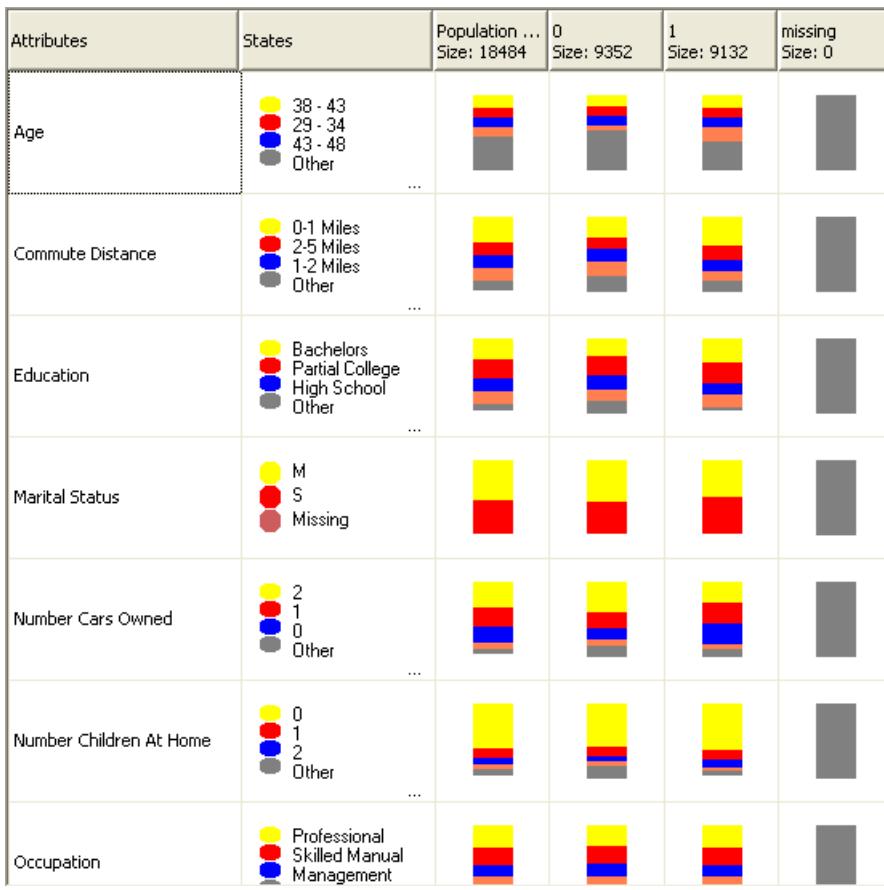

As an ongoing promotional strategy, the marketing department for the Adventure Works Cycle company has decided to target potential customers by mailing out fliers. To reduce costs, they want to send fliers only to those customers who are likely to respond. The company stores information in a database about demographics and response to a previous mailing. They want to use this data to see how demographics such as age and location can help predict response to a promotion, by comparing potential customers to customers who have similar characteristics and who have purchased from the company in the past. Specifically, they want to see the differences between those customers who bought a bicycle and those customers who did not.

By using the Microsoft Naïve Bayes algorithm, the marketing department can quickly predict an outcome for a particular customer profile, and can therefore determine which customers are most likely to respond to the fliers. By using the Microsoft Naïve Bayes Viewer in Visual Studio with Analysis Services projects, they can also visually investigate specifically which input columns contribute to positive responses to fliers.

How the Algorithm Works

The Microsoft Naïve Bayes algorithm calculates the probability of every state of each input column, given each possible state of the predictable column.

To understand how this works, use the Microsoft Naïve Bayes Viewer in Visual Studio with Analysis Services projects (as shown in the following graphic) to visually explore how the algorithm distributes states.

Here, the Microsoft Naïve Bayes Viewer lists each input column in the dataset, and shows how the states of each column are distributed, given each state of the predictable column.

You would use this view of the model to identify the input columns that are important for differentiating between states of the predictable column.

For example, in the row for Commute Distance shown here, the distribution of input values is visibly different for buyers vs. non-buyers. What this tells you is that the input, Commute Distance = 0-1 miles, is a potential predictor.

The viewer also provides values for the distributions, so you can see that for customers who commute from one to two miles to work, the probability of them buying a bike is 0.387, and the probability that they will not buy a bike is 0.287. In this example, the algorithm uses the numeric information, derived from customer characteristics (such as commute distance), to predict whether a customer will buy a bike.

For more information about using the Microsoft Naïve Bayes Viewer, see [Browse a Model Using the Microsoft Naïve Bayes Viewer](#).

Data Required for Naïve Bayes Models

When you prepare data for use in training a Naïve Bayes model, you should understand the requirements for the algorithm, including how much data is needed, and how the data is used.

The requirements for a Naïve Bayes model are as follows:

- **A single key column** Each model must contain one numeric or text column that uniquely identifies each record. Compound keys are not allowed.
- **Input columns** In a Naïve Bayes model, all columns must be either discrete, or the values must have been binned. For information about how to discretize (bin) columns, see [Discretization Methods \(Data Mining\)](#).
- **Variables must be independent.** For a Naïve Bayes model, it is also important to ensure that the input attributes are independent of each other. This is particularly important when you use the model for

prediction. If you use two columns of data that are already closely related, the effect would be to multiply the influence of those columns, which can obscure other factors that influence the outcome.

Conversely, the ability of the algorithm to identify correlations among variables is useful when you are exploring a model or dataset, to identify relationships among inputs.

- **At least one predictable column** The predictable attribute must contain discrete or discretized values.

The values of the predictable column can be treated as inputs. This practice can be useful when you are exploring a new dataset, to find relationships among the columns.

Viewing the Model

To explore the model, you can use the **Microsoft Naive Bayes Viewer**. The viewer shows you how the input attributes relate to the predictable attribute. The viewer also provides a detailed profile of each cluster, a list of the attributes that distinguish each cluster from the others, and the characteristics of the entire training data set. For more information, see [Browse a Model Using the Microsoft Naive Bayes Viewer](#).

If you want to know more detail, you can browse the model in the [Microsoft Generic Content Tree Viewer \(Data Mining\)](#). For more information about the type of information stored in the model, see [Mining Model Content for Naive Bayes Models \(Analysis Services - Data Mining\)](#).

Making Predictions

After the model has been trained, the results are stored as a set of patterns, which you can explore or use to make predictions.

You can create queries to return predictions about how new data relates to the predictable attribute, or you can retrieve statistics that describe the correlations found by the model.

For information about how to create queries against a data mining model, see [Data Mining Queries](#). For examples of how to use queries with a Naive Bayes model, see [Naive Bayes Model Query Examples](#).

Remarks

- Supports the use of Predictive Model Markup Language (PMML) to create mining models.
- Supports drillthrough.
- Does not support the creation of data mining dimensions.
- Supports the use of OLAP mining models.

[Microsoft Naive Bayes Algorithm Technical Reference](#)

Microsoft Naive Bayes Algorithm Technical Reference

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Naive Bayes algorithm is a classification algorithm provided by Microsoft SQL Server Analysis Services for use in predictive modeling. The algorithm calculates the conditional probability between input and predictable columns, and assumes that the columns are independent. This assumption of independence leads to the name Naive Bayes.

Implementation of the Microsoft Naive Bayes Algorithm

This algorithm is less computationally intense than other Microsoft algorithms, and therefore is useful for quickly generating mining models to discover relationships between input columns and predictable columns. The algorithm considers each pair of input attribute values and output attribute values.

A description of the mathematical properties of Bayes Theorem is beyond the scope of this documentation; for more information, see the paper by Microsoft Research titled [Learning Bayesian Networks: The Combination of Knowledge and Statistical Data](#).

For a description of how probabilities in all models are adjusted to account for potential missing values, see [Missing Values \(Analysis Services - Data Mining\)](#).

Feature Selection

The Microsoft Naive Bayes algorithm performs automatic feature selection to limit the number of values that are considered when building the model. For more information, see [Feature Selection \(Data Mining\)](#).

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Naive Bayes	Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	Naive Bayes only accepts discrete or discretized attributes; therefore, it cannot use the interestingness score.

The algorithm is designed to minimize processing time and efficiently select the attributes that have the greatest importance; however, you can control the data that is used by the algorithm by setting parameters as follows:

- To limit the values that are used as inputs, decrease the value of MAXIMUM_INPUT_ATTRIBUTES.
- To limit the number of attributes analyzed by the model, decrease the value of MAXIMUM_OUTPUT_ATTRIBUTES.
- To limit the number of values that can be considered for any one attribute, decrease the value of MINIMUM_STATES.

Customizing the Naive Bayes Algorithm

The Microsoft Naive Bayes algorithm supports several parameters that affect the behavior, performance, and accuracy of the resulting mining model. You can also set modeling flags on the model columns to control how data is processed, or set flags on the mining structure to specify how missing values or nulls should be handled.

Setting Algorithm Parameters

The Microsoft Naive Bayes algorithm supports several parameters that affect the performance and accuracy of the resulting mining model. The following table describes each parameter.

MAXIMUM_INPUT_ATTRIBUTES

Specifies the maximum number of input attributes that the algorithm can handle before it invokes feature selection. Setting this value to 0 disables feature selection for input attributes.

The default is 255.

MAXIMUM_OUTPUT_ATTRIBUTES

Specifies the maximum number of output attributes that the algorithm can handle before it invokes feature selection. Setting this value to 0 disables feature selection for output attributes.

The default is 255.

MINIMUM_DEPENDENCY_PROBABILITY

Specifies the minimum dependency probability between input and output attributes. This value is used to limit the size of the content that is generated by the algorithm. This property can be set from 0 to 1. Larger values reduce the number of attributes in the content of the model.

The default is 0.5.

MAXIMUM_STATES

Specifies the maximum number of attribute states that the algorithm supports. If the number of states that an attribute has is greater than the maximum number of states, the algorithm uses the attribute's most popular states and treats the remaining states as missing.

The default is 100.

Modeling Flags

The Microsoft Decision Trees algorithm supports the following modeling flags. When you create the mining structure or mining model, you define modeling flags to specify how values in each column are handled during analysis. For more information, see [Modeling Flags \(Data Mining\)](#).

MODELING FLAG	DESCRIPTION
MODEL_EXISTENCE_ONLY	Means that the column will be treated as having two possible states: Missing and Existing. A null is a missing value. Applies to mining model column.
NOT NULL	Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training. Applies to mining structure column.

Requirements

A Naive Bayes tree model must contain a key column, at least one predictable attribute, and at least one input attribute. No attribute can be continuous; if your data contains continuous numeric data, it will be ignored or discretized.

Input and Predictable Columns

The Microsoft Naive Bayes algorithm supports the specific input columns and predictable columns that are listed in the following table. For more information about what the content types mean when used in a mining model,

see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Cyclical, Discrete, Discretized, Key, Table, and Ordered
Predictable attribute	Cyclical, Discrete, Discretized, Table, and Ordered

NOTE

Cyclical and Ordered content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

[Mining Model Content for Naive Bayes Models \(Analysis Services - Data Mining\)](#)

Mining Model Content for Naive Bayes Models (Analysis Services - Data Mining)

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes mining model content that is specific to models that use the Microsoft Naive Bayes algorithm. For an explanation of how to interpret statistics and structure shared by all model types, and general definitions of terms related to mining model content, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

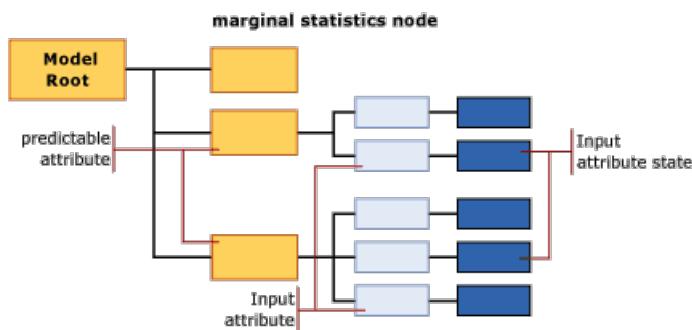

Understanding the Structure of a Naive Bayes Model

A Naive Bayes model has a single parent node that represents the model and its metadata, and underneath that parent node, any number of independent trees that represent the predictable attributes that you selected. In addition to trees for the attributes, each model contains one marginal statistics node (NODE_TYPE = 26) that provides descriptive statistics about the set of training cases. For more information, see [Information in the Marginal Statistics Node](#).

For each predictable attribute and value, the model outputs a tree that contains information describing how the various input columns affected the outcome of that particular predictable. Each tree contains the predictable attribute and its value (NODE_TYPE = 9), and then a series of nodes that represent the input attributes (NODE_TYPE = 10). Because the input attributes typically have multiple values, each input attribute (NODE_TYPE = 10) may have multiple child nodes (NODE_TYPE = 11), each for a specific state of the attribute.

NOTE

Because a Naive Bayes model does not permit continuous data types, all the values of the input columns are treated as discrete or discretized. You can specify how a value is discretized. For more information, [Change the Discretization of a Column in a Mining Model](#).

Model Content for a Naive Bayes Model

This section provides detail and examples only for those columns in the mining model content that have particular relevance for Naive Bayes models.

For information about general-purpose columns in the schema rowset, such as MODEL_CATALOG and MODEL_NAME, that are not described here, or for explanations of mining model terminology, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

The names of the attributes that correspond to this node.

Model root The name of the predictable attribute.

Marginal statistics Not applicable

Predictable attribute The name of the predictable attribute.

Input attribute The name of the input attribute.

Input attribute state The name of the input attribute only. To get the state, use MSOLAP_NODE_SHORT_CAPTION.

NODE_NAME

The name of the node.

This column contains the same value as NODE_UNIQUE_NAME.

For more information about node naming conventions, see [Using Node Names and IDs](#).

NODE_UNIQUE_NAME

The unique name of the node. The unique names are assigned according to a convention that provides information about the relationships among the nodes. For more information about node naming conventions, see [Using Node Names and IDs](#).

NODE_TYPE

A Naive Bayes model outputs the following node types:

NODE TYPE ID	DESCRIPTION
26 (NaiveBayesMarginalStatNode)	Contains statistics that describes the entire set of training cases for the model.
9 (Predictable attribute)	Contains the name of the predictable-attribute.
10 (Input attribute)	Contains the name of an input attribute column, and child nodes that contains the values for the attribute.
11 (Input attribute state)	Contains the values or discretized values of all input attributes that were paired with a particular output attribute.

NODE_CAPTION

The label or a caption associated with the node. This property is primarily for display purposes.

Model root blank

Marginal statistics blank

Predictable attribute The name of the predictable attribute.

Input attribute The name of the predictable attribute and the current input attribute. Ex:

Bike Buyer -> Age

Input attribute state The name of the predictable attribute and the current input attribute, plus the value of the input. Ex:

Bike Buyer -> Age = Missing

CHILDREN_CARDINALITY

The number of children that the node has.

Model root Count of predictable attributes in the model plus 1 for the marginal statistics node.

Marginal statistics By definition has no children.

Predictable attribute Count of the input attributes that were related to the current predictable attribute.

Input attribute Count of the discrete or discretized values for the current input attribute.

Input attribute state Always 0.

PARENT_UNIQUE_NAME

The unique name of the parent node. For more information about relating parent and child nodes, see [Using Node Names and IDs](#).

NODE_DESCRIPTION

The same as the node caption.

NODE_RULE

An XML representation of the node caption.

MARGINAL_RULE

The same as the node rule.

NODE_PROBABILITY

The probability associated with this node.

Model root Always 0.

Marginal statistics Always 0.

Predictable attribute Always 1.

Input attribute Always 1.

Input attribute state A decimal number that represents the probability of the current value. Values for all input attribute states under the parent input attribute node sum to 1.

MARGINAL_PROBABILITY

The same as the node probability.

NODE_DISTRIBUTION

A table that contains the probability histogram for the node. For more information, see [NODE_DISTRIBUTION Table](#).

NODE_SUPPORT

The number of cases that support this node.

Model root Count of all cases in training data.

Marginal statistics Always 0.

Predictable attribute Count of all cases in training data.

Input attribute Count of all cases in training data.

Input attribute state Count of cases in training data that contain only this particular value.

MSOLAP_MODEL_COLUMN

A label used for display purposes. Usually the same as ATTRIBUTE_NAME.

MSOLAP_NODE_SCORE

Represents the importance of the attribute or value within the model.

Model root Always 0.

Marginal statistics Always 0.

Predictable attribute Always 0.

Input attribute Interestingness score for the current input attribute in relation to the current predictable attribute.

Input attribute state Always 0.

MSOLAP_NODE_SHORT_CAPTION

A text string that represents the name or the value of a column.

Model root Blank

Marginal statistics Blank

Predictable attribute The name of the predictable attribute.

Input attribute The name of the input attribute.

Input attribute state The value or discretized value of the input attribute.

Using Node Names and IDs

The naming of the nodes in a Naive Bayes model provides additional information about the type of node, to make it easier to understand the relationships among the information in the model. The following table shows the convention for the IDs that are assigned to different node types.

NODE TYPE	CONVENTION FOR NODE ID
Model root (1)	Always 0.
Marginal statistics node (26)	An arbitrary ID value.
Predictable attribute (9)	Hexadecimal number beginning with 10000000 Example: 10000001, 1000000b
Input attribute (10)	A two-part hexadecimal number where the first part is always 20000000, and the second part starts with the hexadecimal identifier of the related predictable attribute. Example: 2000000b00000000 In this case, the related predictable attribute is 1000000b.

NODE TYPE	CONVENTION FOR NODE ID
Input attribute state (11)	<p>A three-part hexadecimal number where the first part is always 30000000, the second part starts with the hexadecimal identifier of the related predictable attribute, and the third part represents the identifier of the value.</p> <p>Example: 30000000b00000000200000000</p> <p>In this case, the related predictable attribute is 10000000b.</p>

You can use the IDs to relate input attributes and states to a predictable attribute. For example, the following query returns the names and captions for nodes that represent the possible combinations of input and predictable attributes for the model, `TM_NaiveBayes`.

```
SELECT NODE_NAME, NODE_CAPTION
FROM TM_NaiveBayes.CONTENT
WHERE NODE_TYPE = 10
```

Expected results:

NODE_NAME	NODE_CAPTION
200000000000000001	Bike Buyer -> Commute Distance
200000000000000002	Bike Buyer -> English Education
200000000000000003	Bike Buyer -> English Occupation
200000000000000009	Bike Buyer -> Marital Status
20000000000000000a	Bike Buyer -> Number Children At Home
20000000000000000b	Bike Buyer -> Region
20000000000000000c	Bike Buyer -> Total Children

You can then use the IDs of the parent nodes to retrieve the child nodes. The following query retrieves the nodes that contain values for the `Marital Status` attribute, together with the probability of each node.

```
SELECT NODE_NAME, NODE_CAPTION, NODE_PROBABILITY
FROM TM_NaiveBayes.CONTENT
WHERE NODE_TYPE = 11
AND [PARENT_UNIQUE_NAME] = '2000000000000009'
```

NOTE

The name of the column, `PARENT_UNIQUE_NAME`, must be enclosed in brackets to distinguish it from the reserved keyword of the same name.

Expected results:

NODE_NAME	NODE_CAPTION	NODE_PROBABILITY
3000000000000000900000000	Bike Buyer -> Marital Status = Missing	0
3000000000000000900000001	Bike Buyer -> Marital Status = S	0.457504004
3000000000000000900000002	Bike Buyer -> Marital Status = M	0.542495996

NODE_DISTRIBUTION Table

The nested table column, NODE_DISTRIBUTION, typically contains statistics about the distribution of values in the node. In a Naive Bayes model, this table is populated only for the following nodes:

NODE_TYPE	CONTENT OF NESTED TABLE
Model root (1)	Blank.
Marginal statistics node (24)	Contains summary information for all predictable attributes and input attributes, for entire set of training data.
Predictable attribute (9)	Blank.
Input attribute (10)	Blank.
Input attribute state (11)	Contains statistics that describe the distribution of values in the training data for this particular combination of a predictable value and input attribute value.

You can use the node IDs or node captions to retrieve increasing levels of detail. For example, the following query retrieves specific columns from the NODE_DISTRIBUTION table for only those input attribute nodes that are related to the value, 'Marital Status = S' .

```
SELECT FLATTENED NODE_CAPTION,
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE, [SUPPORT], [PROBABILITY], VALUETYPE
FROM NODE_DISTRIBUTION) as t
FROM TM_NaiveBayes.content
WHERE NODE_TYPE = 11
AND NODE_CAPTION = 'Bike Buyer -> Marital Status = S'
```

Expected results:

NODE_CAPTION	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VALUETYPE
Bike Buyer -> Marital Status = S	Bike Buyer	Missing	0	0	1
Bike Buyer -> Marital Status = S	Bike Buyer	0	3783	0.472934117	4
Bike Buyer -> Marital Status = S	Bike Buyer	1	4216	0.527065883	4

NODE_CAPTION	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VALUETYPE
--------------	------------------	-------------------	-----------	---------------	-------------

In these results, the value of the SUPPORT column tells you the count of customers with the specified marital status who purchased a bike. The PROBABILITY column contains the probability of each attribute value, as calculated for this node only. For general definitions of terms used in the NODE DISTRIBUTION table, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Information in the Marginal Statistics Node

In a Naive Bayes model, the nested table for the marginal statistics node contains the distribution of values for the entire set of training data. For example, the following table contains a partial list of the statistics in the nested NODE DISTRIBUTION table for the model, `TM_NaiveBayes` :

ATTRIBUTE_NAME	ATTRIBUTE_VALUE	SUPPORT	PROBABILITY	VARIANCE	VALUETYPE
Bike Buyer	Missing	0	0	0	1
Bike Buyer	0	8869	0.507263784	0	4
Bike Buyer	1	8615	0.492736216	0	4
Marital Status	Missing	0	0	0	1
Marital Status	S	7999	0.457504004	0	4
Marital Status	M	9485	0.542495996	0	4
Total Children	Missing	0	0	0	1
Total Children	0	4865	0.278254404	0	4
Total Children	3	2093	0.119709449	0	4
Total Children	1	3406	0.19480668	0	4

The [Bike Buyer] column is included because the marginal statistics node always contains a description of the predictable attribute and its possible values. All other columns that are listed represent input attributes, together with the values that were used in the model. Values can only be missing, discrete or discretized.

In a Naive Bayes model, there can be no continuous attributes; therefore, all numeric data is represented as either discrete (VALUE_TYPE = 4) or discretized (VALUE_TYPE = 5).

A **Missing** value (VALUE_TYPE = 1) is added to every input and output attribute to represent potential values that were not present in the training data. You must be careful to distinguish between "missing" as a string and the default **Missing** value. For more information, see [Missing Values \(Analysis Services - Data Mining\)](#).

Data Mining Queries

Microsoft Naive Bayes Algorithm

Naive Bayes Model Query Examples

7/16/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create either a content query, which provides details about the patterns discovered in analysis, or you can create a prediction query, which uses the patterns in the model to make predictions for new data. You can also retrieve metadata about the model by using a query against the data mining schema rowset. This section explains how to create these queries for models that are based on the Microsoft Naive Bayes algorithm.

Content Queries

[Getting model metadata by using DMX](#)

[Retrieving a summary of training data](#)

[Finding more information about attributes](#)

[Using system stored procedures](#)

Prediction Queries

[Predicting outcomes using a singleton query](#)

[Getting predictions with probability and support values](#)

[Predicting associations](#)

Finding Information about a Naive Bayes Model

The model content of a Naive Bayes model provides aggregated information about the distribution of values in the training data. You can also retrieve information about the metadata of the model by creating queries against the data mining schema rowsets.

Sample Query 1: Getting Model Metadata by Using DMX

By querying the data mining schema rowset, you can find metadata for the model. This might include when the model was created, when the model was last processed, the name of the mining structure that the model is based on, and the name of the columns used as the predictable attribute. You can also return the parameters that were used when the model was created.

```
SELECT MODEL_CATALOG, MODEL_NAME, DATE_CREATED, LAST_PROCESSED,  
SERVICE_NAME, PREDICTION_ENTITY, FILTER  
FROM $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'TM_NaiveBayes_Filtered'
```

Sample results:

MODEL_CATALOG	AdventureWorks
MODEL_NAME	TM_NaiveBayes_Filtered

DATE_CREATED	3/1/2008 19:15
LAST_PROCESSED	3/2/2008 20:00
SERVICE_NAME	Microsoft_Naive_Bayes
PREDICTION_ENTITY	Bike Buyer,Yearly Income
FILTER	[Region] = 'Europe' OR [Region] = 'North America'

The model used for this example is based on the Naive Bayes model you create in the [Basic Data Mining Tutorial](#), but was modified by adding a second predictable attribute and applying a filter to the training data.

Sample Query 2: Retrieving a Summary of Training Data

In a Naive Bayes model, the marginal statistics node stores aggregated information about the distribution of values in the training data. This summary is convenient and saves you from having to create SQL queries against the training data to find the same information.

The following example uses a DMX content query to retrieve the data from the node (NODE_TYPE = 24).

Because the statistics are stored in a nested table, the FLATTENED keyword is used to make the results easier to view.

```
SELECT FLATTENED MODEL_NAME,
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE, [SUPPORT], [PROBABILITY], VALUETYPE FROM NODE DISTRIBUTION) AS t
FROM TM_NaiveBayes.CONTENT
WHERE NODE_TYPE = 26
```

NOTE

You must enclose the name of the columns, SUPPORT and PROBABILITY, in brackets to distinguish them from the Multidimensional Expressions (MDX) reserved keywords of the same names.

Partial results:

MODEL_NAME	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VALUETYPE
TM_NaiveBayes	Bike Buyer	Missing	0	0	1
TM_NaiveBayes	Bike Buyer	0	8869	0.507263784	4
TM_NaiveBayes	Bike Buyer	1	8615	0.492736216	4
TM_NaiveBayes	Gender	Missing	0	0	1
TM_NaiveBayes	Gender	F	8656	0.495081217	4
TM_NaiveBayes	Gender	M	8828	0.504918783	4

For example, these results tell you the number of training cases for each discrete value (VALUETYPE = 4), together with the computed probability, adjusted for missing values (VALUETYPE = 1).

For a definition of the values provided in the NODE DISTRIBUTION table in a Naive Bayes model, see [Mining Model Content for Naive Bayes Models \(Analysis Services - Data Mining\)](#). For more information about how support and probability calculations are affected by missing values, see [Missing Values \(Analysis Services - Data Mining\)](#).

Sample Query 3: Finding More Information about Attributes

Because a Naive Bayes model often contains complex information about the relationships among different attributes, the easiest way to view these relationships is to use the [Microsoft Naive Bayes Viewer](#). However, you can create DMX queries to return the data.

The following example shows how to return information from the model about a particular attribute, `Region`.

```
SELECT NODE_TYPE, NODE_CAPTION,  
NODE_PROBABILITY, NODE_SUPPORT, MSOLAP_NODE_SCORE  
FROM TM_NaiveBayes.CONTENT  
WHERE ATTRIBUTE_NAME = 'Region'
```

This query returns two types of nodes: the node that represents the input attribute (`NODE_TYPE` = 10), and nodes for each value of the attribute (`NODE_TYPE` = 11). The node caption is used to identify the node, rather than the node name, because the caption shows both the attribute name and attribute value.

<code>NODE_TYPE</code>	<code>NODE_CAPTION</code>	<code>NODE_PROBABILITY</code>	<code>NODE_SUPPORT</code>	<code>MSOLAP_NODE_SCORE</code>	<code>NODE_TYPE</code>
10	Bike Buyer -> Region	1	17484	84.51555875	10
11	Bike Buyer -> Region = Missing	0	0	0	11
11	Bike Buyer -> Region = North America	0.508236102	8886	0	11
11	Bike Buyer -> Region = Pacific	0.193891558	3390	0	11
11	Bike Buyer -> Region = Europe	0.29787234	5208	0	11

Some of the columns stored in the nodes are the same that you can get from the marginal statistics nodes, such as the node probability score and the node support values. However, the `MSOLAP_NODE_SCORE` is a special value provided only for the input attribute nodes, and indicates the relative importance of this attribute in the model. You can see much the same information in the Dependency Network pane of the viewer; however, the viewer does not provide scores.

The following query returns the importance scores of all attributes in the model:

```
SELECT NODE_CAPTION, MSOLAP_NODE_SCORE  
FROM TM_NaiveBayes.CONTENT  
WHERE NODE_TYPE = 10  
ORDER BY MSOLAP_NODE_SCORE DESC
```

Sample results:

NODE_CAPTION	MSOLAP_NODE_SCORE
Bike Buyer -> Total Children	181.3654836
Bike Buyer -> Commute Distance	179.8419482
Bike Buyer -> English Education	156.9841928
Bike Buyer -> Number Children At Home	111.8122599
Bike Buyer -> Region	84.51555875
Bike Buyer -> Marital Status	23.13297354
Bike Buyer -> English Occupation	2.832069191

By browsing the model content in the [Microsoft Generic Content Tree Viewer](#), you will get a better idea of what statistics might be interesting. Some simple examples were demonstrated here; more often you may need to execute multiple queries or store the results and process them on the client.

Sample Query 4: Using System Stored Procedures

In addition to writing your own content queries, you can use some Analysis Services system stored procedures to explore the results. To use a system stored procedure, prefix the stored procedure name with the CALL keyword:

```
CALL GetPredictableAttributes ('TM_NaiveBayes')
```

Partial results:

ATTRIBUTE_NAME	NODE_UNIQUE_NAME
Bike Buyer	100000001

NOTE

These system stored procedures are for internal communication between the Analysis Services server and the client and should only be used for convenience when developing and testing mining models. When you create queries for a production system, you should always write your own queries by using DMX.

For more information about Analysis Services system stored procedures, see [Data Mining Stored Procedures \(Analysis Services - Data Mining\)](#).

Using a Naïve Bayes Model to Make Predictions

The Microsoft Naïve Bayes algorithm is typically used less for prediction than it is for exploration of relationships among the input and predictable attributes. However, the model supports the use of prediction functions for both prediction and association.

Sample Query 5: Predicting Outcomes using a Singleton Query

The following query uses a singleton query to provide a new value and predict, based on the model, whether a customer with these characteristics is likely to buy a bike. The easiest way to create a singleton query on a regression model is by using the **Singleton Query Input** dialog box. For example, you can build the following DMX query by selecting the `TM_NaiveBayes` model, choosing **Singleton Query**, and selecting values from the

dropdown lists for [Commute Distance] and [Gender].

```
SELECT
    Predict([TM_NaiveBayes].[Bike Buyer])
FROM
    [TM_NaiveBayes]
NATURAL PREDICTION JOIN
(SELECT '5-10 Miles' AS [Commute Distance],
     'F' AS [Gender]) AS t
```

Example results:

EXPRESSION
0

The prediction function returns the most likely value, in this case, 0, which means this type of customer is unlikely to purchase a bike.

Sample Query 6: Getting Predictions with Probability and Support Values

In addition to predicting an outcome, you often want to know how strong the prediction is. The following query uses the same singleton query as the previous example, but adds the prediction function, [PredictHistogram \(DMX\)](#), to return a nested table that contains statistics in support of the prediction.

```
SELECT
    Predict([TM_NaiveBayes].[Bike Buyer]),
    PredictHistogram([TM_NaiveBayes].[Bike Buyer])
FROM
    [TM_NaiveBayes]
NATURAL PREDICTION JOIN
(SELECT '5-10 Miles' AS [Commute Distance],
     'F' AS [Gender]) AS t
```

Example results:

BIKE BUYER	\$SUPPORT	\$PROBABILITY	\$ADJUSTEDPROBABILITY	\$VARIANCE	\$STDEV
0	10161.5714	0.581192599	0.010530981	0	0
1	7321.428768	0.418750215	0.008945684	0	0
	0.999828444	5.72E-05	5.72E-05	0	0

The final row in the table shows the adjustments to support and probability for the missing value. Variance and standard deviation values are always 0, because Naive Bayes models cannot model continuous values.

Sample Query 7: Predicting Associations

The Microsoft Naive Bayes algorithm can be used for association analysis, if the mining structure contains a nested table with the predictable attribute as the key. For example, you could build a Naive Bayes model by using the mining structure created in [Lesson 3: Building a Market Basket Scenario \(Intermediate Data Mining Tutorial\)](#) of the data mining tutorial. The model used in this example was modified to add information about income and customer region in the case table.

The following query example shows a singleton query that predicts products that are related to purchases of the product, [Road Tire Tube]. You might use this information to recommend products to a specific type of customer.

```

SELECT PredictAssociation([Association].[v Assoc Seq Line Items])
FROM [Association_NB]
NATURAL PREDICTION JOIN
(SELECT 'High' AS [Income Group],
'Europe' AS [Region],
(SELECT 'Road Tire Tube' AS [Model])
AS [v Assoc Seq Line Items])
AS t

```

Partial results:

MODEL
Women's Mountain Shorts
Water Bottle
Touring-3000
Touring-2000
Touring-1000

Function List

All Microsoft algorithms support a common set of functions. However, the Microsoft Naive Bayes algorithm supports the additional functions that are listed in the following table.

Prediction Function	Usage
IsDescendant (DMX)	Determines whether one node is a child of another node in the model.
Predict (DMX)	Returns a predicted value, or set of values, for a specified column.
PredictAdjustedProbability (DMX)	Returns the weighted probability.
PredictAssociation (DMX)	Predicts membership in an associative dataset.
PredictNodeID (DMX)	Returns the Node_ID for each case.
PredictProbability (DMX)	Returns probability for the predicted value.
PredictSupport (DMX)	Returns the support value for a specified state.

To see the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

Microsoft Neural Network Algorithm

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The Microsoft Neural Network algorithm is an implementation of the popular and adaptable neural network architecture for machine learning. The algorithm works by testing each possible state of the input attribute against each possible state of the predictable attribute, and calculating probabilities for each combination based on the training data. You can use these probabilities for both classification or regression tasks, to predict an outcome based on some input attributes. A neural network can also be used for association analysis.

When you create a mining model using the Microsoft Neural Network algorithm, you can include multiple outputs, and the algorithm will create multiple networks. The number of networks contained in a single mining model depends on the number of states (or attribute values) in the input columns, as well as the number of predictable columns that the mining model uses and the number of states in those columns.

Example

The Microsoft Neural Network algorithm is useful for analyzing complex input data, such as from a manufacturing or commercial process, or business problems for which a significant quantity of training data is available but for which rules cannot be easily derived by using other algorithms.

Suggested scenarios for using the Microsoft Neural Network algorithm include the following:

- Marketing and promotion analysis, such as measuring the success of a direct mail promotion or a radio advertising campaign
- Predicting stock movement, currency fluctuation, or other highly fluid financial information from historical data
- Analyzing manufacturing and industrial processes
- Text mining
- Any prediction model that analyzes complex relationships between many inputs and relatively fewer outputs

How the Algorithm Works

The Microsoft Neural Network algorithm creates a network that is composed of up to three layers of nodes (sometimes called *neurons*). These layers are the *input layer*, the *hidden layer*, and the *output layer*.

Input layer: Input nodes define all the input attribute values for the data mining model, and their probabilities.

Hidden layer: Hidden nodes receive inputs from input nodes and provide outputs to output nodes. The hidden layer is where the various probabilities of the inputs are assigned weights. A weight describes the relevance or importance of a particular input to the hidden node. The greater the weight that is assigned to an input, the more important the value of that input is. Weights can be negative, which means that the input can inhibit, rather than favor, a specific result.

Output layer: Output nodes represent predictable attribute values for the data mining model.

For a detailed explanation of how the input, hidden, and output layers are constructed and scored, see [Microsoft Neural Network Algorithm Technical Reference](#).

Data Required for Neural Network Models

A neural network model must contain a key column, one or more input columns, and one or more predictable columns.

Data mining models that use the Microsoft Neural Network algorithm are heavily influenced by the values that you specify for the parameters that are available to the algorithm. The parameters define how data is sampled, how data is distributed or expected to be distributed in each column, and when feature selection is invoked to limit the values that are used in the final model.

For more information about setting parameters to customize model behavior, see [Microsoft Neural Network Algorithm Technical Reference](#).

Viewing a Neural Network Model

To work with the data and see how the model correlates inputs with outputs, you can use the **Microsoft Neural Network Viewer**. With this custom viewer, you can filter on input attributes and their values, and see graphs that show how they affect the outputs. Tooltips in the viewer show the probability and lift associated with each pair of input and output values. For more information, see [Browse a Model Using the Microsoft Neural Network Viewer](#).

The easiest way to explore the structure of the model is to use the **Microsoft Generic Content Tree Viewer**. You can view the inputs, outputs, and networks created by the model, and click on any node to expand it and see statistics related to the input, output, or hidden layer nodes. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#).

Creating Predictions

After the model has been processed, you can use the network and the weights stored within each node to make predictions. A neural network model supports regression, association, and classification analysis. Therefore, the meaning of each prediction might be different. You can also query the model itself, to review the correlations that were found and retrieve related statistics. For examples of how to create queries against a neural network model, see [Neural Network Model Query Examples](#).

For general information about how to create a query on a data mining model, see [Data Mining Queries](#).

Remarks

- Does not support drillthrough or data mining dimensions. This is because the structure of the nodes in the mining model does not necessarily correspond directly to the underlying data.
- Does not support the creation of models in Predictive Model Markup Language (PMML) format.
- Supports the use of OLAP mining models.
- Does not support the creation of data mining dimensions.

[Neural Network Model Query Examples](#)

[Microsoft Logistic Regression Algorithm](#)

Microsoft Neural Network Algorithm Technical Reference

7/16/2019 • 13 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Neural Network uses a *Multilayer Perceptron* network, also called a *Back-Propagated Delta Rule network*, composed of up to three layers of neurons, or *perceptrons*. These layers are an input layer, an optional hidden layer, and an output layer.

A detailed discussion of Multilayer Perceptron neural networks is outside the scope of this documentation. This topic explains the basic implementation of the algorithm, including the method used to normalize input and output values, and feature selection methods used to reduce attribute cardinality. This topic describes the parameters and other settings that can be used to customize the behavior of the algorithm, and provides links to additional information about querying the model.

Implementation of the Microsoft Neural Network Algorithm

In a Multilayer Perceptron neural network, each neuron receives one or more inputs and produces one or more identical outputs. Each output is a simple non-linear function of the sum of the inputs to the neuron. Inputs pass forward from nodes in the input layer to nodes in the hidden layer, and then pass from the hidden layer to the output layer; there are no connections between neurons within a layer. If no hidden layer is included, as in a logistic regression model, inputs pass forward directly from nodes in the input layer to nodes in the output layer.

There are three types of neurons in a neural network that is created with the Microsoft Neural Network algorithm:

Input neurons

Input neurons provide input attribute values for the data mining model. For discrete input attributes, an input neuron typically represents a single state from the input attribute. This includes missing values, if the training data contains nulls for that attribute. A discrete input attribute that has more than two states generates one input neuron for each state, and one input neuron for a missing state, if there are any nulls in the training data. A continuous input attribute generates two input neurons: one neuron for a missing state, and one neuron for the value of the continuous attribute itself. Input neurons provide inputs to one or more hidden neurons.

Hidden neurons

Hidden neurons receive inputs from input neurons and provide outputs to output neurons.

Output neurons

Output neurons represent predictable attribute values for the data mining model. For discrete input attributes, an output neuron typically represents a single predicted state for a predictable attribute, including missing values. For example, a binary predictable attribute produces one output node that describes a missing or existing state, to indicate whether a value exists for that attribute. A Boolean column that is used as a predictable attribute generates three output neurons: one neuron for a true value, one neuron for a false value, and one neuron for a missing or existing state. A discrete predictable attribute that has more than two states generates one output neuron for each state, and one output neuron for a missing or existing state. Continuous predictable columns generate two output neurons: one neuron for a missing or existing state, and one neuron for the value of the continuous column itself. If more than 500 output neurons are generated by reviewing the set of predictable columns, Analysis Services generates a new network in the mining model to represent the additional output

neurons.

A neuron receives input from other neurons, or from other data, depending on which layer of the network it is in. An input neuron receives inputs from the original data. Hidden neurons and output neurons receive inputs from the output of other neurons in the neural network. Inputs establish relationships between neurons, and the relationships serve as a path of analysis for a specific set of cases.

Each input has a value assigned to it, called the *weight*, which describes the relevance or importance of that particular input to the hidden neuron or the output neuron. The greater the weight that is assigned to an input, the more relevant or important the value of that input. Weights can be negative, which implies that the input can inhibit, rather than activate, a specific neuron. The value of each input is multiplied by the weight to emphasize the importance of an input for a specific neuron. For negative weights, the effect of multiplying the value by the weight is to deemphasize the importance.

Each neuron has a simple non-linear function assigned to it, called the *activation function*, which describes the relevance or importance of a particular neuron to that layer of a neural network. Hidden neurons use a *hyperbolic tangent* function (*tanh*) for their activation function, whereas output neurons use a *sigmoid* function for activation. Both functions are nonlinear, continuous functions that allow the neural network to model nonlinear relationships between input and output neurons.

Training Neural Networks

Several steps are involved in training a data mining model that uses the Microsoft Neural Network algorithm. These steps are heavily influenced by the values that you specify for the algorithm parameters.

The algorithm first evaluates and extracts training data from the data source. A percentage of the training data, called the *holdout data*, is reserved for use in assessing the accuracy of the network. Throughout the training process, the network is evaluated immediately after each iteration through the training data. When the accuracy no longer increases, the training process is stopped.

The values of the *SAMPLE_SIZE* and *HOLDOUT_PERCENTAGE* parameters are used to determine the number of cases to sample from the training data and the number of cases to be put aside for the holdout data. The value of the *HOLDOUT_SEED* parameter is used to randomly determine the individual cases to be put aside for the holdout data.

NOTE

These algorithm parameters are different from the *HOLDOUT_SIZE* and *HOLDOUT_SEED* properties, which are applied to a mining structure to define a testing data set.

The algorithm next determines the number and complexity of the networks that the mining model supports. If the mining model contains one or more attributes that are used only for prediction, the algorithm creates a single network that represents all such attributes. If the mining model contains one or more attributes that are used for both input and prediction, the algorithm provider constructs a network for each attribute.

For input and predictable attributes that have discrete values, each input or output neuron respectively represents a single state. For input and predictable attributes that have continuous values, each input or output neuron respectively represents the range and distribution of values for the attribute. The maximum number of states that is supported in either case depends on the value of the *MAXIMUM_STATES* algorithm parameter. If the number of states for a specific attribute exceeds the value of the *MAXIMUM_STATES* algorithm parameter, the most popular or relevant states for that attribute are chosen, up to the maximum number of states allowed, and the remaining states are grouped as missing values for the purposes of analysis.

The algorithm then uses the value of the *HIDDEN_NODE_RATIO* parameter when determining the initial number of neurons to create for the hidden layer. You can set *HIDDEN_NODE_RATIO* to 0 to prevent the creation of a hidden layer in the networks that the algorithm generates for the mining model, to treat the neural

network as a logistic regression.

The algorithm provider iteratively evaluates the weight for all inputs across the network at the same time, by taking the set of training data that was reserved earlier and comparing the actual known value for each case in the holdout data with the network's prediction, in a process known as *batch learning*. After the algorithm has evaluated the entire set of training data, the algorithm reviews the predicted and actual value for each neuron. The algorithm calculates the degree of error, if any, and adjusts the weights that are associated with the inputs for that neuron, working backward from output neurons to input neurons in a process known as *backpropagation*. The algorithm then repeats the process over the entire set of training data. Because the algorithm can support many weights and output neurons, the conjugate gradient algorithm is used to guide the training process for assigning and evaluating weights for inputs. A discussion of the conjugate gradient algorithm is outside the scope of this documentation.

Feature Selection

If the number of input attributes is greater than the value of the *MAXIMUM_INPUT_ATTRIBUTES* parameter, or if the number of predictable attributes is greater than the value of the *MAXIMUM_OUTPUT_ATTRIBUTES* parameter, a feature selection algorithm is used to reduce the complexity of the networks that are included in the mining model. Feature selection reduces the number of input or predictable attributes to those that are most statistically relevant to the model.

Feature selection is used automatically by all Analysis Services data mining algorithms to improve analysis and reduce processing load. The method used for feature selection in neural network models depends on the data type of the attribute. For reference, the following table shows the feature selection methods used for neural network models, and also shows the feature selection methods used for the Logistic Regression algorithm, which is based on the Neural Network algorithm.

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Neural Network	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	The Neural Networks algorithm can use both entropy-based and Bayesian scoring methods, as long as the data contains continuous columns. Default.
Logistic Regression	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	Because you cannot pass a parameter to this algorithm to control feature election behavior, the defaults are used. Therefore, if all attributes are discrete or discretized, the default is BDEU.

The algorithm parameters that control feature selection for a neural network model are *MAXIMUM_INPUT_ATTRIBUTES*, *MAXIMUM_OUTPUT_ATTRIBUTES*, and *MAXIMUM_STATES*. You can also control the number of hidden layers by setting the *HIDDEN_NODE_RATIO* parameter.

Scoring Methods

Scoring is a kind of normalization, which in the context of training a neural network model means the process of converting a value, such as a discrete text label, into a value that can be compared with other types of inputs and weighted in the network. For example, if one input attribute is Gender and the possible values are Male and Female, and another input attribute is Income, with a variable range of values, the values for each attribute are not directly comparable, and therefore must be encoded to a common scale so that the weights can be

computed. Scoring is the process of normalizing such inputs to numeric values: specifically, to a probability range. The functions used for normalization also help to distribute input value more evenly on a uniform scale so that extreme values do not distort the results of analysis.

Outputs of the neural network are also encoded. When there is a single target for output (that is, prediction), or multiple targets that are used for prediction only and not for input, the model creates a single network and it might not seem necessary to normalize the values. However, if multiple attributes are used for input and prediction, the model must create multiple networks; therefore, all values must be normalized, and the outputs too must be encoded as they exit the network.

Encoding for inputs is based on summing each discrete value in the training cases, and multiplying that value by its weight. This is called a *weighted sum*, which is passed to the activation function in the hidden layer. A z-score is used for encoding, as follows:

Discrete values

$\mu = p$ - the prior probability of a state

$\text{StdDev} = \sqrt{p(1-p)}$

Continuous values

Value present= $1 - \mu/\sigma$

No existing value= $-\mu/\sigma$

After the values have been encoded, the inputs go through weighted summing, with network edges as weights.

Encoding for outputs uses the sigmoid function, which has properties that make it very useful for prediction. One such property is that, regardless of how the original values are scaled, and regardless of whether values are negative or positive, the output of this function is always a value between 0 and 1, which is suited for estimating probabilities. Another useful property is that the sigmoid function has a smoothing effect, so that as values move farther away from point of inflection, the probability for the value moves towards 0 or 1, but slowly.

Customizing the Neural Network Algorithm

The Microsoft Neural Network algorithm supports several parameters that affect the behavior, performance, and accuracy of the resulting mining model. You can also modify the way that the model processes data by setting modeling flags on columns, or by setting distribution flags to specify how values within the column are handled.

Setting Algorithm Parameters

The following table describes the parameters that can be used with the Microsoft Neural Network algorithm.

HIDDEN_NODE_RATIO

Specifies the ratio of hidden neurons to input and output neurons. The following formula determines the initial number of neurons in the hidden layer:

$\text{HIDDEN_NODE_RATIO} * \text{SQRT}(\text{Total input neurons} * \text{Total output neurons})$

The default value is 4.0.

HOLDOUT_PERCENTAGE

Specifies the percentage of cases within the training data used to calculate the holdout error, which is used as part of the stopping criteria while training the mining model.

The default value is 30.

HOLDOUT_SEED

Specifies a number that is used to seed the pseudo-random generator when the algorithm randomly determines

the holdout data. If this parameter is set to 0, the algorithm generates the seed based on the name of the mining model, to guarantee that the model content remains the same during reprocessing.

The default value is 0.

MAXIMUM_INPUT_ATTRIBUTES

Determines the maximum number of input attributes that can be supplied to the algorithm before feature selection is employed. Setting this value to 0 disables feature selection for input attributes.

The default value is 255.

MAXIMUM_OUTPUT_ATTRIBUTES

Determines the maximum number of output attributes that can be supplied to the algorithm before feature selection is employed. Setting this value to 0 disables feature selection for output attributes.

The default value is 255.

MAXIMUM_STATES

Specifies the maximum number of discrete states per attribute that is supported by the algorithm. If the number of states for a specific attribute is greater than the number that is specified for this parameter, the algorithm uses the most popular states for that attribute and treats the remaining states as missing.

The default value is 100.

SAMPLE_SIZE

Specifies the number of cases to be used to train the model. The algorithm uses either this number or the percentage of total of cases not included in the holdout data as specified by the HOLDOUT_PERCENTAGE parameter, whichever value is smaller.

In other words, if HOLDOUT_PERCENTAGE is set to 30, the algorithm will use either the value of this parameter, or a value equal to 70 percent of the total number of cases, whichever is smaller.

The default value is 10000.

Modeling Flags

The following modeling flags are supported for use with the Microsoft Neural Network algorithm.

NOT NULL

Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training.

Applies to mining structure columns.

MODEL_EXISTENCE_ONLY

Indicates that the model should only consider whether a value exists for the attribute or if a value is missing. The exact value does not matter.

Applies to mining model columns.

Distribution Flags

The following distribution flags are supported for use with the Microsoft Neural Network algorithm. The flags are used as hints to the model only; if the algorithm detects a different distribution it will use the found distribution, not the distribution provided in the hint.

Normal

Indicates that values within the column should be treated as though they represent the normal, or Gaussian, distribution.

Uniform

Indicates that values within the column should be treated as though they are distributed uniformly; that is, the

probability of any value is roughly equal, and is a function of the total number of values.

Log Normal

Indicates that values within the column should be treated as though distributed according to the *log normal* curve, which means that the logarithm of the values is distributed normally.

Requirements

A neural network model must contain at least one input column and one output column.

Input and Predictable Columns

The Microsoft Neural Network algorithm supports the specific input columns and predictable columns that are listed in the following table.

COLUMN	CONTENT TYPES
Input attribute	Continuous, Cyclical, Discrete, Discretized, Key, Table, and Ordered
Predictable attribute	Continuous, Cyclical, Discrete, Discretized, and Ordered

NOTE

Cyclical and Ordered content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

Mining Model Content for Neural Network Models (Analysis Services - Data Mining)

7/16/2019 • 10 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

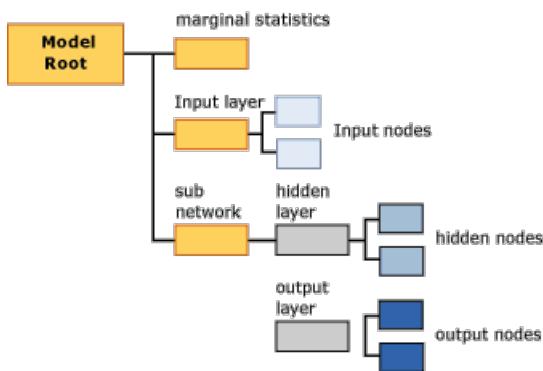

This topic describes mining model content that is specific to models that use the Microsoft Neural Network algorithm. For an explanation of how to interpret statistics and structure shared by all model types, and general definitions of terms related to mining model content, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Understanding the Structure of a Neural Network Model

Each neural network model has a single parent node that represents the model and its metadata, and a marginal statistics node (NODE_TYPE = 24) that provides descriptive statistics about the input attributes. The marginal statistics node is useful because it summarizes information about inputs, so that you do not need to query data from the individual nodes.

Underneath these two nodes, there are at least two more nodes, and might be many more, depending on how many predictable attributes the model has.

- The first node (NODE_TYPE = 18) always represents the top node of the input layer. Beneath this top node, you can find input nodes (NODE_TYPE = 21) that contain the actual input attributes and their values.
- Successive nodes each contain a different *subnetwork* (NODE_TYPE = 17). Each subnetwork always contains a hidden layer (NODE_TYPE = 19), and an output layer (NODE_TYPE = 20) for that subnetwork.

The information in the input layer is straightforward: the top node for each input layer (NODE_TYPE = 18) serves as an organizer for a collection of input nodes (NODE_TYPE = 21). The content of the input nodes is described in the following table.

Each subnetwork (NODE_TYPE = 17) represents the analysis of the influence of the input layer on a particular predictable attribute. If there are multiple predictable outputs, there are multiple subnetworks. The hidden layer for each subnetwork contains multiple hidden nodes (NODE_TYPE = 22) that contain details about the weights for each transition that ends in that particular hidden node.

The output layer (NODE_TYPE = 20) contains output nodes (NODE_TYPE = 23) that each contain distinct values of the predictable attribute. If the predictable attribute is a continuous numeric data type, there is only one output node for the attribute.

NOTE

The logistic regression algorithm uses a special case of a neural network that has only one predictable outcome and potentially many inputs. Logistic regression does not use a hidden layer.

The easiest way to explore the structure of the inputs and subnetworks is to use the **Microsoft Generic Content Tree viewer**. You can click any node to expand it and see the child nodes, or view the weights and other statistics that is contained in the node.

To work with the data and see how the model correlates inputs with outputs, use the **Microsoft Neural Network Viewer**. By using this custom viewer, you can filter on input attributes and their values, and graphically see how they affect the outputs. The tooltips in the viewer show you the probability and lift associated with each pair of inputs and output values. For more information, see [Browse a Model Using the Microsoft Neural Network Viewer](#).

Model Content for a Neural Network Model

This section provides detail and examples only for those columns in the mining model content that have particular relevance for neural networks. For information about general-purpose columns in the schema rowset, such as MODEL_CATALOG and MODEL_NAME, that are not described here, or for explanations of mining model terminology, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

The names of the attributes that correspond to this node.

NODE	CONTENT
Model root	Blank
Marginal statistics	Blank
Input layer	Blank
Input node	Input attribute name
Hidden layer	Blank
Hidden node	Blank
Output layer	Blank
Output node	Output attribute name

NODE_NAME

The name of the node. This column contains the same value as NODE_UNIQUE_NAME.

NODE_UNIQUE_NAME

The unique name of the node.

For more information about how the names and IDs provide structural information about the model, see the section, [Using Node Names and IDs](#).

NODE_TYPE

A neural network model outputs the following node types:

NODE TYPE ID	DESCRIPTION
1	Model.
17	Organizer node for the subnetwork.
18	Organizer node for the input layer.
19	Organizer node for the hidden layer.
20	Organizer node for the output layer.
21	Input attribute node.
22	Hidden layer node
23	Output attribute node.
24	Marginal statistics node.

NODE_CAPTION

A label or a caption associated with the node. In neural network models, always blank.

CHILDREN_CARDINALITY

An estimate of the number of children that the node has.

NODE	CONTENT
Model root	Indicates the count of child nodes, which includes at least 1 network, 1 required marginal node, and 1 required input layer. For example, if the value is 5, there are 3 subnetworks.
Marginal statistics	Always 0.
Input layer	Indicates the number of input attribute-values pairs that were used by the model.
Input node	Always 0.
Hidden layer	Indicates the number of hidden nodes that were created by the model.
Hidden node	Always 0.
Output layer	Indicates the number of output values.
Output node	Always 0.

PARENT_UNIQUE_NAME

The unique name of the node's parent. NULL is returned for any nodes at the root level.

For more information about how the names and IDs provide structural information about the model, see the section, [Using Node Names and IDs](#).

NODE_DESCRIPTION

A user-friendly description of the node.

NODE	CONTENT
Model root	Blank
Marginal statistics	Blank
Input layer	Blank
Input node	Input attribute name
Hidden layer	Blank
Hidden node	Integer that indicates the sequence of the hidden node in the list of hidden nodes.
Output layer	Blank
Output node	If the output attribute is continuous, contains the name of the output attribute. If the output attribute is discrete or discretized, contains the name of the attribute and the value.

NODE_RULE

An XML description of the rule that is embedded in the node.

NODE	CONTENT
Model root	Blank
Marginal statistics	Blank
Input layer	Blank
Input node	An XML fragment that contains the same information as the NODE_DESCRIPTION column.
Hidden layer	Blank
Hidden node	Integer that indicates the sequence of the hidden node in the list of hidden nodes.
Output layer	Blank
Output node	An XML fragment that contains the same information as the NODE_DESCRIPTION column.

MARGINAL_RULE

For neural network models, always blank.

NODE_PROBABILITY

The probability associated with this node. For neural network models, always 0.

MARGINAL_PROBABILITY

The probability of reaching the node from the parent node. For neural network models, always 0.

NODE_DISTRIBUTION

A nested table that contains statistical information for the node. For detailed information about the contents of this table for each node type, see the section, [Understanding the NODE_DISTRIBUTION Table](#).

NODE_SUPPORT

For neural network models, always 0.

NOTE

Support probabilities are always 0 because the output of this model type is not probabilistic. Only the weights are meaningful for the algorithm; therefore, the algorithm does not compute probability, support, or variance.

To get information about the support in the training cases for specific values, see the marginal statistics node.

MSOLAP_MODEL_COLUMN

|Node|Content|

|-----|-----|

|Model root|Blank|

|Marginal statistics|Blank|

|Input layer|Blank|

|Input node|Input attribute name.|

|Hidden layer|Blank|

|Hidden node|Blank|

|Output layer|Blank|

|Output node|Input attribute name.|

MSOLAP_NODE_SCORE

For a neural network model, always 0.

MSOLAP_NODE_SHORT_CAPTION

For neural network models, always blank.

Remarks

The purpose of training a neural network model is to determine the weights that are associated with each transition from an input to a midpoint, and from a midpoint to an endpoint. Therefore, the input layer of the model principally exists to store the actual values that were used to build the model. The hidden layer stores the weights that were computed, and provides pointers back to the input attributes. The output layer stores the predictable values, and also provides pointers back to the midpoints in the hidden layer.

Using Node Names and IDs

The naming of the nodes in a neural network model provides additional information about the type of node, to make it easier to relate the hidden layer to the input layer, and the output layer to the hidden layer. The following table shows the convention for the IDs that are assigned to nodes in each layer.

NODE TYPE	CONVENTION FOR NODE ID
Model root (1)	0000000000000000.
Marginal statistics node (24)	1000000000000000
Input layer (18)	3000000000000000
Input node (21)	Starts at 6000000000000000
Subnetwork (17)	2000000000000000
Hidden layer (19)	4000000000000000
Hidden node (22)	Starts at 7000000000000000
Output layer (20)	5000000000000000
Output node (23)	Starts at 8000000000000000

You can determine which input attributes are related to a specific hidden layer node by viewing the NODE DISTRIBUTION table in the hidden node (NODE_TYPE = 22). Each row of the NODE DISTRIBUTION table contains the ID of an input attribute node.

Similarly, you can determine which hidden layers are related to an output attribute by viewing the NODE DISTRIBUTION table in the output node (NODE_TYPE = 23). Each row of the NODE DISTRIBUTION table contains the ID of a hidden layer node, together with the related coefficient.

Interpreting the Information in the NODE DISTRIBUTION Table

The NODE DISTRIBUTION table can be empty in some nodes. However, for input nodes, hidden layer nodes, and output nodes, the NODE DISTRIBUTION table stores important and interesting information about the model. To help you interpret this information, the NODE DISTRIBUTION table contains a VALUETYPE column for each row that tells you whether the value in the ATTRIBUTE_VALUE column is Discrete (4), Discretized (5), or Continuous (3).

Input Nodes

The input layer contains a node for each value of the attribute that was used in the model.

Discrete attribute: The input node stores only the name of the attribute and its value in the ATTRIBUTE_NAME and ATTRIBUTE_VALUE columns. For example, if [Work Shift] is the column, a separate node is created for each value of that column that was used in the model, such as AM and PM. The NODE DISTRIBUTION table for each node lists only the current value of the attribute.

Discretized numeric attribute: The input node stores the name of the attribute, and the value, which can be a range or a specific value. All values are represented by expressions, such as '77.4 - 87.4' or '< 64.0' for the value of the [Time Per Issue]. The NODE DISTRIBUTION table for each node lists only the current value of the attribute.

Continuous attribute: The input node stores the mean value of the attribute. The NODE DISTRIBUTION table for each node lists only the current value of the attribute.

Hidden Layer Nodes

The hidden layer contains a variable number of nodes. In each node, the NODE DISTRIBUTION table contains

mappings from the hidden layer to the nodes in the input layer. The ATTRIBUTE_NAME column contains a node ID that corresponds to a node in the input layer. The ATTRIBUTE_VALUE column contains the weight associated with that combination of input node and hidden layer node. The last row in the table contains a coefficient that represents the weight of that hidden node in the hidden layer.

Output Nodes

The output layer contains one output node for each output value that was used in the model. In each node, the NODE DISTRIBUTION table contains mappings from the output layer to the nodes in the hidden layer. The ATTRIBUTE_NAME column contains a node ID that corresponds to a node in the hidden layer. The ATTRIBUTE_VALUE column contains the weight associated with that combination of output node and hidden layer node.

The NODE DISTRIBUTION table has the following additional information, depending on whether the type of the attribute:

Discrete attribute: The final two rows of the NODE DISTRIBUTION table contain a coefficient for the node as a whole, and the current value of the attribute.

Discretized numeric attribute: Identical to discrete attributes, except that the value of the attribute is a range of values.

Continuous attribute: The final two rows of the NODE DISTRIBUTION table contain the mean of the attribute, the coefficient for the node as a whole, and the variance of the coefficient.

Neural Network Model Query Examples

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create a content query, which provides details about the patterns discovered in analysis, or a prediction query, which uses the patterns in the model to make predictions for new data. For example, a content query for a neural network model might retrieve model metadata such as the number of hidden layers. Alternatively, a prediction query might suggest classifications based on an input and optionally provide probabilities for each classification.

This section explains how to create queries for models that are based on the Microsoft Neural Network algorithm.

Content queries

[Getting Model Metadata by Using DMX](#)

[Retrieving Model Metadata from the Schema Rowset](#)

[Retrieving the Input Attributes for the Model](#)

[Retrieving Weights from the Hidden Layer](#)

Prediction queries

[Creating a Singleton Prediction](#)

Finding Information about a Neural Network Model

All mining models expose the content learned by the algorithm according to a standardized schema, the mining model schema rowset. This information provides details about the model and includes the basic metadata, structures discovered in analysis, and parameters that are used when processing. You can create queries against the model content by using Data Mining Extension (DMX) statements.

Sample Query 1: Getting Model Metadata by Using DMX

The following query returns some basic metadata about a model that was built by using the Microsoft Neural Network algorithm. In a neural network model, the parent node of the model contains only the name of the model, the name of the database where the model is stored, and the number of child nodes. However, the marginal statistics node (NODE_TYPE = 24) provides both this basic metadata and some derived statistics about the input columns used in the model.

The following sample query is based on the mining model that you create in the [Intermediate Data Mining Tutorial](#), named `Call Center Default NN`. The model uses data from a call center to explore possible correlations between staffing and the number of calls, orders, and issues. The DMX statement retrieves data from the marginal statistics node of the neural network model. The query includes the FLATTENED keyword, because the input attribute statistics of interest are stored in a nested table, NODE DISTRIBUTION. However, if your query provider supports hierarchical rowsets you do not need to use the FLATTENED keyword.

```

SELECT FLATTENED MODEL_CATALOG, MODEL_NAME,
(   SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE,
    [SUPPORT], [PROBABILITY], VALUETYPE
    FROM NODE DISTRIBUTION
) AS t
FROM [Call Center Default NN].CONTENT
WHERE NODE_TYPE = 24

```

NOTE

You must enclose the name of the nested table columns SUPPORT and PROBABILITY in brackets to distinguish them from the reserved keywords of the same name.

Example results:

MODEL_CATALOG	MODEL_NAME	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.SUPPORT	T.PROBABILITY	T.VALUETYPE
Adventure Works DW Multidimensional 2012	Call Center NN	Average Time Per Issue	Missing	0	0	1
Adventure Works DW Multidimensional 2012	Call Center NN	Average Time Per Issue	< 64.7094100096	11	0.407407407	5

For a definition of what the columns in the schema rowset mean in the context of a neural network model, see [Mining Model Content for Neural Network Models \(Analysis Services - Data Mining\)](#).

Sample Query 2: Retrieving Model Metadata from the Schema Rowset

You can find the same information that is returned in a DMX content query by querying the data mining schema rowset. However, the schema rowset provides some additional columns. The following sample query returns the date that the model was created, the date it was modified, and the date that the model was last processed. The query also returns the predictable columns, which are not easily available from the model content, and the parameters that were used to build the model. This information can be useful for documenting the model.

```

SELECT MODEL_NAME, DATE_CREATED, LAST_PROCESSED, PREDICTION_ENTITY, MINING_PARAMETERS
from $system.DMSCHEMA_MINING_MODELS
WHERE MODEL_NAME = 'Call Center Default NN'

```

Example results:

MODEL_NAME	Call Center Default NN
DATE_CREATED	1/10/2008 5:07:38 PM
LAST_PROCESSED	1/10/2008 5:24:02 PM

PREDICTION_ENTITY	Average Time Per Issue, Grade Of Service, Number Of Orders
MINING_PARAMETERS	HOLDOUT_PERCENTAGE=30, HOLDOUT_SEED=0, MAXIMUM_INPUT_ATTRIBUTES=255, MAXIMUM_OUTPUT_ATTRIBUTES=255, MAXIMUM_STATES=100, SAMPLE_SIZE=10000, HIDDEN_NODE_RATIO=4

Sample Query 3: Retrieving the Input Attributes for the Model

You can retrieve the input attribute-value pairs that were used to create the model by querying the child nodes (NODE_TYPE = 20) of the input layer (NODE_TYPE = 18). The following query returns a list of input attributes from the node descriptions.

```
SELECT NODE_DESCRIPTION
FROM [Call Center Default NN].CONTENT
WHERE NODE_TYPE = 2
```

Example results:

NODE_DESCRIPTION
Average Time Per Issue=64.7094100096 - 77.4002099712
Day Of Week=Fri.
Level 1 Operators

Only a few representative rows from the results are shown here. However, you can see that the NODE_DESCRIPTION provides slightly different information depending on the data type of the input attribute.

- If the attribute is a discrete or discretized value, the attribute and either its value or its discretized range are returned.
- If the attribute is a continuous numeric data type, the NODE_DESCRIPTION contains only the attribute name. However, you can retrieve the nested NODE_DISTRIBUTION table to obtain the mean, or return the NODE_RULE to obtain the minimum and maximum values of the numeric range.

The following query shows how to query the nested NODE_DISTRIBUTION table to return the attributes in one column, and their values in another column. For continuous attributes, the value of the attribute is represented by its mean.

```
SELECT FLATTENED
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE
FROM NODE_DISTRIBUTION) as t
FROM [Call Center Default NN -- Predict Service and Orders].CONTENT
WHERE NODE_TYPE = 21
```

Example results:

T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE
Average Time Per Issue	64.7094100096 - 77.4002099712
Day Of Week	Fri.
Level 1 Operators	3.2962962962963

The minimum and maximum range values are stored in the NODE_RULE column, and are represented as an XML fragment, as shown in the following example:

```
<NormContinuous field="Level 1 Operators">
<LinearNorm orig="2.83967303681711" norm="-1" />
<LinearNorm orig="3.75291955577548" norm="1" />
</NormContinuous>
```

Sample Query 4: Retrieving Weights from the Hidden Layer

The model content of a neural network model is structured in a way that makes it easy to retrieve details about any node in the network. Moreover, the ID numbers of the nodes provide information that helps you identify relationships among the node types.

The following query demonstrates how to retrieve the coefficients that are stored under a particular node of the hidden layer. The hidden layer consists of an organizer node (NODE_TYPE = 19), which contains only metadata, and multiple child nodes (NODE_TYPE = 22), which contain the coefficients for the various combinations of attributes and values. This query returns only the coefficient nodes.

```
SELECT FLATTENED TOP 1 NODE_UNIQUE_NAME,
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE, VALUETYPE
FROM NODE_DISTRIBUTION) as t
FROM [Call Center Default NN -- Predict Service and Orders].CONTENT
WHERE NODE_TYPE = 22
AND [PARENT_UNIQUE_NAME] = '4000000020000000' FROM [Call Center Default NN].CONTENT
```

Example results:

NODE_UNIQUE_NAME	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE	T.VALUETYPE
7000000020000000	6000000000000000a	-0.178616518	7
7000000020000000	6000000000000000b	-0.267561918	7
7000000020000000	6000000000000000c	0.11069497	7
7000000020000000	6000000000000000d	0.123757712	7
7000000020000000	6000000000000000e	0.294565343	7
7000000020000000	6000000000000000f	0.22245318	7
7000000020000000		0.188805045	7

The partial results shown here demonstrate how the neural network model content relates the hidden node to the input nodes.

- The unique names of nodes in the hidden layer always begin with 70000000.
- The unique names of nodes in the input layer always begin with 60000000.

Thus, these results tell you that the node denoted by the ID 7000000020000000 had six different coefficients (VALUETYPE = 7) passed to it. The values of the coefficients are in the ATTRIBUTE_VALUE column. You can determine exactly which input attribute the coefficient is for by using the node ID in the ATTRIBUTE_NAME column. For example, the node ID 6000000000000000a refers to input attribute and value, Day of Week = 'Tue.' You can use the node ID to create a query, or you can browse to the node by using the [Microsoft Generic Content Tree Viewer](#).

Similarly, if you query the NODE_DISTRIBUTION table of the nodes in the output layer (NODE_TYPE = 23), you can see the coefficients for each output value. However, in the output layer, the pointers refer back to the nodes of the hidden layer. For more information, see [Mining Model Content for Neural Network Models \(Analysis Services - Data Mining\)](#).

Using a Neural Network Model to Make Predictions

The Microsoft Neural Network algorithm supports both classification and regression. You can use prediction functions with these models to provide new data and create either singleton or batch predictions.

Sample Query 5: Creating a Singleton Prediction

The easiest way to build a prediction query on a neural network model is to use the Prediction Query Builder, available on the **Mining Prediction** tab of Data Mining Designer in both SQL Server Management Studio and Visual Studio with Analysis Services projects. You can browse the model in the Microsoft Neural Network Viewer to filter attributes of interest and view trends, and then switch to the **Mining Prediction** tab to create a query and predict new values for those trends.

For example, you can browse the call center model to view correlations between the order volumes and other attributes. To do this, open the model in the viewer, and for **Input**, select **<All>**. Next, for **Output**, select **Number of Orders**. For **Value 1**, select the range that represents the most orders, and for **Value 2**, select the range that represents the fewest orders. You can then see at a glance all the attributes that the model correlates with order volume.

By browsing the results in the viewer, you find that certain days of the week have low order volumes, and that an increase in the number of operators seems to be correlated with higher sales. You could then use a prediction query on the model to test a "what if" hypothesis and ask if increasing the number of level 2 operators on a low-volume day would increase orders. To do this, create a query such as the following:

```
SELECT Predict([Call Center Default NN].[Number of Orders]) AS [Predicted Orders],
PredictProbability([Call Center Default NN].[Number of Orders]) AS [Probability]
FROM [Call Center Default NN]
NATURAL PREDICTION JOIN
(SELECT 'Tue.' AS [Day of Week],
13 AS [Level 2 Operators]) AS t
```

Example results:

PREDICTED ORDERS	PROBABILITY
364	0.9532...

The predicted sales volume is higher than the current range of sales for Tuesday, and the probability of the prediction is very high. However, you might want to create multiple predictions by using a batch process to test a variety of hypotheses on the model.

NOTE

The Data Mining Add-Ins for Excel 2007 provide logistic regression wizards that make it easy to answer complex questions, such as how many Level Two Operators would be needed to improve service grade to a target level for a specific shift. The data mining add-ins are a free download, and include wizards that are based on the neural network and/or logistic regression algorithms. For more information, see the [Data Mining Add-ins for Office 2007](#) Web site.

List of Prediction Functions

All Microsoft algorithms support a common set of functions. There are no prediction functions that are specific to the Microsoft Neural Network algorithm; however, the algorithm supports the functions that are listed in the following table.

Prediction Function	Usage
IsDescendant (DMX)	Determines whether one node is a child of another node in the neural network graph.
PredictAdjustedProbability (DMX)	Returns the weighted probability.
PredictHistogram (DMX)	Returns a table of values related to the current predicted value.
PredictVariance (DMX)	Returns variance for the predicted value.
PredictProbability (DMX)	Returns probability for the predicted value.
PredictStdev (DMX)	Returns the standard deviance for the predicted value.
PredictSupport (DMX)	For neural network and logistic regression models, returns a single value that represents the size of the training set for the entire model.

For a list of the functions that are common to all Microsoft algorithms, see [Algorithm Reference \(Analysis Services - Data Mining\)](#). For the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

Microsoft Sequence Clustering Algorithm

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Sequence Clustering algorithm is a unique algorithm that combines sequence analysis with clustering. You can use this algorithm to explore data that contains events that can be linked in a *sequence*. The algorithm finds the most common sequences, and performs clustering to find sequences that are similar. The following examples illustrate the types of sequences that you might capture as data for machine learning, to provide insight about common problems or business scenarios:

- Clickstreams or click paths generated when users navigate or browse a Web site
- Logs that list events preceding an incident, such as a hard disk failure or server deadlock
- Transaction records that describe the order in which a customer adds items to a online shopping cart
- Records that follow customer or patient interactions over time, to predict service cancellations or other poor outcomes

This algorithm is similar in many ways to the Microsoft Clustering algorithm. However, instead of finding clusters of cases that contain similar attributes, the Microsoft Sequence Clustering algorithm finds clusters of cases that contain similar paths in a sequence.

Example

The Adventure Works Cycles web site collects information about what pages site users visit, and about the order in which the pages are visited. Because the company provides online ordering, customers must log in to the site. This provides the company with click information for each customer profile. By using the Microsoft Sequence Clustering algorithm on this data, the company can find groups, or clusters, of customers who have similar patterns or sequences of clicks. The company can then use these clusters to analyze how users move through the Web site, to identify which pages are most closely related to the sale of a particular product, and to predict which pages are most likely to be visited next.

How the Algorithm Works

The Microsoft Sequence Clustering algorithm is a hybrid algorithm that combines clustering techniques with Markov chain analysis to identify clusters and their sequences. One of the hallmarks of the Microsoft Sequence Clustering algorithm is that it uses sequence data. This data typically represents a series of events or transitions between states in a dataset, such as a series of product purchases or Web clicks for a particular user. The algorithm examines all transition probabilities and measures the differences, or distances, between all the possible sequences in the dataset to determine which sequences are the best to use as inputs for clustering. After the algorithm has created the list of candidate sequences, it uses the sequence information as an input for clustering using Expectation maximization (EM).

For a detailed description of the implementation, see [Microsoft Sequence Clustering Algorithm Technical Reference](#).

Data Required for Sequence Clustering Models

When you prepare data for use in training a sequence clustering model, you should understand the requirements for the particular algorithm, including how much data is needed, and how the data is used.

The requirements for a sequence clustering model are as follows:

- **A single key column** A sequence clustering model requires a key that identifies records.
- **A sequence column** For sequence data, the model must have a nested table that contains a sequence ID column. The sequence ID can be any sortable data type. For example, you can use a Web page identifier, an integer, or a text string, as long as the column identifies the events in a sequence. Only one sequence identifier is allowed for each sequence, and only one type of sequence is allowed in each model.
- **Optional non sequence attributes** The algorithm supports the addition of other attributes that are not related to sequencing. These attributes can include nested columns.

For example, in the example cited earlier of the Adventure Works Cycles Web site, a sequence clustering model might include order information as the case table, demographics about the specific customer for each order as non-sequence attributes, and a nested table containing the sequence in which the customer browsed the site or put items into a shopping cart as the sequence information.

For more detailed information about the content types and data types supported for sequence clustering models, see the Requirements section of [Microsoft Sequence Clustering Algorithm Technical Reference](#).

Viewing a Sequence Clustering Model

The mining model that this algorithm creates contains descriptions of the most common sequences in the data. To explore the model, you can use the **Microsoft Sequence Cluster Viewer**. When you view a sequence clustering model, Analysis Services shows you clusters that contain multiple transitions. You can also view pertinent statistics. For more information, see [Browse a Model Using the Microsoft Sequence Cluster Viewer](#).

If you want to know more detail, you can browse the model in the [Microsoft Generic Content Tree Viewer](#). The content stored for the model includes the distribution for all values in each node, the probability of each cluster, and details about the transitions. For more information, see [Mining Model Content for Sequence Clustering Models \(Analysis Services - Data Mining\)](#).

Creating Predictions

After the model has been trained, the results are stored as a set of patterns. You can use the descriptions of the most common sequences in the data to predict the next likely step of a new sequence. However, because the algorithm includes other columns, you can use the resulting model to identify relationships between sequenced data and inputs that are not sequential. For example, if you add demographic data to the model, you can make predictions for specific groups of customers. Prediction queries can be customized to return a variable number of predictions, or to return descriptive statistics.

For information about how to create queries against a data mining model, see [Data Mining Queries](#). For examples of how to use queries with a sequence clustering model, see [Sequence Clustering Model Query Examples](#).

Remarks

- Does not support the use of Predictive Model Markup Language (PMML) to create mining models.
- Supports drillthrough.
- Supports the use of OLAP mining models and the creation of data mining dimensions.

Microsoft Sequence Clustering Algorithm Technical Reference

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Sequence Clustering algorithm is a hybrid algorithm that uses Markov chain analysis to identify ordered sequences, and combines the results of this analysis with clustering techniques to generate clusters based on the sequences and other attributes in the model. This topic describes the implementation of the algorithm, how to customize the algorithm, and special requirements for sequence clustering models.

For more general information about the algorithm, including how to browse and query sequence clustering models, see [Microsoft Sequence Clustering Algorithm](#).

Implementation of the Microsoft Sequence Clustering Algorithm

The Microsoft Sequence Clustering model uses Markov models to identify sequences and determine the probability of sequences. A Markov model is a directed graph that stores the transitions between different states. The Microsoft Sequence Clustering algorithm uses n-order Markov chains, not a Hidden Markov model.

The number of orders in a Markov chain tells you how many states are used to determine the probability of the current states. In a first-order Markov model, the probability of the current state depends only on the previous state. In a second-order Markov chain, the probability of a state depends on the previous two states, and so forth. For each Markov chain, a transition matrix stores the transitions for each combination of states. As the length of the Markov chain increases, the size of the matrix also increases exponentially, and the matrix becomes extremely sparse. Processing time also increases proportionally.

It might be helpful to visualize the chain by using the example of clickstream analysis, which analyzes visits to Web pages on a site. Each user creates a long sequence of clicks for each session. When you create a model to analyze user behavior on a Web site, the data set used for training is a sequence of URLs, converted to a graph that includes the count of all instances of the same click path. For example, the graph contains the probability that the user moves from page 1 to page 2 (10%), the probability that the user moves from page 1 to page 3 (20%), and so forth. When you put all the possible paths and pieces of the paths together, you obtain a graph that might be much longer and more complex than any single observed path.

By default, the Microsoft Sequence Clustering algorithm uses the Expectation Maximization (EM) method of clustering. For more information, see [Microsoft Clustering Algorithm Technical Reference](#).

The targets of clustering are both the sequential and nonsequential attributes. Each cluster is randomly selected using a probability distribution. Each cluster has a Markov chain that represents the complete set of paths, and a matrix that contains the sequence state transitions and probabilities. Based on the initial distribution, Bayes rule is used to calculate the probability of any attribute, including a sequence, in a specific cluster.

The Microsoft Sequence Clustering algorithm supports the addition of nonsequential attributes to the model. This means that these additional attributes are combined with the sequence attributes to create clusters of cases with similar attributes, just like in a typical clustering model.

A sequence clustering model tends to create many more clusters than a typical clustering model. Therefore, the Microsoft Sequence Clustering algorithm performs *cluster decomposition* to separate clusters based on sequences and other attributes.

Feature Selection in a Sequence Clustering Model

Feature selection is not invoked when building sequences; however, feature selection applies at the clustering stage.

Model Type	Feature Selection Method	Comments
Sequence Clustering	Not used	Feature selection is not invoked; however, you can control the behavior of the algorithm by setting the value of the parameters MINIMUM_SUPPORT and MINIMUM_PROBABILITY.
Clustering	Interestingness score	Although the clustering algorithm may use discrete or discretized algorithms, the score of each attribute is calculated as a distance and is continuous; therefore the interestingness score is used.

For more information, see [Feature Selection](#).

Optimizing Performance

The Microsoft Sequence Clustering algorithm supports various ways to optimize processing:

- Controlling the number of clusters generated, by setting a value for the CLUSTER_COUNT parameter.
- Reducing the number of sequences included as attributes, by increasing the value of the MINIMUM_SUPPORT parameter. As a result, rare sequences are eliminated.
- Reducing complexity before processing the model, by grouping related attributes.

In general, you can optimize the performance of an n-order Markov chain mode in several ways:

- Controlling the length of the possible sequences.
- Programmatically reducing the value of n.
- Storing only probabilities that exceed a specified threshold.

A complete discussion of these methods is beyond the scope of this topic.

Customizing the Sequence Clustering Algorithm

The Microsoft Sequence Clustering algorithm supports parameters that affect the behavior, performance, and accuracy of the resulting mining model. You can also modify the behavior of the completed model by setting modeling flags that control the way the algorithm processes training data.

Setting Algorithm Parameters

The following table describes the parameters that can be used with the Microsoft Sequence Clustering algorithm.

CLUSTER_COUNT

Specifies the approximate number of clusters to be built by the algorithm. If the approximate number of clusters cannot be built from the data, the algorithm builds as many clusters as possible. Setting the CLUSTER_COUNT parameter to 0 causes the algorithm to use heuristics to best determine the number of clusters to build.

The default is 10.

NOTE

Specifying a non-zero number acts as a hint to the algorithm, which proceeds with the goal of finding the specified number, but may end up finding more or less.

MINIMUM_SUPPORT

Specifies the minimum number of cases that is required in support of an attribute to create a cluster.

The default is 10.

MAXIMUM_SEQUENCE_STATES

Specifies the maximum number of states that a sequence can have.

Setting this value to a number greater than 100 may cause the algorithm to create a model that does not provide meaningful information.

The default is 64.

MAXIMUM_STATES

Specifies the maximum number of states for a non-sequence attribute that the algorithm supports. If the number of states for a non-sequence attribute is greater than the maximum number of states, the algorithm uses the attribute's most popular states and treats the remaining states as **Missing**.

The default is 100.

Modeling Flags

The following modeling flags are supported for use with the Microsoft Sequence Clustering algorithm.

NOT NULL

Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training.

Applies to the mining structure column.

MODEL_EXISTENCE_ONLY

Means that the column will be treated as having two possible states: **Missing** and **Existing**. A null is treated as a **Missing** value.

Applies to the mining model column.

For more information about the use of Missing values in mining models, and how missing values affect probability scores, see [Missing Values \(Analysis Services - Data Mining\)](#).

Requirements

The case table must have a case ID column. Optionally the case table can contain other columns that store attributes about the case.

The Microsoft Sequence Clustering algorithm requires sequence information, stored as a nested table. The nested table must have a single Key Sequence column. A **Key Sequence** column can contain any type of data that can be sorted, including string data types, but the column must contain unique values for each case.

Moreover, before you process the model, you must ensure that both the case table and the nested table are sorted in ascending order on the key that relates the tables.

NOTE

If you create a model that uses the Microsoft Sequence algorithm but do not use a sequence column, the resulting model will not contain any sequences, but will simply cluster cases based on other attributes that are included in the model.

Input and Predictable Columns

The Microsoft Sequence Clustering algorithm supports the specific input columns and predictable columns that are listed in the following table. For more information about what the content types mean when used in a mining model, see [Content Types \(Data Mining\)](#).

COLUMN	CONTENT TYPES
Input attribute	Continuous, Cyclical, Discrete, Discretized, Key, Key Sequence, Table, and Ordered
Predictable attribute	Continuous, Cyclical, Discrete, Discretized, Table, and Ordered

Remarks

- Use the [PredictSequence \(DMX\)](#) function for Prediction of Sequences. For more information about the editions of SQL Server that support Sequence Prediction, see [Features Supported by the Editions of SQL Server 2012](#) (<https://go.microsoft.com/fwlink/?LinkId=232473>).
- The Microsoft Sequence Clustering algorithm does not support using the Predictive Model Markup Language (PMML) to create mining models.
- The Microsoft Sequence Clustering algorithm supports drillthrough, the use of OLAP mining models, and the use of data mining dimensions.

Mining Model Content for Sequence Clustering Models

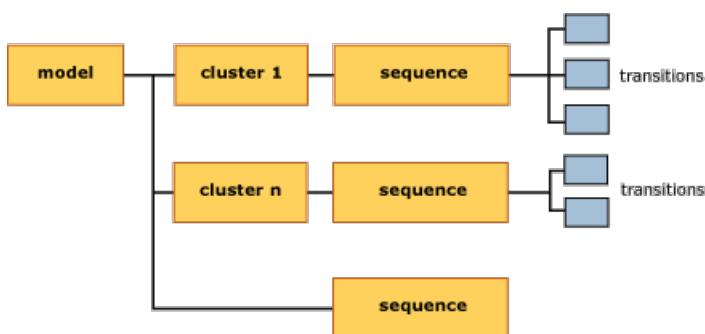

7/16/2019 • 12 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes mining model content that is specific to models that use the Microsoft Sequence Clustering algorithm. For an explanation of general and statistical terminology related to mining model content that applies to all model types, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Understanding the Structure of a Sequence Clustering Model

A sequence clustering model has a single parent node (NODE_TYPE = 1) that represents the model and its metadata. The parent node, which is labeled **(All)**, has a related sequence node (NODE_TYPE = 13) that lists all the transitions that were detected in the training data.

The algorithm also creates a number of clusters, based on the transitions that were found in the data and any other input attributes included when creating the model, such as customer demographics and so forth. Each cluster (NODE_TYPE = 5) contains its own sequence node (NODE_TYPE = 13) that lists only the transitions that were used in generating that specific cluster. From the sequence node, you can drill down to view the details of individual state transitions (NODE_TYPE = 14).

For an explanation of sequence and state transitions, with examples, see [Microsoft Sequence Clustering Algorithm](#).

Model Content for a Sequence Clustering Model

This section provides additional information about columns in the mining model content that have particular relevance for sequence clustering.

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

Always blank.

NODE_NAME

The name of the node. Currently the same value as NODE_UNIQUE_NAME.

NODE_UNIQUE_NAME

The unique name of the node.

NODE_TYPE

A sequence clustering model outputs the following node types:

NODE_TYPE_ID	DESCRIPTION
1 (Model)	Root node for model
5 (Cluster)	Contains a count of transitions in the cluster, a list of the attributes, and statistics that describe the values in the cluster.
13 (Sequence)	Contains a list of transitions included in the cluster.
14 (Transition)	Describes a sequence of events as a table in which the first row contains the starting state, and all other rows contain successive states, together with support and probability statistics.

NODE_GUID

Blank.

NODE_CAPTION

A label or a caption associated with the node for display purposes.

You can rename the cluster captions while you are using the model; however, the new name is not persisted if you close the model.

CHILDREN_CARDINALITY

An estimate of the number of children that the node has.

Model root Cardinality value equals the number of clusters plus one. For more information, see [Cardinality](#).

Cluster nodes Cardinality is always 1, because each cluster has a single child node, which contains the list of sequences in the cluster.

Sequence nodes Cardinality indicates the number of transitions that are included in that cluster. For example, the cardinality of the sequence node for the model root tells you how many transitions were found in the entire model.

PARENT_UNIQUE_NAME

The unique name of the node's parent.

NULL is returned for any nodes at the root level.

NODE_DESCRIPTION

Same as node caption.

NODE_RULE

Always blank.

MARGINAL_RULE

Always blank.

NODE_PROBABILITY

Model root Always 0.

Cluster nodes The adjusted probability of the cluster in the model. The adjusted probabilities do not sum to 1, because the clustering method used in sequence clustering permits partial membership in multiple clusters.

Sequence nodes Always 0.

Transition nodes Always 0.

MARGINAL_PROBABILITY

Model root Always 0.

Cluster nodes The same value as NODE_PROBABILITY.

Sequence nodes Always 0.

Transition nodes Always 0.

NODE_DISTRIBUTION

A table that contains probabilities and other information. For more information, see [NODE DISTRIBUTION Table](#).

NODE_SUPPORT

The number of transitions that support this node. Therefore, if there are 30 examples of sequence "Product A followed by Product B" in the training data, the total support is 30.

Model root Total number of transitions in the model.

Cluster nodes Raw support for the cluster, meaning the number of training cases that contribute cases to this cluster.

Sequence nodes Always 0.

Transition nodes Percentage of cases in the cluster that represent a specific transition. Can be 0, or can have a positive value. Calculated by taking the raw support for the cluster node, and multiplying by the probability of the cluster.

From this value, you can tell how many training cases contributed to the transition.

MSOLAP_MODEL_COLUMN

Not applicable.

MSOLAP_NODE_SCORE

Not applicable.

MSOLAP_NODE_SHORT_CAPTION

Same as NODE_DESCRIPTION.

Understanding Sequences, States and Transitions

A sequence clustering model has a unique structure that combines two kinds of objects with very different types of information: the first are clusters, and the second are state transitions.

The clusters created by sequence clustering are like the clusters created by the Microsoft Clustering algorithm. Each cluster has a profile and characteristics. However, in sequence clustering, each cluster additionally contains a single child node that lists the sequences in that cluster. Each sequence node contains multiple child nodes that describe the state transitions in detail, with probabilities.

There are almost always more sequences in the model than you can find in any single case, because the sequences can be chained together. Microsoft Analysis Services stores pointers from one state to the other so that you can count the number of times each transition happens. You can also find information about how many times the sequence occurred, and measure its probability of occurring as compared to the entire set of observed states.

The following table summarizes how information is stored in the model, and how the nodes are related.

NODE	HAS CHILD NODE	NODE DISTRIBUTION TABLE
Model root	Multiple cluster nodes Node with sequences for entire model	<p>Lists all products in the model, with support and probability.</p> <p>Because the clustering method permits partial membership in multiple clusters, support and probability can have fractional values. That is, instead of counting a single case once, each case can potentially belong to multiple clusters. Therefore, when the final cluster membership is determined, the value is adjusted by the probability of that cluster.</p>
Sequence node for model	Multiple transition nodes	<p>Lists all products in the model, with support and probability.</p> <p>Because the number of sequences is known for the model, at this level, calculations for support and probability are straightforward:</p> <p>Support = count of cases</p> <p>Probability = raw probability of each sequence in model. All probabilities should sum to 1.</p>
Individual cluster nodes	Node with sequences for that cluster only	<p>Lists all products in a cluster, but provides support and probability values only for products that are characteristic of the cluster.</p> <p>Support represents the adjusted support value for each case in this cluster. Probability values are adjusted probability.</p>
Sequence nodes for individual clusters	Multiple nodes with transitions for sequences in that cluster only	Exactly the same information as in individual cluster nodes.
Transitions	No children	<p>Lists transitions for the related first state.</p> <p>Support is an adjusted support value, indicating the cases that take part in each transition. Probability is the adjusted probability, represented as a percentage.</p>

NODE DISTRIBUTION Table

The NODE DISTRIBUTION table provides detailed probability and support information for the transitions and sequences for a specific cluster.

A row is always added to the transition table to represent possible **Missing** values. For information about what the **Missing** value means, and how it affects calculations, see [Missing Values \(Analysis Services - Data Mining\)](#).

The calculations for support and probability differ depending on whether the calculation applies to the training cases or to the finished model. This is because the default clustering method, Expectation Maximization (EM), assumes that any case can belong to more than one cluster. When calculating support for the cases in the model, it is possible to use raw counts and raw probabilities. However, the probabilities for any particular sequence in a cluster must be weighted by the sum of all possible sequence and cluster combinations.

Cardinality

In a clustering model, the cardinality of the parent node generally tells you how many clusters are in the model. However, a sequence clustering model has two kinds of nodes at the cluster level: one kind of node contains clusters, and the other kind of node contains a list of sequences for the model as a whole.

Therefore, to learn the number of clusters in the model, you can take the value of NODE_CARDINALITY for the (All) node and subtract one. For example, if the model created 9 clusters, the cardinality of the model root is 10. This is because the model contains 9 cluster nodes, each with its own sequence node, plus one additional sequence node labeled cluster 10, which represents the sequences for the model.

Walkthrough of Structure

An example might help clarify how the information is stored, and how you can interpret it. For example, you can find the largest order, meaning the longest observed chain in the underlying **AdventureWorksDW2012** data, by using the following query:

```
USE AdventureWorksDW2012
SELECT DISTINCT OrderNumber, Count(*)
FROM vAssocSeqLineItems
GROUP BY OrderNumber
ORDER BY Count(*) DESC
```

From these results, you find that the order numbers 'SO72656', 'SO58845', and 'SO70714' contain the largest sequences, with eight items each. By using the order IDs, you can view the details of a particular order to see which items were purchased, and in what order.

ORDERNUMBER	LINENUMBER	MODEL
SO58845	1	Mountain-500
SO58845	2	LL Mountain Tire
SO58845	3	Mountain Tire Tube
SO58845	4	Fender Set - Mountain
SO58845	5	Mountain Bottle Cage
SO58845	6	Water Bottle
SO58845	7	Sport-100
SO58845	8	Long-Sleeve Logo Jersey

However, some customers who purchase the Mountain-500 might purchase different products. You can view all the products that follow the Mountain-500 by viewing the list of sequences in the model. The following procedures walk you through viewing these sequences by using the two viewers provided in Analysis Services:

To view related sequences by using the Sequence Clustering viewer

1. In Object Explorer, right-click the [Sequence Clustering] model, and select Browse.
2. In the Sequence Clustering viewer, click the **State Transitions** tab.
3. In the **Cluster** dropdown list, ensure that **Population (All)** is selected.
4. Move the slider bar at the left of the pane all the way to the top, to show all links.
5. In the diagram, locate **Mountain-500**, and click the node in the diagram.
6. The highlighted lines point to the next states (the products that were purchased after the Mountain-500) and the numbers indicate the probability. Compare these to the results in the generic model content viewer.

To view related sequences by using the generic model content viewer

1. In Object Explorer, right-click the [Sequence Clustering] model, and select Browse.
2. In the viewer dropdown list, select the **Microsoft Generic Content Tree Viewer**.
3. In the **Node caption** pane, click the node named **Sequence level for cluster 16**.
4. In the Node details pane, find the NODE_DISTRIBUTION row, and click anywhere in the nested table.

The top row is always for the Missing value. This row is sequence state 0.

5. Press the down arrow key, or use the scroll bars, to move down through the nested table until you see the row, Mountain-500.

This row is sequence state 20.

NOTE

You can obtain the row number for a particular sequence state programmatically, but if you are just browsing, it might be easier to simply copy the nested table into an Excel workbook.

6. Return to the Node caption pane, and expand the node, **Sequence level for cluster 16**, if it is not already expanded.
7. Look among its child nodes for **Transition row for sequence state 20**. Click the transition node.
8. The nested NODE_DISTRIBUTION table contains the following products and probabilities. Compare these to the results in the **State Transition** tab of the Sequence Clustering viewer.

The following table shows the results from the NODE_DISTRIBUTION table, together with the rounded probability values that are displayed in the graphical viewer.

PRODUCT	SUPPORT (NODE_DISTRIBUTION TABLE)	PROBABILITY (NODE_DISTRIBUTION TABLE)	PROBABILITY (FROM GRAPH)
Missing	48.447887	0.138028169	(not shown)
Cycling Cap	10.876056	0.030985915	0.03
Fender Set - Mountain	80.087324	0.228169014	0.23
Half-Finger Gloves	0.9887324	0.002816901	0.00
Hydration Pack	0.9887324	0.002816901	0.00
LL Mountain Tire	51.414085	0.146478873	0.15

PRODUCT	SUPPORT (NODE DISTRIBUTION TABLE)	PROBABILITY (NODE DISTRIBUTION TABLE)	PROBABILITY (FROM GRAPH)
Long-Sleeve Logo Jersey	2.9661972	0.008450704	0.01
Mountain Bottle Cage	87.997183	0.250704225	0.25
Mountain Tire Tube	16.808451	0.047887324	0.05
Short-Sleeve Classic Jersey	10.876056	0.030985915	0.03
Sport-100	20.76338	0.05915493	0.06
Water Bottle	18.785915	0.053521127	0.25

Although the case that we initially selected from the training data contained the product 'Mountain-500' followed by 'LL Mountain Tire', you can see that there are many other possible sequences. To find detailed information for any particular cluster, you must repeat the process of drilling down from the list of sequences in the cluster to the actual transitions for each state, or product.

You can jump from the sequence listed in one particular cluster, to the transition row. From that transition row, you can determine which product is next, and jump back to that product in the list of sequences. By repeating this process for each first and second state you can work through long chains of states.

Using Sequence Information

A common scenario for sequence clustering is to track user clicks on a Web site. For example, if the data were from records of customer purchases on the Adventure Works e-commerce Web site, the resulting sequence clustering model could be used to infer user behavior, to redesign the e-commerce site to solve navigation problems, or to promote sales.

For example, analysis might show that users always follow a particular chain of products, regardless of demographics. Also, you might find that users frequently exit the site after clicking on a particular product. Given that finding, you might ask what additional paths you could provide to users that would induce users to stay on the Web site.

If you do not have additional information to use in classifying your users, then you can simply use the sequence information to collect data about navigation to better understand overall behavior. However, if you can collect information about customers and match that information with your customer database, you can combine the power of clustering with prediction on sequences to provide recommendations that are tailored to the user, or perhaps based on the path of navigation to the current page.

Another use of the extensive state and transition information compiled by a sequence clustering model is to determine which possible paths are never used. For example, if you have many visitors going to pages 1-4, but visitors never continue on to page 5, you might investigate whether there are problems that prevent navigation to page 5. You can do this by querying the model content, and comparing it against a list of possible paths. Graphs that tell you all the navigation paths in a Web site can be created programmatically, or by using a variety of site analysis tools.

To find out how to obtain the list of observed paths by querying the model content, and to see other examples of queries on a sequence clustering model, see [Sequence Clustering Model Query Examples](#).

Sequence Clustering Model Query Examples

Sequence Clustering Model Query Examples

7/16/2019 • 13 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create either a content query, which provides details about the information stored in the model, or you can create a prediction query, which uses the patterns in the model to make predictions based on new data that you provide. For a sequence clustering model, content queries typically provide additional details about the clusters that were found, or the transitions within those clusters. You can also retrieve metadata about the model by using a query.

Prediction queries on a sequence clustering model typically make recommendations based either on the sequences and transitions, on non-sequence attributes that were included in the model, or on a combination of sequence and non-sequence attributes.

This section explains how to create queries for models that are based on the Microsoft Sequence Clustering algorithm. For general information about creating queries, see [Data Mining Queries](#).

Content Queries

[Using the Data Mining Schema Rowset to return model parameters](#)

[Getting a list of sequences for a state](#)

[Using system stored procedures](#)

Prediction Queries

[Predict next state or states](#)

Finding Information about the Sequence Clustering Model

To create meaningful queries on the content of a mining model, you must understand the structure of the model content, and which node types store what kind of information. For more information, see [Mining Model Content for Sequence Clustering Models \(Analysis Services - Data Mining\)](#).

Sample Query 1: Using the Data Mining Schema Rowset to Return Model Parameters

By querying the data mining schema rowset, you can find various kinds of information about the model, including basic metadata, the date and time that the model was created and last processed, the name of the mining structure that the model is based on, and the column used as the predictable attribute.

The following query returns the parameters that were used to build and train the model, [\[Sequence Clustering\]](#). You can create this model in Lesson 5 of the [Basic Data Mining Tutorial](#).

```
SELECT MINING_PARAMETERS  
from $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'Sequence Clustering'
```

Example results:

MINING_PARAMETERS
CLUSTER_COUNT=15,MINIMUM_SUPPORT=10,MAXIMUM_STATES=100,MAXIMUM_SEQUENCE_STATES=64

Note that this model was built by using the default value of 10 for CLUSTER_COUNT. When you specify a non-zero number of clusters for CLUSTER_COUNT, the algorithm treats this number as a hint for the approximate number of clusters to find. However, in the process of analysis, the algorithm may find more or fewer clusters. In this case, the algorithm found that 15 clusters best fit the training data. Therefore, the list of parameter values for the completed model reports the count of clusters as determined by the algorithm, not the value passed in when creating the model.

How does this behavior differ from letting the algorithm determine the best number of clusters? As an experiment, you can create another clustering model that uses this same data, but set CLUSTER_COUNT to 0. When you do this, the algorithm detects 32 clusters. Therefore, by using the default value of 10 for CLUSTER_COUNT, you constrain the number of results.

The value of 10 is used by default because reducing the number of clusters makes it easier for most people to browse and understand groupings in the data. However, each model and set of data is different. You may wish to experiment with different numbers of clusters to see which parameter value yields the most accurate model.

Sample Query 2: Getting a List of Sequences for a State

The mining model content stores the sequences that are found in the training data as a first state coupled with a list of all related second states. The first state is used as the label for the sequence, and the related second states are called transitions.

For example, the following query returns the complete list of first states in the model, before the sequences are grouped into clusters. You can get this list by returning the list of sequences (NODE_TYPE = 13) that have the model root node as parent (PARENT_UNIQUE_NAME = 0). The FLATTENED keyword makes the results easier to read.

NOTE

The name of the columns, PARENT_UNIQUE_NAME, Support, and Probability must be enclosed in brackets to distinguish them from the reserved keywords of the same name.

```
SELECT FLATTENED NODE_UNIQUE_NAME,
       (SELECT ATTRIBUTE_VALUE AS [Product 1],
        [Support] AS [Sequence Support],
        [Probability] AS [Sequence Probability])
    FROM NODE_DISTRIBUTION) AS t
   FROM [Sequence Clustering].CONTENT
 WHERE NODE_TYPE = 13
 AND [PARENT_UNIQUE_NAME] = 0
```

Partial results:

NODE_UNIQUE_NAME	PRODUCT 1	SEQUENCE SUPPORT	SEQUENCE PROBABILITY
1081327	Missing	0	#####
1081327	All-Purpose Bike Stand	17	0.00111
1081327	Bike Wash	64	0.00418
1081327	(rows 4-36 omitted)		
1081327	Women's Mountain Shorts	506	0.03307

The list of sequences in the model is always sorted alphabetically in ascending order. The ordering of the

sequences is important because you can find the related transitions by looking at the order number of the sequence. The **Missing** value is always transition 0.

For example, in the previous results, the product "Women's Mountain Shorts" is the sequence number 37 in the model. You can use that information to view all of the products that were ever purchased after "Women's Mountain Shorts."

To do this, first, you reference the value returned for NODE_UNIQUE_NAME in the previous query, to get the ID of the node that contains all sequences for the model. You pass this value to the query as the ID of the parent node, to get only the transitions included in this node, which happens to contain a list of all sequences for the model. However, if you wanted to see the list of transitions for a specific cluster, you could pass in the ID of the cluster node, and see only the sequences associated with that cluster.

```
SELECT NODE_UNIQUE_NAME  
FROM [Sequence Clustering].CONTENT  
WHERE NODE_DESCRIPTION = 'Transition row for sequence state 37'  
AND [PARENT_UNIQUE_NAME] = '1081327'
```

Example results:

NODE_UNIQUE_NAME
1081365

The node represented by this ID contains a list of the sequences that follow the "Women's Mountain Shorts" product, together with the support and probability values.

```
SELECT FLATTENED  
(SELECT ATTRIBUTE_VALUE AS Product2,  
[Support] AS [P2 Support],  
[Probability] AS [P2 Probability]  
FROM NODE_DISTRIBUTION) AS t  
FROM [Sequence Clustering].CONTENT  
WHERE NODE_UNIQUE_NAME = '1081365'
```

Example results:

T.PRODUCT2	T.P2 SUPPORT	T.P2 PROBABILITY
Missing	230.7419	0.456012
Classic Vest	8.16129	0.016129
Cycling Cap	60.83871	0.120235
Half-Finger Gloves	30.41935	0.060117
Long-Sleeve Logo Jersey	86.80645	0.171554
Racing Socks	28.93548	0.057185
Short-Sleeve Classic Jersey	60.09677	0.118768

Note that support for the various sequences related to Women's Mountain Shorts is 506 in the model. The support values for the transitions also add up to 506. However, the numbers are not whole numbers, which

seems a bit odd if you expect support to simply represent a count of cases that contain each transition. However, because the method for creating clusters calculates partial membership, the probability of any transition within a cluster must be weighted by its probability of belonging to that particular cluster.

For example, if there are four clusters, a particular sequence might have a 40% chance of belonging to cluster 1, a 30% chance of belonging to cluster 2, a 20% chance of belonging to cluster 3, and a 10% chance of belonging to cluster 4. After the algorithm determines the cluster that the transition is mostly likely to belong to, it weights the probabilities within the cluster by the cluster prior probability.

Sample Query 3: Using System Stored Procedures

You can see from these query samples that the information stored in the model is complex, and that you might need to create multiple queries to get the information that you need. However, the Microsoft Sequence Clustering viewer provides a powerful set of tools for graphically browsing the information contained in a sequence clustering model, and you can also use the viewer to query and drill down into the model.

In most cases, the information that is presented in the Microsoft Sequence Clustering viewer is created by using Analysis Services system stored procedures to query the model. You can write Data Mining Extensions (DMX) queries against the model content to retrieve the same information, but the Analysis Services system stored procedures provide a convenient shortcut when for exploration or for testing models.

NOTE

System stored procedures are used for internal processing by the server and by the clients that Microsoft provides for interacting with the Analysis Services server. Therefore, Microsoft reserves the right to change them at any time. Although they are described here for your convenience, we do not support their use in a production environment. To ensure stability and compatibility in a production environment, you should always write your own queries by using DMX.

This section provides some samples of how to use the system stored procedures to create queries against a sequence clustering model:

Cluster Profiles and Sample Cases

The Cluster Profiles tab shows you a list of the clusters in the model, the size of each cluster, and a histogram that indicates the states included in the cluster. There are two system stored procedures that you can use in queries to retrieve similar information:

- `GetClusterProfile` returns the characteristics of the cluster, with all the information that is found in the `NODE_DISTRIBUTION` table for the cluster.
- `GetNodeGraph` returns nodes and edges that can be used to construct a mathematical graph representation of the clusters, corresponding to what you see on the first tab of the Sequence Clustering view. The nodes are clusters, and the edges represent weights or strength.

The following example illustrates how to use the system stored procedure, `GetClusterProfiles`, to return all of the clusters in the model, with their respective profiles. This stored procedure executes a series of DMX statements that return the complete set of profiles in the model. However, to use this stored procedure you must know the address of the model.

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterProfiles('Sequence Clustering',  
2147483647, 0)
```

The following example illustrates how to retrieve the profile for a specific cluster, Cluster 12, by using the system stored procedure `GetNodeGraph`, and specifying the cluster ID, which is usually the same as the number in the cluster name.

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetNodeGraph('Sequence Clustering','12',0)
```

If you omit the cluster ID, as shown in the following query, `GetNodeGraph` returns an ordered, flattened list of all cluster profiles:

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetNodeGraph('Sequence Clustering','','0')
```

The **Cluster Profile** tab also displays a histogram of model sample cases. These sample cases represent the idealized cases for the model. These cases are not stored in the model the same way that the training data is; you must use a special syntax to retrieve the sample cases for the model.

```
SELECT * FROM [Sequence Clustering].SAMPLE_CASES WHERE IsInNode('12')
```

For more information, see [SELECT FROM <model>.SAMPLE_CASES \(DMX\)](#).

Cluster Characteristics and Cluster Discrimination

The **Cluster Characteristics** tab summarizes the main attributes of each cluster, ranked by probability. You can find out how many cases belong to a cluster, and what the distribution of cases is like in the cluster: Each characteristic has certain support. To see the characteristics of a particular cluster, you must know the ID of the cluster.

The following examples uses the system stored procedure, `GetClusterCharacteristics`, to return all the characteristics of Cluster 12 that have a probability score over the specified threshold of 0.0005.

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterCharacteristics('Sequence Clustering','12',0.0005)
```

To return the characteristics of all clusters, you can leave the cluster ID empty.

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterCharacteristics('Sequence Clustering','','0.0005')
```

The following example calls the system stored procedure `GetClusterDiscrimination` to compare the characteristics of Cluster 1 and Cluster 12.

```
CALL System.Microsoft.AnalysisServices.System.DataMining.Clustering.GetClusterDiscrimination('Sequence Clustering','1','12',0.0005,true)
```

If you want to write your own query in DMX to compare two clusters, or compare a cluster with its complement, you must first retrieve one set of characteristics, and then retrieve the characteristics for the specific cluster that you are interested in, and compare the two sets. This scenario is more complicated and typically requires some client processing.

States and Transitions

The **State Transitions** tab of the Microsoft Sequence Clustering performs complicated queries on the back end to retrieve and compare the statistics for different clusters. To reproduce these results requires a more complex query and some client processing.

However, you can use the DMX queries described in Example 2 of the section, [Content Queries](#), to retrieve probabilities and states for sequences or for individual transitions.

Using the Model to Make Predictions

Prediction queries on a sequence clustering model can use many of the prediction functions that are used with other clustering models. In addition, you can use the special prediction function, [PredictSequence \(DMX\)](#), to make recommendations or to predict next states.

Sample Query 4: Predict Next State or States

You can use the [PredictSequence \(DMX\)](#) function to predict the next most likely state, given a value. You can also predict multiple next states: for example, you can return a list of the top three products that a customer is likely to purchase, to present a list of recommendations.

The following sample query is a singleton prediction query that returns the top five predictions, together with their probability. Because the model includes a nested table, you must use the nested table,

[v Assoc Seq Line Items], as the column reference when making predictions. Also, when you supply values as input, you must join both the case table and the nested table columns, as shown by the nested SELECT statements.

```
SELECT FLATTENED PredictSequence([v Assoc Seq Line Items], 7)
  FROM [Sequence Clustering]
  NATURAL PREDICTION JOIN
  (SELECT (SELECT 1 as [Line Number],
    'All-Purpose Bike Stand' as [Model]) AS [v Assoc Seq Line Items])
  AS t
```

Example results:

EXPRESSION.\$SEQUENCE	EXPRESSION.LINE NUMBER	EXPRESSION.MODEL
1		Cycling Cap
2		Cycling Cap
3		Sport-100
4		Long-Sleeve logo Jersey
5		Half-Finger Gloves
6		All-Purpose Bike Stand
7		All-Purpose Bike Stand

There are three columns in the results, even though you might only expect one column, because the query always returns a column for the case table. Here the results are flattened; otherwise, the query would return a single column that contains two nested table columns.

The column \$sequence is a column returned by default by the [PredictSequence](#) function to order the prediction results. The column, [Line Number], is required to match the sequence keys in the model, but the keys are not output.

Interestingly, the top predicted sequences after All-Purpose Bike Stand are Cycling Cap and Cycling Cap. This is not an error. Depending on how the data is presented to the customer, and how it is grouped when training the model, it is very possible to have sequences of this kind. For example, a customer might purchase a cycling cap (red) and then another cycling cap (blue), or purchase two in a row if there were no way to specify quantity.

The values in rows 6 and 7 are placeholders. When you reach the end of the chain of possible transitions, rather than terminating the prediction results, the value that was passed as an input is added to the results. For example, if you increased the number of predictions to 20, the values for rows 6-20 would all be the same, All-Purpose Bike Stand.

Function List

All Microsoft algorithms support a common set of functions. However, the Microsoft Sequence Clustering algorithm supports the additional functions that are listed in the following table.

Prediction Function	Usage
Cluster (DMX)	Returns the cluster that is most likely to contain the input case
ClusterDistance (DMX)	Returns the distance of the input case from the specified cluster, or if no cluster is specified, the distance of the input case from the most likely cluster. This function can be used with any kind of clustering model (EM, K-Means, etc.), but the results differ depending on the algorithm.
ClusterProbability (DMX)	Returns the probability that the input case belongs to the specified cluster.
IsInNode (DMX)	Indicates whether the specified node contains the current case.
PredictAdjustedProbability (DMX)	Returns the adjusted probability of a specified state.
PredictAssociation (DMX)	Predicts associative membership.
PredictCaseLikelihood (DMX)	Returns the likelihood that an input case will fit in the existing model.
PredictHistogram (DMX)	Returns a table that represents a histogram for the prediction of a given column.
PredictNodeId (DMX)	Returns the Node_ID of the node to which the case is classified.
PredictProbability (DMX)	Returns the probability for a specified state.
PredictSequence (DMX)	Predicts future sequence values for a specified set of sequence data.
PredictStdev (DMX)	Returns the predicted standard deviation for the specified column.
PredictSupport (DMX)	Returns the support value for a specified state.
PredictVariance (DMX)	Returns the variance of a specified column.

For a list of the functions that are common to all Microsoft algorithms, see [General Prediction Functions \(DMX\)](#).

For the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

[Mining Model Content for Sequence Clustering Models \(Analysis Services - Data Mining\)](#)

Microsoft Time Series Algorithm

7/16/2019 • 10 minutes to read • [Edit Online](#)

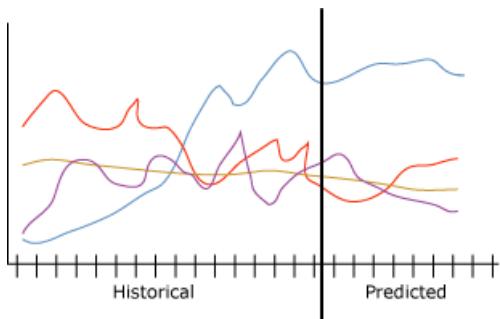

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Time Series algorithm provides multiple algorithms that are optimized for forecasting continuous values, such as product sales, over time. Whereas other Microsoft algorithms, such as decision trees, require additional columns of new information as input to predict a trend, a time series model does not. A time series model can predict trends based only on the original dataset that is used to create the model. You can also add new data to the model when you make a prediction and automatically incorporate the new data in the trend analysis.

The following diagram shows a typical model for forecasting sales of a product in four different sales regions over time. The model that is shown in the diagram shows sales for each region plotted as red, yellow, purple, and blue lines. The line for each region has two parts:

- Historical information appears to the left of the vertical line and represents the data that the algorithm uses to create the model.
- Predicted information appears to the right of the vertical line and represents the forecast that the model makes.

The combination of the source data and the prediction data is called a *series*.

An important feature of the Microsoft Time Series algorithm is that it can perform cross prediction. If you train the algorithm with two separate, but related, series, you can use the resulting model to predict the outcome of one series based on the behavior of the other series. For example, the observed sales of one product can influence the forecasted sales of another product. Cross prediction is also useful for creating a general model that can be applied to multiple series. For example, the predictions for a particular region are unstable because the series lacks good quality data. You could train a general model on an average of all four regions, and then apply the model to the individual series to create more stable predictions for each region.

Example

The management team at Adventure Works Cycles wants to predict monthly bicycle sales for the coming year. The company is especially interested in whether the sale of one bike model can be used to predict the sale of another model. By using the Microsoft Time Series algorithm on historical data from the past three years, the company can produce a data mining model that forecasts future bike sales. Additionally, the company can perform cross predictions to see whether the sales trends of individual bike models are related.

Each quarter, the company plans to update the model with recent sales data and update their predictions to model recent trends. To correct for stores that do not accurately or consistently update sales data, they will create a general prediction model, and use that to create predictions for all regions.

How the Algorithm Works

In SQL Server 2005 (9.x), the Microsoft Time Series algorithm used a single auto-regressive time series method, named ARTXP. The ARTXP algorithm was optimized for short-term predictions, and therefore, excelled at predicting the next likely value in a series. Beginning in SQL Server 2008, the Microsoft Time Series algorithm added a second algorithm, ARIMA, which was optimized for long-term prediction. For a detailed explanation about the implementation of the ARTXP and ARIMA algorithms, see [Microsoft Time Series Algorithm Technical Reference](#).

By default, the Microsoft Time Series algorithm uses a mix of the algorithms when it analyzes patterns and making predictions. The algorithm trains two separate models on the same data: one model uses the ARTXP algorithm, and one model uses the ARIMA algorithm. The algorithm then blends the results of the two models to yield the best prediction over a variable number of time slices. Because ARTXP is best for short-term predictions, it is weighted more heavily at the beginning of a series of predictions. However, as the time slices that you are predicting move further into the future, ARIMA is weighted more heavily.

You can also control the mix of algorithms to favor either short- or long-term prediction in the times series. Beginning in SQL Server 2008 Standard, you can specify that which algorithm to use:

- Use only ARTXP for short-term prediction.
- Use only ARIMA for long-term prediction.
- Use the default blending of the two algorithms.

Beginning in SQL Server 2008 Enterprise, you can also customize how the Microsoft Time Series algorithm blends the models for prediction. When you use a mixed model, the Microsoft Time Series algorithm blends the two algorithms in the following way:

- Only ARTXP is always used for making the first couple of predictions.
- After the first couple of predictions, a combination of ARIMA and ARTXP is used.
- As the number of prediction steps increases, predictions rely more heavily on ARIMA until ARTXP is no longer used.
- You control the mixing point, the rate at which the weight of ARTXP is decreased, and the weight of ARIMA is increased by setting the PREDICTION_SMOOTHING parameter.

Both algorithms can detect seasonality in data at multiple levels. For example, your data might contain monthly cycles nested within yearly cycles. To detect these seasonal cycles, you can either provide a periodicity hint or specify that the algorithm should automatically detect periodicity.

In addition to periodicity, there are several other parameters that control the behavior of the Microsoft Time Series algorithm when it detects periodicity, makes predictions, or analyzes cases. For information about how to set algorithm parameters, see [Microsoft Time Series Algorithm Technical Reference](#).

Data Required for Time Series Models

When you prepare data for use in training any data mining model, make sure that you understand the requirements for the particular model and how the data is used.

Each forecasting model must contain a case series, which is the column that specifies the time slices or other series over which change occurs. For example, the data in the previous diagram shows the series for historical and forecasted bicycle sales over a period of several months. For this model, each region is a series, and the date column contains the time series, which is also the case series. In other models, the case series can be a text field or some identifier such as a customer ID or transaction ID. However, a time series model must always use a date, time, or some other unique numeric value for its case series.

The requirements for a time series model are as follows:

- **A single key time column** Each model must contain one numeric or date column that is used as the case series, which defines the time slices that the model will use. The data type for the key time column can be either a datetime data type or a numeric data type. However, the column must contain continuous values, and the values must be unique for each series. The case series for a time series model cannot be stored in two columns, such as a Year column and a Month column.
- **A predictable column** Each model must contain at least one predictable column around which the algorithm will build the time series model. The data type of the predictable column must have continuous values. For example, you can predict how numeric attributes, such as income, sales, or temperature, change over time. However, you cannot use a column that contains discrete values, such as purchasing status or level of education, as the predictable column.
- **An optional series key column** Each model can have an additional key column that contains unique values that identify a series. The optional series key column must contain unique values. For example, a single model can contain sales for many product models, as long as there is only one record for each product name for every time slice.

You can define input data for the Microsoft Time Series model in several different ways. However, because the format of the input cases affects the definition of the mining model, you must consider your business needs and prepare your data accordingly. The following two examples illustrate how the input data affects the model. In both examples, the completed mining model contains patterns for four distinct series:

- Sales for Product A
- Sales for Product B
- Volume for Product A
- Volume for Product B

In both examples, you can predict new future sales and volume for each product. You cannot predict new values for product or for time.

Example 1: Time Series Data Set with Series Represented as Column Values

This example uses the following table of input cases:

TIMEID	PRODUCT	SALES	VOLUME
1/2001	A	1000	600
2/2001	A	1100	500
1/2001	B	500	900
2/2001	B	300	890

The TimeID column in the table contains a time identifier, and has two entries for each day. The TimeID column becomes the case series. Therefore, you would designate this column as the key time column for the time series model.

The Product column defines a product in the database. This column contains the product series. Therefore, you would designate this column as a second key for the time series model.

The Sales column describes the gross profits of the specified product for one day, and the Volume column describes the quantity of the specified product that remains in the warehouse. These two columns contain the

data that is used to train the model. Both Sales and Volume can be predictable attributes for each series in the Product column.

Example 2: Time Series Data Set with Each Series in Separate Column

Although this example uses basically the same input data as the first example, the input data is structured differently, as shown in the following table:

TIMEID	A_SALES	A_VOLUME	B_SALES	B_VOLUME
1/2001	1000	600	500	900
2/2001	1100	500	300	890

In this table, the TimeID column still contains the case series for the time series model, which you designate as the key time column. However, the previous Sales and Volume columns are now split into two columns and each of those columns are preceded by the product name. As a result, only a single entry exists for each day in the TimeID column. This creates a time series model that would contain four predictable columns: A_Sales, A_Volume, B_Sales, and B_Volume.

Furthermore, because you have separated the products into different columns, you do not have to specify an additional series key column. All the columns in the model are either a case series column or a predictable column.

Viewing a Time Series Model

After the model has been trained, the results are stored as a set of patterns, which you can explore or use to make predictions.

To explore the model, you can use the [Time Series Viewer](#). The viewer includes a chart that displays future predictions, and a tree view of the periodic structures in the data.

If you want to know more about how the predictions are calculated, you can browse the model in the [Microsoft Generic Content Tree Viewer](#). The content stored for the model includes details such as the periodic structures detected by the ARIMA and ARTXP algorithms, the equation used to blend the algorithms, and other statistics.

Creating Time Series Predictions

By default, when you view a time series model, Analysis Services shows you five predictions for the series. However, you can create queries to return a variable number of predictions, and you can extra columns to the predictions to return descriptive statistics. For information about how to create queries against a time series model, see [Time Series Model Query Examples](#). For examples of how to use Data Mining Extensions (DMX) to make time series predictions, see [PredictTimeSeries \(DMX\)](#).

When using the Microsoft Time Series algorithm to make predictions, you should consider the following additional restrictions and requirements:

- Cross-prediction is only available when you use a mixed model, or when you use a model based solely on the ARTXP algorithm. If you use a model based only on the ARIMA algorithm, cross-prediction is not possible.
- A time series model can make predictions that differ, sometimes significantly, depending on the 64-bit operating system that the server uses. These differences occur due to the way that an Itanium-based system represents and handles numbers for floating-point arithmetic, which differs from the way that an x64-based system does these calculations. Because prediction results can be specific to the operating system, we recommend that you evaluate models on the same operating system that you will use in production.

Remarks

- Does not support using the Predictive Model Markup Language (PMML) to create mining models.
- Supports the use of OLAP mining models.
- Does not support the creation of data mining dimensions.
- Supports drillthrough.

Microsoft Time Series Algorithm Technical Reference

7/16/2019 • 14 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The Microsoft Time Series algorithm includes two separate algorithms for analyzing time series:

- The ARTXP algorithm, which was introduced in SQL Server 2005 (9.x), is optimized for predicting the next likely value in a series.
- The ARIMA algorithm was added in SQL Server 2008 to improve accuracy for long-term prediction.

By default, Analysis Services uses each algorithm separately to train the model and then blends the results to yield the best prediction for a variable number of predictions. You can also choose to use just one of the algorithms, based on your data and prediction requirements. In SQL Server 2008 Enterprise, you can also customize the cut-off point that controls the blend of algorithms during prediction.

This topic provides additional information about how each algorithm is implemented, and how you can customize the algorithm by setting parameters to fine-tune the analysis and prediction results.

Implementation of the Microsoft Time Series Algorithm

Microsoft Research developed the original ARTXP algorithm that was used in SQL Server 2005, basing the implementation on the Microsoft Decision Trees algorithm. Therefore, the ARTXP algorithm can be described as an autoregressive tree model for representing periodic time series data. This algorithm relates a variable number of past items to each current item that is being predicted. The name ARTXP derives from the fact that the autoregressive tree method (an ART algorithm) is applied to multiple unknown prior states. For a detailed explanation of the ARTXP algorithm, see [Autoregressive Tree Models for Time-Series Analysis](#).

The ARIMA algorithm was added to the Microsoft Time Series algorithm in SQL Server 2008 to improve long-term prediction. It is an implementation of the process for computing autoregressive integrated moving averages that was described by Box and Jenkins. The ARIMA methodology makes it possible to determine dependencies in observations taken sequentially in time, and can incorporate random shocks as part of the model. The ARIMA method also supports multiplicative seasonality. Readers who want to learn more about the ARIMA algorithm are encouraged to read the seminal work by Box and Jenkins; this section is intended to provide specific details about how the ARIMA methodology has been implemented in the Microsoft Time Series algorithm.

By default, the Microsoft Time Series algorithm uses both methods, ARTXP and ARIMA, and blends the results to improve prediction accuracy. If you want to use only a specific method, you can set the algorithm parameters to use only ARTXP or only ARIMA, or to control how the results of the algorithms are combined. Note that the ARTXP algorithm supports cross-prediction, but the ARIMA algorithm does not. Therefore, cross-prediction is available only when you use a blend of algorithms, or when you configure the model to use only ARTXP.

Understanding ARIMA Difference Order

This section introduces some terminology needed to understand the ARIMA model, and discusses the specific implementation of *differencing* in the Microsoft Time Series algorithm. For a full explanation of these terms and concepts, we recommend a review of Box and Jenkins.

- A term is a component of a mathematical equation. For example, a term in a polynomial equation might include a combination of variables and constants.
- The ARIMA formula that is included in the Microsoft Time Series algorithm uses both *autoregressive* and *moving average* terms.
- Time series models can be *stationary* or *nonstationary*. *Stationary models* are those that revert to a mean, though they might have cycles, whereas *nonstationary* models do not have a focus of equilibrium and are subject to greater variance or change introduced by *shocks*, or external variables.
- The goal of *differencing* is to make a time series stabilize and become stationary.
- The *order of difference* represents the number of times that the difference between values is taken for a time series.

The Microsoft Time Series algorithm works by taking values in a data series and attempting to fit the data to a pattern. If the data series is not already stationary, the algorithm applies an order of difference. Each increase in the order of difference tends to make the time series more stationary.

For example, if you have the time series (z_1, z_2, \dots, z_n) and perform calculations using one order of difference, you obtain a new series $(y_1, y_2, \dots, y_{n-1})$, where $y_i = z_{i+1} - z_i$. When the difference order is 2, the algorithm generates another series $(x_1, x_2, \dots, x_{n-2})$, based on the y series that was derived from the first order equation. The correct amount of differencing depends on the data. A single order of differencing is most common in models that show a constant trend; a second order of differencing can indicate a trend that varies with time.

By default, the order of difference used in the Microsoft Time Series algorithm is -1, meaning that the algorithm will automatically detect the best value for the difference order. Typically, that best value is 1 (when differencing is required), but under certain circumstances the algorithm will increase that value to a maximum of 2.

The Microsoft Time Series algorithm determines the optimal ARIMA difference order by using the autoregression values. The algorithm examines the AR values and sets a hidden parameter, ARIMA_AR_ORDER, representing the order of the AR terms. This hidden parameter, ARIMA_AR_ORDER, has a range of values from -1 to 8. At the default value of -1, the algorithm will automatically select the appropriate difference order.

Whenever the value of ARIMA_AR_ORDER is greater than 1, the algorithm multiplies the time series by a polynomial term. If one term of the polynomial formula resolves to a root of 1 or close to 1, the algorithm attempts to preserve the stability of the model by removing the term and increasing the difference order by 1. If the difference order is already at the maximum, the term is removed and the difference order does not change.

For example, if the value of AR = 2, the resulting AR polynomial term might look like this:

$1 - 1.4B + .45B^2 = (1 - .9B)(1 - .5B)$. Note the term $(1 - .9B)$ which has a root of about 0.9. The algorithm eliminates this term from the polynomial formula but cannot increase the difference order by one because it is already at the maximum value of 2.

It is important to note that the only way that you can **force** a change in difference order is to use the unsupported parameter, ARIMA_DIFFERENCE_ORDER. This hidden parameter controls how many times the algorithm performs differencing on the time series, and can be set by typing a custom algorithm parameter. However, we do not recommend that you change this value unless you are prepared to experiment and are familiar with the calculations involved. Also note that there is currently no mechanism, including hidden parameters, to let you control the threshold at which the increase in difference order is triggered.

Finally, note that the formula described above is the simplified case, with no seasonality hints. If seasonality hints are provided, then a separate AR polynomial term is added to the left of the equation for each seasonality hint, and the same strategy is applied to eliminate terms that might destabilize the differenced series.

Customizing the Microsoft Time Series Algorithm

The Microsoft Time Series algorithm supports the following parameters that affect the behavior, performance, and accuracy of the resulting mining model.

NOTE

The Microsoft Time Series algorithm is available in all editions of SQL Server; however, some advanced features, including parameters for customizing the time series analysis, are supported only in specific editions of SQL Server. For a list of features that are supported by the editions of SQL Server, see [Features Supported by the Editions of SQL Server](#).

Detection of Seasonality

Both ARIMA and ARTXP algorithms support detection of seasonality or periodicity. Analysis Services uses Fast Fourier transformation to detect seasonality before training. However, you can affect seasonality detection, and the results of time series analysis, by setting algorithm parameters.

- By changing the value of *AUTODETECT_SEASONALITY*, you can influence the number of possible time segments that are generated.
- By setting a value or multiple values for *PERIODICITY_HINT*, you can provide the algorithm with information about expected cycles in the data and potentially increase the accuracy of detection.

NOTE

Both the ARTXP and ARIMA algorithms are very sensitive to seasonality hints. Therefore, providing the wrong hint can adversely affect results.

Choosing an Algorithm and Specifying the Blend of Algorithms

By default, or when you select the MIXED option, Analysis Services combines the algorithms and assigns them equal weight. However, in Enterprise Edition, you can specify a particular algorithm, or you can customize the proportion of each algorithm in the results by setting a parameter that weights the results towards either the short or the long-term prediction. By default, the *FORECAST_METHOD* parameter is set to MIXED, and Analysis Services uses both algorithms and then weights their values to maximize the strengths of each algorithm.

- To control the choice of algorithm, you set the *FORECAST_METHOD* parameter.
- If you want to use cross-prediction, you must use either the ARTXP or the MIXED option because ARIMA does not support cross-prediction.
- Set the *FORECAST_METHOD* to ARTXP if you want to favor short-term prediction.
- Set the *FORECAST_METHOD* to ARIMA if you want to improve long-term prediction.

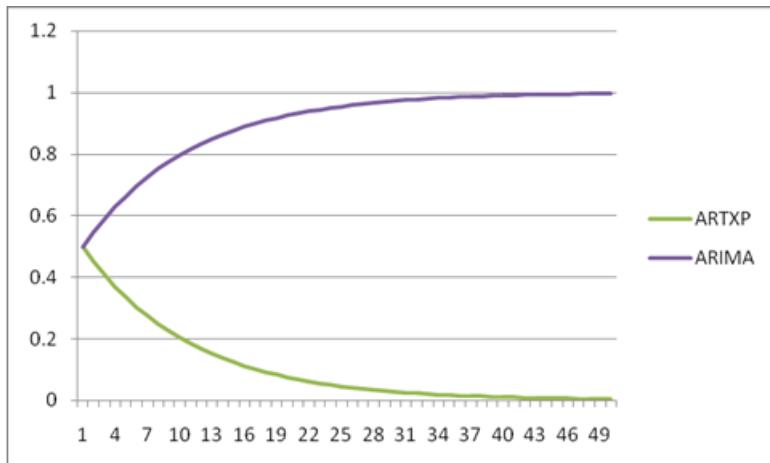

In Enterprise Edition, you can also customize how Analysis Services mixes the combination of the ARIMA and ARTXP algorithms. You can control both the starting point for the mixture, and the rate of change by setting the *PREDICTION_SMOOTHING* parameter:

- If you set *PREDICTION_SMOOTHING* to 0, the model uses ARTXP only.
- If you set *PREDICTION_SMOOTHING* to 1, the model uses ARIMA only.
- If you set *PREDICTION_SMOOTHING* to a value between 0 and 1, the model weights the ARTXP algorithm as an exponentially decreasing function of the prediction steps. At the same time, the model also weights the ARIMA algorithm as the 1-complement of the ARTXP weight. The model uses normalization and a stabilization constant to smooth the curves.

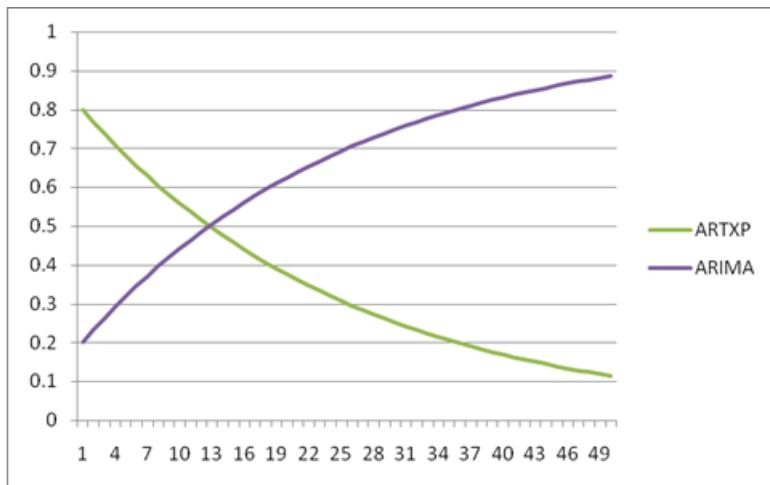

In general, if you predict up to 5 time slices, ARTXP is almost always the better choice. However, as you

increase the number of time slices to predict, ARIMA typically performs better.

The following diagram illustrates how the model blends the algorithms when *PREDICTION_SMOOTHING* is set to the default value, 0.5. ARIMA and ARTXP are weighted equally at first, but as the number of prediction steps increases, ARIMA is weighed more heavily.

In contrast, the following diagram illustrates the blending of the algorithms when *PREDICTION_SMOOTHING* is set to 0.2. For step 0, the model weights ARIMA as 0.2 and ARTXP as 0.8. Thereafter, the weight of ARIMA exponentially increases and the weight of ARTXP exponentially decreases.

Setting Algorithm Parameters

The following table describes the parameters that can be used with the Microsoft Time Series algorithm.

PARAMETER	DESCRIPTION
<i>AUTO_DETECT_PERIODICITY</i>	Specifies a numeric value between 0 and 1 that detects periodicity. The default is 0.6. If the value is closer to 0, periodicity is detected only for strongly periodic data. Setting this value closer to 1 favors the discovery of many patterns that are almost periodic and the automatic generation of periodicity hints. Note: Dealing with many periodicity hints will likely lead to significantly longer model training times, but more accurate models.

PARAMETER	DESCRIPTION
<i>COMPLEXITY_PENALTY</i>	<p>Controls the growth of the decision tree. The default is 0.1.</p> <p>Decreasing this value increases the chance of a split. Increasing this value decreases the chance of a split.</p> <p>Note: This parameter is only available in some editions of SQL Server.</p>
<i>FORECAST_METHOD</i>	<p>Specifies which algorithm to use for analysis and prediction. Possible values are ARTXP, ARIMA, or MIXED. The default is MIXED.</p>
<i>HISTORIC_MODEL_COUNT</i>	<p>Specifies the number of historic models that will be built. The default is 1.</p> <p>Note: This parameter is only available in some editions of SQL Server.</p>
<i>HISTORICAL_MODEL_GAP</i>	<p>Specifies the time lag between two consecutive historic models. The default is 10. The value represents a number of time units, where the unit is defined by the model.</p> <p>For example, setting this value to g causes historic models to be built for data that is truncated by time slices at intervals of g, 2*g, 3*g, and so on.</p> <p>Note: This parameter is only available in some editions of SQL Server.</p>
<i>INSTABILITY_SENSITIVITY</i>	<p>Controls the point at which prediction variance exceeds a certain threshold, after which the ARTXP algorithm suppresses predictions. The default value is 1.</p> <p>Note: This parameter does not apply to models that use ARIMA only.</p> <p>The default value of 1 provides the same behavior as in SQL Server 2005 (9.x). Analysis Services monitors the normalized standard deviation for each prediction. As soon as this value exceeds the threshold for any prediction, the time series algorithm returns a NULL and stops the prediction process.</p> <p>A value of 0 stops instability detection. This means that you can create an infinite number of predictions, regardless of the variance.</p> <p>Note: This parameter can only be modified in SQL Server Enterprise. In SQL Server Standard, Analysis Services uses only the default value of 1.</p>
<i>MAXIMUM_SERIES_VALUE</i>	<p>Specifies the maximum value to use for predictions. This parameter is used, together with <i>MINIMUM_SERIES_VALUE</i>, to constrain the predictions to some expected range. For example, you can specify that the predicted sales quantity for any day should never exceed the number of products in inventory.</p> <p>Note: This parameter is only available in some editions of SQL Server.</p>

PARAMETER	DESCRIPTION
<i>MINIMUM_SERIES_VALUE</i>	<p>Specifies the minimum value that can be predicted. This parameter is used, together with <i>MAXIMUM_SERIES_VALUE</i>, to constrain the predictions to some expected range. For example, you can specify that the predicted sales quantity should never be a negative number.</p> <p>Note: This parameter is only available in some editions of SQL Server.</p>
<i>MINIMUM_SUPPORT</i>	<p>Specifies the minimum number of time slices that are required to generate a split in each time series tree. The default is 10.</p>
<i>MISSING_VALUE_SUBSTITUTION</i>	<p>Specifies how gaps in historical data are filled. By default, gaps in data are not allowed. The following table lists the possible values for this parameter:</p> <p>Previous: Repeats the value from the previous time slice.</p> <p>Mean: Uses a moving average of time slices used in training.</p> <p>Numeric constant: Uses the specified number to replace all missing values.</p> <p>None: Default. Replaces missing values with values plotted along the curve of the trained model.</p> <p>Note that if your data contains multiple series, the series cannot have ragged edges. That is, all series should have the same start and end points. Analysis Services also uses the value of this parameter to fill gaps in new data when you perform a PREDICTION JOIN on time series model.</p>
<i>PERIODICITY_HINT</i>	<p>Provides a hint to the algorithm as to the periodicity of the data. For example, if sales vary by year, and the unit of measurement in the series is months, the periodicity is 12. This parameter takes the format of {n [, n]}, where n is any positive number.</p> <p>The n in the brackets [] is optional and can be repeated as frequently as needed. For example, to provide multiple periodicity hints for data supplied monthly, you might enter {12, 3, 1} to detect patterns for the year, quarter, and month. However, periodicity has a strong effect on model quality. If the hint that you give differs from the actual periodicity, your results can be adversely affected.</p> <p>The default is {1}.</p> <p>Note that the braces are required. Also, this parameter has a string data type. Therefore, if you type this parameter as part of a Data Mining Extensions (DMX) statement, you must enclose the number and braces in quotation marks.</p>

PARAMETER	DESCRIPTION
<i>PREDICTION_SMOOTHING</i>	<p>Specifies how the model should be mixed to optimize forecasting. You can type any value between 0 and 1 or use one of the following values:</p> <p>0: Specifies that prediction uses ARTXP only. Forecasting is optimized for fewer predictions.</p> <p>1: Specifies that prediction uses ARIMA only. Forecasting is optimized for many predictions.</p> <p>0.5: Default. Specifies that for prediction both algorithms should be used and the results blended.</p> <p>When doing prediction smoothing, use the <i>FORECAST_METHOD</i> parameter to control training. Note that this parameter is only available in some editions of SQL Server.</p>

Modeling Flags

The Microsoft Time Series algorithm supports the following modeling flags. When you create the mining structure or mining model, you define modeling flags to specify how values in each column are handled during analysis. For more information, see [Modeling Flags \(Data Mining\)](#).

MODELING FLAG	DESCRIPTION
NOT NULL	<p>Indicates that the column cannot contain a null. An error will result if Analysis Services encounters a null during model training.</p> <p>Applies to mining structure columns.</p>
MODEL_EXISTENCE_ONLY	<p>Means that the column will be treated as having two possible states: Missing and Existing. A null is a missing value.</p> <p>Applies to mining model columns.</p>

Requirements

A time series model must contain a key time column that contains unique values, input columns, and at least one predictable column.

Input and Predictable Columns

The Microsoft Time Series algorithm supports the specific input column content types, predictable column content types, and modeling flags that are listed in the following table.

COLUMN	CONTENT TYPES
Input attribute	Continuous, Key, Key Time, and Table
Predictable attribute	Continuous, Table

NOTE

Cyclical and Ordered content types are supported, but the algorithm treats them as discrete values and does not perform special processing.

Mining Model Content for Time Series Models (Analysis Services - Data Mining)

7/16/2019 • 25 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

All mining models use the same structure to store their content. This structure is defined according to the data mining content schema rowset. However, within that standard structure, the nodes that contain information are arranged in different ways to represent various kinds of trees. This topic describes how the nodes are organized, and what each node means, for mining models that are based on the Microsoft Time Series algorithm.

For an explanation of general mining model content that applies to all model types, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

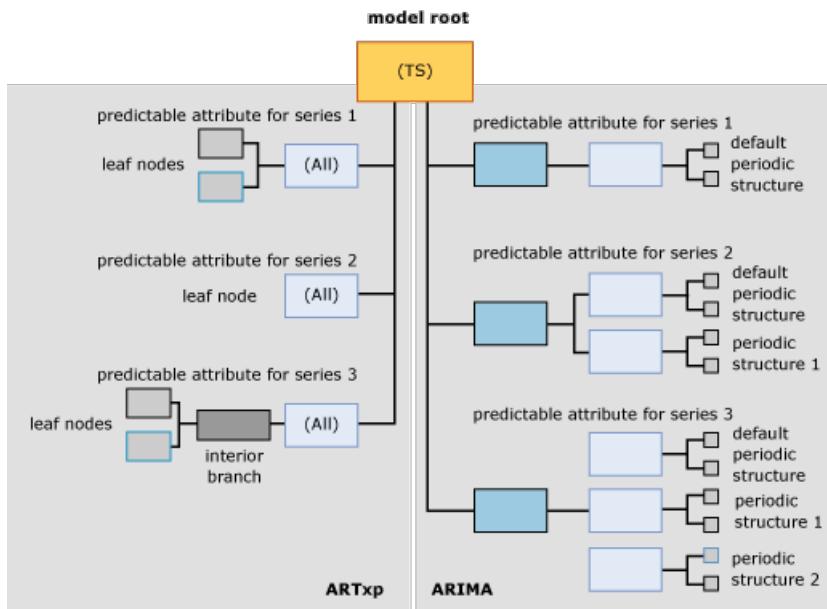

When reviewing this topic, you might find it useful follow along by browsing the contents of a time series model. You can create a time series model by completing the Basic Data Mining tutorial. The model you create in the tutorial is a mixed model that trains data by using both the ARIMA and ARTXP algorithms. For information about how to view the contents of a mining model, see [Data Mining Model Viewers](#).

Understanding the Structure of a Time Series Model

A time series model has a single parent node that represents the model and its metadata. Underneath that parent node, there are one or two time series trees, depending on the algorithm that you used to create the model.

If you create a mixed model, two separate trees are added to the model, one for ARIMA and one for ARTXP. If you choose to use only the ARTXP algorithm or only the ARIMA algorithm, you will have a single tree that corresponds to that algorithm. You specify which algorithm to use by setting the FORECAST_METHOD parameter. For more information about whether to use ARTXP, ARIMA, or a mixed model, see [Microsoft Time Series Algorithm](#).

The following diagram shows an example of a time series data mining model that was created with the default settings, to create a mixed model. So that you can more easily compare the differences between the two models, here the ARTXP model is shown on the left side of the diagram and the ARIMA model is shown in the right side of the diagram. Whereas ARTXP is a tree-like structure that splits into smaller and smaller branches, the structure created by the ARIMA algorithm is more like a pyramid built upwards from smaller components.

The important point to remember is that information is arranged within the ARIMA and ARTXP trees in completely different ways, and you should consider the two trees as related only at the root node. Although the two representations are presented in one model for convenience, they should be treated as two independent models. ARTXP represents an actual tree structure, but ARIMA does not.

When you use the Microsoft Generic Model Content Tree Viewer to view a model that uses both ARIMA and ARTXP, the nodes for the ARTXP and ARIMA models are all presented as child nodes of the parent time series model. However, you can easily tell them apart by the labels applied to the nodes.

- The first set of nodes is labeled (All), and represents the results of analysis by the ARTXP algorithm.
- The second set of nodes is labeled ARIMA, and represents the results of analysis by the ARIMA algorithm.

WARNING

The name (All) on the ARTXP tree is retained only for backward compatibility. Prior to SQL Server 2008, the Time Series algorithm used a single algorithm for analysis, the ARTXP algorithm.

The following sections explain how the nodes are arranged within each of these model types.

Structure of an ARTXP Model

The ARTXP algorithm creates a model similar to a decision trees model. It groups predictable attributes and splits them whenever significant differences are found. Therefore, each ARTXP model contains a separate branch for each predictable attribute. For example, the Basic Data Mining tutorial creates a model that predicts the amount of sales for several regions. In this case, **[Amount]** is the predictable attribute and a separate branch is created for each region. If you had two predictable attributes, **[Amount]** and **[Quantity]**, a separate branch would be created for each combination of an attribute and a region.

The top node for the ARTXP branch contains the same information that is in a decision tree root node. This includes the number of children for that node (CHILDREN_CARDINALITY), the number of cases that meet the conditions of this node (NODE_SUPPORT), and a variety of descriptive statistics (NODE DISTRIBUTION).

If the node does not have any children, this means that no significant conditions were found that would justify dividing the cases into further subgroups. The branch ends at this point and the node is termed a *leaf node*. The leaf node contains the attributes, coefficients, and values that are the building blocks of the ARTXP formula.

Some branches may have additional splits, similar to a decision trees model. For example, the branch of the tree that represents sales for the Europe region splits into two branches. A split occurs when a condition is found that causes a significant difference between the two groups. The parent node tells you the name of the attribute that

caused the split, such as [Amount], and how many cases there are in the parent node. The leaf nodes provide more detail: the value of the attribute, such as [Sales] > 10,000 vs. [Sales] < 10,000), the number of cases that support each condition, and the ARTXP formula.

NOTE

If you want to view the formulas, you can find the complete regression formula at the leaf node level, but not in an intermediate or root node.

Structure of an ARIMA Model

The ARIMA algorithm creates a single piece of information for each combination of a data series (such as **[Region]**) and a predictable attribute (such as **[Sales Amount]**)-the equation that describes the change of the predictable attribute over time.

The equation for each series is derived from multiple components, one for each periodic structure that was found in the data. For example, if you have sales data that is collected on a monthly basis, the algorithm might detect monthly, quarterly, or yearly periodic structures.

The algorithm outputs a separate set of parent and child nodes for each periodicity it finds. The default periodicity is 1, for a single time slice, and is automatically added into all models. You can specify possible periodic structures by entering multiple values in the PERIODICITY_HINT parameter. However, if the algorithm does not detect a periodic structure, it will not output results for that hint.

Each periodic structure that is output in the model content contains the following component nodes:

- A node for the *autoregressive order* (AR)
- A node for the *moving average* (MA)

For information about the meaning of these terms, see [Microsoft Time Series Algorithm](#).

The *difference order* is an important part of the formula, and is represented in the equation. For more information about how the difference order is used, see [Microsoft Time Series Algorithm Technical Reference](#).

Model Content for Time Series

This section provides detail and examples only for those columns in the mining model content that have particular relevance for time series models.

For information about general-purpose columns in the schema rowset, such as MODEL_CATALOG and MODEL_NAME, or for explanations of mining model terminology, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

MODEL_CATALOG

Name of the database where the model is stored.

MODEL_NAME

Name of the model.

ATTRIBUTE_NAME

The predictable attribute for the data series represented in the node. (The same value as for MSOLAP_MODEL_COLUMN.)

NODE_NAME

The name of the node.

Currently, this column contains the same value as NODE_UNIQUE_NAME, although this might change in future releases.

NODE_UNIQUE_NAME

The unique name of the node. The model parent node is always named **TS**.

ARTXP: Each node is represented by TS followed by a hexadecimal numeric value. The order of the nodes is unimportant.

For example, the ARTXP nodes directly under the TS tree might be numbered TS00000001-TS0000000b.

ARIMA: Each node in an ARIMA tree is represented by TA followed by a hexadecimal numeric value. The child nodes contain the unique name of the parent node followed by another hexadecimal number indicating the sequence within the node.

All ARIMA trees are structured exactly the same. Each root contains the nodes and naming convention exemplified in the following table:

ARIMA NODE ID AND TYPE	EXAMPLE OF NODE NAME
ARIMA Root (27)	TA0000000b
ARIMA Periodic Structure (28)	TA0000000b00000000
ARIMA Auto Regressive (29)	TA0000000b000000000
ARIMA Moving Average (30)	TA0000000b000000001

NODE_TYPE

A time series model outputs the following node types, depending on the algorithm.

ARTXP:

NODE TYPE ID	DESCRIPTION
1 (Model)	Time series
3 (Interior)	Represents an interior branch within an ARTXP time series tree.
16 (Time series tree)	Root of ARTXP tree that corresponds to a predictable attribute and series.
15 (Time series)	Leaf node in ARTXP tree.

ARIMA:

NODE TYPE ID	DESCRIPTION
27 (ARIMA Root)	The top node of an ARIMA tree.
28 (ARIMA Periodic Structure)	Component of an ARIMA tree that describes a single periodic structure.
29 (ARIMA Autoregressive)	Contains a coefficient for a single periodic structure.
30 (ARIMA Moving Average)	Contains a coefficient for a single periodic structure.

NODE_CAPTION

A label or caption that is associated with the node.

This property is primarily for display purposes.

ARTXP: Contains the split condition for the node, displayed as a combination of attribute and value range.

ARIMA: Contains the short form of the ARIMA equation.

For information about the format of the ARIMA equation, see [Mining Legend for ARIMA](#).

CHILDREN_CARDINALITY

The number of direct children that the node has.

PARENT_UNIQUE_NAME

The unique name of the node's parent. NULL is returned for any nodes at the root level.

NODE_DESCRIPTION

A description in text of the rules, splits, or formulas in the current node.

ARTXP: For more information, see [Understanding the ARTXP Tree](#).

ARIMA: For more information, see [Understanding the ARIMA Tree](#).

NODE_RULE

An XML description of the rules, splits, or formulas in the current node.

ARTXP: The NODE_RULE generally corresponds to the NODE_CAPTION.

ARIMA: For more information, see [Understanding the ARIMA Tree](#).

MARGINAL_RULE

An XML description of the split or content that is specific to that node.

ARTXP: The MARGINAL_RULE generally corresponds to the NODE_DESCRIPTION.

ARIMA: Always blank; use NODE_RULE instead.

NODE_PROBABILITY

ARTXP: For tree nodes, always 1. For leaf nodes, the probability of reaching the node from the model root node.

ARIMA: Always 0.

MARGINAL_PROBABILITY

ARTXP: For tree nodes, always 1. For leaf nodes, the probability of reaching the node from the immediate parent node.

ARIMA: Always 0.

NODE_DISTRIBUTION

A table that contains the probability histogram of the node. In a time series model, this nested table contains all the components required to assemble the actual regression formula.

For more information about the node distribution table in an ARTXP tree, see [Understanding the ARTXP Tree](#).

For more information about the node distribution table in an ARIMA tree, see [Understanding the ARIMA Tree](#).

If you wish to see all the constants and other components composed into a readable format, use the [Time Series Viewer](#), click the node, and open the **Mining Legend**.

NODE_SUPPORT

The number of cases that support this node.

ARTXP: For the **(All)** node, indicates the total number of time slices included in the branch.

For terminal nodes, indicates the number of time slices that are included in the range that is described by NODE_CAPTION. The number of time slices in the terminal nodes always sums to the NODE_SUPPORT value of the branch (**All**) node.

ARIMA: A count of cases that support the current periodic structure. The value for support is repeated in all nodes of the current periodic structure.

MSOLAP_MODEL_COLUMN

The predictable attribute for the data series represented in the node. (The same value as for ATTRIBUTE_NAME.)

MSOLAP_NODE_SCORE

A numeric value that characterizes the information value of the tree or split.

ARTXP: Value is always 0.0 for nodes without a split. For nodes with a split, the value represents the interestingness score of the split.

For more information about scoring methods, see [Feature Selection \(Data Mining\)](#).

ARIMA: The Bayesian Information Criterion (BIC) score of the ARIMA model. The same score is set on all the ARIMA nodes related to the equation.

MSOLAP_NODE_SHORT_CAPTION

ARTXP: Same information as the NODE_DESCRIPTION.

ARIMA: Same information as the NODE_CAPTION: that is, the short form of the ARIMA equation.

Understanding the ARTXP Tree

The ARTXP model clearly separates the areas of the data that are linear from the areas of the data that split on some other factor. Wherever the changes in the predictable attribute can be directly represented as a function of the independent variables, a regression formula is calculated to represent that relationship.

For example, if there is a direct correlation between time and sales for most of the data series, each series would be contained within a time series tree (NODE_TYPE = 16) that has no child nodes for each data series, only a regression equation. However, if the relationship is not linear, an ARTXP time series tree can split on conditions into child nodes, just like a decision tree model. By viewing the model content in the [Microsoft Generic Content Tree Viewer](#) you can see where the splits occur, and how it affects the trend line.

To better understand this behavior, you can review the time series model created in the [Basic Data Mining Tutorial](#). This model, based on the AdventureWorks data warehouse, does not use particularly complex data. Therefore, there are not many splits in the ARTXP tree. However, even this relatively simple model illustrates three different kinds of splits:

- The [Amount] trend line for the Pacific region splits on the time key. A split on the time key means that there is a change in the trend at a certain point in time. The trend line was linear only up to a certain point, and then the curve assumed a different shape. For example, one time series might continue until August 6, 2002, and another time series start after that date.
- The [Amount] trend line for the North America region splits on another variable. In this case, the trend for North America splits based on the value for the same model in the Europe region. In other words, the algorithm detected that when the value for Europe changes, the value for North America A also changes.
- The trend line for Europe region splits on itself.

What does each split mean? Interpreting the information conveyed by the model content is an art that requires a deep understanding of the data and its meaning in the business context.

- The apparent link between the trends for the North America and Europe regions may signify only that the data series for Europe has more entropy, which causes the trend for the North America to appear weaker.

Or, there might be no significant difference in the scoring for the two, and the correlation could be accidental, based simply on computing Europe before computing North America. However, you might want to review the data and make sure whether the correlation is false, or investigate to see if some other factor might be involved.

- The split on the time key means that there is a statistically significant change in the gradient of the line. This might have been caused by mathematical factors such as the support for each range, or the calculations of entropy required for the split. Thus, this split might not be interesting in terms of the model's meaning in the real world. However, when you review the time period indicated in the split, you might find interesting correlations that are not represented in the data, such as a sales promotion or other event that began at that time and that may have affected the data.

If the data contained other attributes, you would very likely see more interesting examples of branching in the tree. For example, if you tracked weather information and used that as an attribute for analysis, you might see multiple splits in the tree that represent the complex interaction of sales and weather.

In short, data mining is useful for providing hints about where potentially interesting phenomena occur, but further investigation and the expertise of the business users is necessary to accurately interpret the worth of the information in context.

Elements of the ARTXP Time Series Formula

To view the complete formula for an ARTXP tree or branch, we recommend that you use the **Mining Legend** of the [Microsoft Time Series Viewer](#), which presents all of the constants in a readable format.

- [View the Formula for a Time Series Model \(Data Mining\)](#)

The following section presents a sample equation and explains the basic terms.

Mining Legend for an ARTXP Formula

The following example shows the ARTXP formula for one part of the model, as displayed in the **Mining Legend**. To view this formula, open the [Forecasting] model that you created in the Basic Data Mining Tutorial in the Microsoft Time Series viewer, click the **Model** tab, and select the tree for the R250: Europe data series.

To view the equation used for this example, click the node that represents the date series on or after 7/5/2003.

Example of tree node equation:

```
Quantity = 21.322 -0.293 * Quantity(R250 North America,-7) + 0.069 * Quantity(R250 Europe,-1) + 0.023 *  
Quantity(R250 Europe,-3) -0.142 * Quantity(R750 Europe,-8)
```

In this case, the value 21.322 represents the value that is predicted for Quantity as a function of the following elements of the equation.

For example, one element is `Quantity(R250 North America,-7)`. This notation means the quantity for the North America region at `t-7`, or seven time slices before the current time slice. The value for this data series is multiplied by the coefficient -0.293. The coefficient for each element is derived during the training process and is based on trends in the data.

There are multiple elements in this equation because the model has calculated that the quantity of the R250 model in the Europe region is dependent on the values of several other data series.

Model Content for an ARTXP Formula

The following table shows the same information for the formula, using the contents of the relevant node as displayed in the [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

ATTRIBUTE_NAME	ATTRIBUTE_VALUE	SUPPORT	PROBABILITY	VARIANCE	VALUETYPE
Quantity(R250 Europe,y-intercept)	21.3223433563772	11	0	1.65508795539661	11 (Intercept)
Quantity(R250 Europe,-1)	0.0691694140876526	0	0	0	7 (Coefficient)
Quantity(R250 Europe,-1)	20.6363635858123	0	0	182.380682874818	9 (Statistics)
Quantity(R750 Europe,-8)	-0.1421203048299	0	0	0	7 (Coefficient)
Quantity(R750 Europe,-8)	22.5454545333019	0	0	104.362130048408	9 (Statistics)
Quantity(R250 Europe,-3)	0.0234095979448281	0	0	0	7 (Coefficient)
Quantity(R250 Europe,-3)	24.8181818883176	0	0	176.475304989169	9 (Statistics)
Quantity(R250 North America,-7)	-0.292914186039869	0	0	0	7 (Coefficient)
Quantity(R250 North America,-7)	10.36363640433	0	0	701.882534898676	9 (Statistics)

As you can see from comparing these examples, the mining model content contains the same information that is available in the **Mining Legend**, but with additional columns for *variance* and *support*. The value for support indicates the count of cases that support the trend described by this equation.

Using the ARTXP Time Series Formula

For most business users, the value of the ARTXP model content is that it combines both a tree view and a linear representation of the data.

- If the changes in the predictable attribute can be represented as a linear function of the independent variables, the algorithm will automatically compute the regression equation and output that series in a separate node
- Whenever the relationship cannot be expressed as a linear correlation, the time series branches like a decision tree.

By browsing the model content in the [Microsoft Time Series Viewer](#) you can see where the split occurs, and how it affects the trend line.

If a direct correlation exists between time and sales for any part of the data series, the easiest way to get the formula is to copy the formula from the **Mining Legend**, and then paste it into a document or presentation to help explain the model. Alternatively, you could extract the mean, coefficient, and other information from the NODE_DISTRIBUTION table for that tree and use it to compute extensions of the trend. If the entire series exhibits a consistent linear relationship, the equation is contained in the (All) node. If there is any branching in the tree, the equation is contained in the leaf node.

The following query returns all the ARTXP leaf nodes from a mining model, together with the nested table, NODE DISTRIBUTION, which contains the equation.

```
SELECT MODEL_NAME, ATTRIBUTE_NAME, NODE_NAME,  
NODE_CAPTION,  
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE, [VARIANCE], VALUETYPE  
FROM NODE DISTRIBUTION) as t  
FROM Forecasting.CONTENT  
WHERE NODE_TYPE = 15
```

Understanding the ARIMA Tree

Each structure in an ARIMA model corresponds to a *periodicity* or *periodic structure*. A periodic structure is a pattern of data that repeats throughout the data series. Some minor variation in the pattern is allowed, within statistical limits. Periodicity is measured according to the default time units that were used in the training data. For example, if the training data provides sales data for each day, the default time unit is one day, and all periodic structures are defined as a specified number of days.

Each period that is detected by the algorithm gets its own structure node. For example, if you are analyzing daily sales data, the model might detect periodic structures that represent weeks. In this case, the algorithm will create two periodic structures in the finished model: one for the default daily period, denoted as {1}, and one for weeks, indicated by {7}.

For example, the following query returns all the ARIMA structures from a mining model.

```
SELECT MODEL_NAME, ATTRIBUTE_NAME, NODE_NAME, NODE_CAPTION  
FROM Forecasting.CONTENT  
WHERE NODE_TYPE = 27
```

Example results:

MODEL_NAME	ATTRIBUTE_NAME	NODE_NAME	NODE_TYPE	NODE_CAPTION
Forecasting	M200 Europe:Quantity	TA00000000	27	ARIMA (1,0,1)
Forecasting	M200 North America:Quantity	TA00000001	27	ARIMA (1,0,4) X (1,1,4)(6)
Forecasting	M200 Pacific:Quantity	TA00000002	27	ARIMA (2,0,8) X (1,0,0)(4)
Forecasting	M200 Pacific:Quantity	TA00000002	27	ARIMA (2,0,8) X (1,0,0)(4)
Forecasting	R250 Europe:Quantity	TA00000003	27	ARIMA (1,0,7)
Forecasting	R250 North America:Quantity	TA00000004	27	ARIMA (1,0,2)
Forecasting	R250 Pacific:Quantity	TA00000005	27	ARIMA (2,0,2) X (1,1,2)(12)

MODEL_NAME	ATTRIBUTE_NAME	NODE_NAME	NODE_TYPE	NODE_CAPTION
Forecasting	R750 Europe:Quantity	TA00000006	27	ARIMA (2,1,1) X (1,1,5)(6)
Forecasting	T1000 Europe:Quantity	TA00000009	27	ARIMA (1,0,1)
Forecasting	T1000 North America:Quantity	TA0000000a	27	ARIMA (1,1,1)
Forecasting	T1`000 Pacific:Quantity	TA0000000b	27	ARIMA (1,0,3)

From these results, which you can also browse by using the [Microsoft Generic Content Tree Viewer \(Data Mining\)](#), you can tell at a glance which series are completely linear, which have multiple periodic structures, and what the discovered periodicities are.

For example, the short form of the ARIMA Equation for the M200 Europe series tells you that only the default, or daily, cycle was detected. The short form of the equation is provided in the NODE_CAPTION column.

However, for the M200 North America series, an additional periodic structure was found. The node TA00000001 has two child nodes, one with the equation, (1,0,4), and one with the equation, (1,1,4)(6). These equations are concatenated and presented in the parent node.

For each periodic structure, the model content also provides the *order* and the *moving average* as child nodes. For example, the following query retrieves the child nodes of one of the nodes listed in the previous example. Notice that the column, PARENT_UNIQUE_NAME, must be enclosed in brackets to distinguish it from the reserved keyword of the same name.

```
SELECT *
FROM Forecasting.CONTENT
WHERE [PARENT_UNIQUE_NAME] = 'TA00000001'
```

Because this is an ARIMA tree, not an ARTXP tree, you cannot use the [IsDescendant \(DMX\)](#) function to return the child nodes of this periodic structure. Instead, you can use the attribute and node types to filter the results and return the child nodes that provide more detail about how the equation was built, including the moving averages and difference order.

```
SELECT MODEL_NAME, ATTRIBUTE_NAME, NODE_UNIQUE_NAME,
NODE_TYPE, NODE_CAPTION
FROM Forecasting.CONTENT
WHERE [MSOLAP_MODEL_COLUMN] = 'M200 North America:Quantity'
AND (NODE_TYPE = 29 or NODE_TYPE = 30)
```

Example results:

MODEL_NAME	ATTRIBUTE_NAME	NODE_UNIQUE_NAME	NODE_TYPE	NODE_CAPTION
Forecasting	M200 North America:Quantity	TA00000001000000010	29	ARIMA {1,0,961832044807041}

MODEL_NAME	ATTRIBUTE_NAME	NODE_UNIQUE_NAME	NODE_TYPE	NODE_CAPTION
Forecasting	M200 North America:Quantity	TA0000000100000011	30	ARIMA {1,-3.51073103693271E-02,2.15731642954099,-0.220314343327742,-1.33151478258758}
Forecasting	M200 North America:Quantity	TA0000000100000000	29	ARIMA {1,0.643565911081657}
Forecasting	M200 North America:Quantity	TA0000000100000001	30	ARIMA {1,1.45035399809581E-02,-4.40489283927752E-02,-0.19203901352577,0.242202497643993}

These examples illustrate that the further you drill down into the ARIMA tree, the more detail is revealed, but the important information is combined and presented in the parent node as well.

Time Series Formula for ARIMA

To view the complete formula for any ARIMA node, we recommend that you use the **Mining Legend** of the [Microsoft Time Series Viewer](#), which presents the autoregressive order, moving averages, and other elements of the equation already composed in a consistent format.

- [View the Formula for a Time Series Model \(Data Mining\)](#)

This section presents a sample equation and explains the basic terms.

Mining Legend for ARIMA Formula

The following example shows the ARIMA formula for one part of the model, as displayed in the Mining Legend. To view this formula, open the **Forecasting** model by using the [Microsoft Time Series viewer](#), click the **Model** tab, select the tree for the **R250: Europe** data series, and then click the node that represents the date series on or after 7/5/2003. The mining legend composes all of the constants in a readable format, shown in this example:

ARIMA equation:

```
ARIMA ({1,1},0,{1,1.49791920964142,1.10640053499397,0.888873034670339,-5.05429403071953E-02,-0.905265316720334,-0.961908900643379,-0.649991020901922}) Intercept:56.88888888888889
```

This equation is the long ARIMA format, which includes the values of the coefficients and the intercept. The short format for this equation would be {1,0,7}, where 1 indicates the period as a count of time slices, 0 indicates the term difference order, and 7 indicates the number of coefficients.

NOTE

A constant is calculated by Analysis Services for computing variance, but the constant itself is not displayed anywhere in the user interface. However, you can view the variance for any point in the series as a function of this constant if you select **Show Deviations**, in **Chart** view. The Tooltip for each data series shows the variance for a specific predicted point.

Model Content for ARIMA Formula

An ARIMA model follows a standard structure, with different information contained in nodes of different types. To view the model content for the ARIMA model, change the viewer to the [Microsoft Generic Content Tree](#)

Viewer, and then expand the node that has the attribute name, **R250 Europe: Quantity**.

An ARIMA model for a data series contains the basic periodic equation in four different formats, which you can choose from depending on the application.

NODE_CAPTION: Displays the short format of the equation. The short format tells you how many periodic structures are represented, and how many coefficients they have. For example, if the short format of the equation is $\{4,0,6\}$, the node represents one periodic structure with 6 coefficients. If the short format is something like $\{2,0,8\} \times \{1,0,0\}(4)$, the node contains two periodic structures.

NODE_DESCRIPTION: Displays the long format of the equation, which is also the form of the equation that appears in the **Mining Legend**. The long form of the equation is similar to the short form, except that the actual values of the coefficients are displayed instead of being counted.

NODE_RULE: Displays an XML representation of the equation. Depending on the node type, the XML representation can include single or multiple periodic structures. The following table illustrates how XML nodes are rolled up to higher levels of the ARIMA model.

NODE TYPE	XML CONTENT
27 (ARIMA Root)	Includes all periodic structures for the data series, and the content of all child nodes for each periodic structure.
28 (ARIMA Periodic Structure)	Defines a single periodic structure, including its autoregressive term node and its moving average coefficients.
29 (ARIMA Autoregressive)	Lists the terms for a single periodic structure.
30 (ARIMA Moving Average)	Lists the coefficients for a single periodic structure.

NODE_DISTRIBUTION: Displays terms of the equation in a nested table, which you can query to obtain specific terms. The node distribution table follows the same hierarchical structure as the XML rules. That is, the root node of the ARIMA series (NODE_TYPE = 27) contains the intercept value and the periodicities for the complete equation, which can include multiple periodicities, whereas the child nodes contain only information specific to a certain periodic structure or to the child nodes of that periodic structure.

NODE TYPE	ATTRIBUTE	VALUE TYPE
27 (ARIMA Root)	Intercept	11
	Periodicity	
28 (ARIMA Periodic Structure)	Periodicity	12
	Auto Regressive order	13
	Difference order	15
	Moving average order	14
29 (ARIMA Autoregressive)	Coefficient	7
	(complement of coefficient)	

NODE TYPE	ATTRIBUTE	VALUE TYPE
30 (ARIMA Moving Average)	Value at t	7
	Value at t-1	
	...	
	Value at t-n	

The value for the *moving average order* indicates the number of moving averages in a series. Generally the moving average is calculated $n-1$ times if there are n terms in a series, but the number can be reduced for easier computation.

The value for *autoregressive order* indicates the number of autoregressive series.

The value for *difference order* indicates how many times the series are compared, or differenced.

For an enumeration of the possible value types, see [Microsoft.AnalysisServices.AdomdServer.MiningValueType](#).

Using the ARIMA Tree Information

If you use predictions that are based on the ARIMA algorithm in a business solution, you might want to paste the equation into a report to demonstrate the method that was used to create the prediction. You can use the caption to present the formulas in short format, or the description to present the formulas in long format.

If you are developing an application that uses time series predictions, you might find it useful to obtain the ARIMA equation from the model content and then make your own predictions. To obtain the ARIMA equation for any particular output, you can query the ARIMA root for that particular attribute directly, as shown in the previous examples.

If you know the ID of the node that contains the series you want, you have two options to retrieve the components of the equation:

- Nested table format: Use a DMX query or query via OLEDB client.
- XML representation: Use an XML query.

Remarks

It can be difficult to retrieve information from an ARTXP tree, because information for each split is in a different place within the tree. Therefore, with an ARTXP model, you must get all the pieces and then do some processing to reconstitute the complete formula. Retrieving an equation from an ARIMA model is easier because the formula has been made available throughout the tree. For information about how to create a query to retrieve this information, see [Time Series Model Query Examples](#).

Time Series Model Query Examples

7/16/2019 • 12 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a query against a data mining model, you can create either a content query, which provides details about the patterns discovered in analysis, or you can create a prediction query, which uses the patterns in the model to make predictions for new data. For example, a content query for a time series model might provide additional details about the periodic structures that were detected, while a prediction query might give you predictions for the next 5-10 time slices. You can also retrieve metadata about the model by using a query.

This section explains how to create both kinds of queries for models that are based on the Microsoft Time Series algorithm.

Content Queries

[Retrieving Periodicity Hints for the Model](#)

[Retrieving the Equation for an ARIMA Model](#)

[Retrieving the Equation for an ARTxp Model](#)

Prediction Queries

[Understanding When to Replace and When to Extend Time Series Data](#)

[Making Predictions with EXTEND_MODEL_CASES](#)

[Making Predictions with REPLACE_MODEL_CASES](#)

[Missing Value Substitution in Time Series Models](#)

Getting Information about a Time Series Model

A model content query can provide basic information about the model, such as the parameters that were used when the model was created, the time the model was last processed. The following example illustrates the basic syntax for querying the model content by using the data mining schema rowsets.

Sample Query 1: Retrieving Periodicity Hints for the Model

You can retrieve the periodicities that were found within the time series by querying the ARIMA tree or the ARTXP tree. However, the periodicities in the completed model might not be the same as the periods that you specified as hints when you created the model. To retrieve the hints that were supplied as parameters when you created the model, you can query the mining model content schema rowset by using the following DMX statement:

```
SELECT MINING_PARAMETERS  
FROM $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = '<model name>'
```

Partial results:

MINING_PARAMETERS

```
COMPLEXITY_PENALTY=0.1,MINIMUM_SUPPORT=10,PERIODICITY_HINT={1,3},....
```

The default periodicity hint is {1} and appears in all models; this sample model was created with an additional hint that might not be present in the final model.

NOTE

The results have been truncated here for readability.

Sample Query 2: Retrieving the Equation for an ARIMA Model

You can retrieve the equation for an ARIMA model by querying any node in an individual tree. Remember that each tree within an ARIMA model represents a different periodicity, and if there are multiple data series, each data series will have its own set of periodicity trees. Therefore, to retrieve the equation for a specific data series you must identify the tree first.

For example, the TA prefix tells you that the node is part of an ARIMA tree, whereas the TS prefix is used for ARTXP trees. You can find all ARIMA root trees by querying the model content for nodes with a NODE_TYPE value of 27. You can also use the value of ATTRIBUTE_NAME to find the ARIMA root node for a particular data series. This query example finds the ARIMA nodes that represent quantities sold of the R250 model in the Europe region.

```
SELECT NODE_UNIQUE_NAME  
FROM Forecasting.CONTENT  
WHERE ATTRIBUTE_NAME = 'R250 Europe: Quantity'  
AND NODE_TYPE = 27
```

By using this node ID, you can retrieve details about the ARIMA equation for this tree. The following DMX statement retrieves the short form of the ARIMA equation for the data series. It also retrieves the intercept from the nested table, NODE_DISTRIBUTION. In this example, the equation is obtained by referencing the node unique ID TA00000007. However, you may have to use a different node ID, and you may obtain slightly different results from your model.

```
SELECT FLATTENED NODE_CAPTION as [Short equation],  
(SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE  
FROM NODE DISTRIBUTION) as t  
FROM Forecasting.CONTENT  
WHERE NODE_NAME = 'TA00000007'
```

Example results:

SHORT EQUATION	T.ATTRIBUTE_NAME	T.ATTRIBUTE_VALUE
ARIMA (2,0,7)x(1,0,2)(12)	R250 Europe:Quantity(Intercept)	15.24....
ARIMA (2,0,7)x(1,0,2)(12)	R250 Europe:Quantity(Periodicity)	1
ARIMA (2,0,7)x(1,0,2)(12)	R250 Europe:Quantity(Periodicity)	12

For more information about how to interpret this information, see [Mining Model Content for Time Series Models \(Analysis Services - Data Mining\)](#).

Sample Query 3: Retrieving the Equation for an ARTXP Model

For an ARTxp model, different information is stored at each level of the tree. For more information about the structure of an ARTxp model, and how to interpret the information in the equation, see [Mining Model Content for Time Series Models \(Analysis Services - Data Mining\)](#).

The following DMX statement retrieves information a part of the ARTxp tree that represents the quantity of sales for the R250 model in Europe.

NOTE

The name of the nested table column, VARIANCE, must be enclosed in brackets to distinguish it from the reserved keyword of the same name. The nested table columns, PROBABILITY and SUPPORT, are not included because they are blank in most cases.

```
SELECT NODE_CAPTION as [Split information],  
    (SELECT ATTRIBUTE_NAME, ATTRIBUTE_VALUE,  
        [VARIANCE]  
        FROM NODE_DISTRIBUTION) AS t  
    FROM Forecasting.CONTENT  
    WHERE NODE_ATTRIBUTE_NAME = 'R250 Europe:Quantity'  
    AND NODE_TYPE = 15
```

For more information about how to interpret this information, see [Mining Model Content for Time Series Models \(Analysis Services - Data Mining\)](#).

Creating Predictions on a Time Series Model

Beginning in SQL Server 2008 Enterprise, you can add new data to a time series model and automatically incorporate the new data into the model. You add new data to a time series mining model in one of two ways:

- Use a **PREDICTION JOIN** to join data in an external source to the training data.
- Use a singleton prediction query to provide data one slice at a time. For information about how to create a singleton prediction query, see [Data Mining Query Tools](#).

Understanding the Behavior of Replace and Extend Operations

When you add new data to a time series model, you can specify whether to extend or replace the training data:

- **Extend:** When you extend a data series, Analysis Services adds the new data at the end of the existing training data. The number of training cases also increases.

Extending the model cases is useful for continuously updating the model with new data. For example, if you want to make the training set grow over time, you would simply extend the model.

To extend the data, you create a **PREDICTION JOIN** on a time series model, specify the source of the new data, and use the **EXTEND_MODEL_CASES** argument.

- **Replace:** When you replace the data in the data series, Analysis Services keeps the trained model, but uses the new data values to replace some or all of the existing training cases. Therefore, the size of the training data never changes, but the cases themselves are continually being replaced with newer data. If you supply enough new data, you can replace the training data with a completely new series.

Replacing the model cases is useful when you want to train a model on one set of cases and then apply that model to a different data series.

To replace the data, you create a **PREDICTION JOIN** on a time series model, specify the source of the new data, and use the **REPLACE_MODEL_CASES** argument.

NOTE

You cannot make historical predictions when you add new data.

Regardless of whether you extend or replace the training data, predictions always begin at the time stamp that ends the original training set. In other words, if your new data contains n time slices, and you request predictions for time steps 1 through n, the predictions will coincide with the same period as the new data, and you will not get any new predictions.

To get new predictions for time periods that do not overlap with the new data, you must either start predictions at the time slice n+1, or make sure that you request additional time slices.

For example, assume that the existing model has six months' worth of data. You want to extend this model by adding the sales figures from the last three months. At the same time, you want to make a prediction about the next three months. To obtain only the new predictions when you add the new data, specify the starting point as time slice 4, and the ending point as time slice 7. You could also request a total of six predictions, but the time slices for the first three would overlap with the new data just added.

For query examples and more information about the syntax for using **REPLACE_MODEL_CASES** and **EXTEND_MODEL_CASES**, see [PredictTimeSeries \(DMX\)](#).

Making Predictions with EXTEND_MODEL_CASES

Prediction behavior differs depending on whether you extend or replace the model cases. When you extend a model, the new data is attached to the end of the series and the size of the training set increases. However, the time slices used for prediction queries always start at the end of the original series. Therefore, if you add three new data points and request six predictions, the first three predictions returned overlap with the new data. In this case, Analysis Services returns the actual new data points instead of making a prediction, until all the new data points are used up. Then, Analysis Services makes predictions based on the composite series.

This behavior lets you add new data, and then show your actual sales figures in the prediction chart, instead of seeing projections.

For example, to add three new data points and make three new predictions, you would do the following:

- Create a **PREDICTION JOIN** on a time series model, and specify the source of three months' of new data.
- Request predictions for six time slices. To do this, specify 6 time slices, where the starting point is time slice 1, and the ending point is time slice 7. This is true only for **EXTEND_MODEL_CASES**.
- To get only the new predictions, you specify the starting point as 4 and the ending point as 7.
- You must use the argument **EXTEND_MODEL_CASES**.

The actual sales figures are returned for the first three time slices, and predictions based on the extended model are returned for the next three time slices.

Making Predictions with REPLACE_MODEL_CASES

When you replace the cases in a model, the size of the model stays the same but Analysis Services replaces the individual cases in the model. This is useful for cross-prediction and scenarios in which maintaining the training data set at a consistent size is important.

For example, one of your stores has insufficient sales data. You could create a general model by averaging sales for all stores in a particular region and then training a model. Then, to make predictions for the store without sufficient sales data, you create a **PREDICTION JOIN** on the new sales data for just that store. When you do this, Analysis Services keeps the patterns derived from the regional model, but replaces the existing training cases with the data from the individual store. As a result, your prediction values will be closer to the trend lines

for the individual store.

When you use the **REPLACE_MODEL_CASES** argument, Analysis Services continually adds new cases to the end of the case set and deletes a corresponding number from the beginning of the case set. If you add more new data than was in the original training set, Analysis Services discards the earliest data. If you supply sufficient new values, the predictions can be based on completely new data.

For example, you trained your model on a case data set that contained 1000 rows. You then add 100 rows of new data. Analysis Services drops the first 100 rows from the training set and adds the 100 rows of new data to the end of the set for a total of 1000 rows. If you add 1100 rows of new data, only the most recent 1000 rows are used.

Here is another example. To add three new month's worth of data and make three new predictions, you would do the following actions:

- Create a **PREDICTION JOIN** on a time series model and use the **REPLACE_MODEL_CASE** argument.
- Specify the source of three months' of new data. This data might be from a completely different source than the original training data.
- Request predictions for six time slices. To do this, specify 6 time slices, or specify the starting point as time slice 1, and the ending point as time slice 7.

NOTE

Unlike **EXTEND_MODEL_CASES**, you cannot return the same values that you added as input data. All six values returned are predictions that are based on the updated model, which includes both old and new data.

NOTE

With **REPLACE_MODEL_CASES**, starting at timestamp 1 you get new predictions based on the new data, which replaces the old training data.

For query examples and more information about the syntax for using **REPLACE_MODEL_CASES** and **EXTEND_MODEL_CASES**, see [PredictTimeSeries \(DMX\)](#).

Missing Value Substitution in Time Series Models

When you add new data to a time series model by using a **PREDICTION JOIN** statement, the new dataset cannot have any missing values. If any series is incomplete, the model must supply the missing values by using either a null, a numeric means, a specific numeric mean, or a predicted value. If you specify **EXTEND_MODEL_CASES**, Analysis Services replaces the missing values with predictions based on the original model. If you use **REPLACE_MODEL_CASES**, Analysis Services replaces the missing values with the value that you specify in the *MISSING_VALUE_SUBSTITUTION* parameter.

List of Prediction Functions

All Microsoft algorithms support a common set of functions. However, the Microsoft Time Series algorithm supports the additional functions, listed in the following table.

Prediction Function	Usage

Lag (DMX)	Returns a number of time slices between the date of the current case and the last date of the training set. A typical use of this function is to identify recent training cases so that you can retrieve detailed data about the cases.
PredictNodeId (DMX)	Returns the node ID for the specified predictable column. A typical use of this function is to identify the node that generated a particular predicted value so that you can review the cases associated with the node, or retrieve the equation and other details.
PredictStdev (DMX)	Returns the standard deviation of the predictions in the specified predictable column. This function replaces the INCLUDE_STATISTICS argument, which is not supported for time series models.
PredictVariance (DMX)	Returns the variance of the predictions for the specified predictable column. This function replaces the INCLUDE_STATISTICS argument, which is not supported for time series models.
PredictTimeSeries (DMX)	Returns predicted historical values or future predicted values for a time series. You can also query time series models by using the general prediction function, Predict (DMX) .

For a list of the functions that are common to all Microsoft algorithms, see [General Prediction Functions \(DMX\)](#).
For the syntax of specific functions, see [Data Mining Extensions \(DMX\) Function Reference](#).

Plugin Algorithms

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In addition to the algorithms that Microsoft SQL Server Analysis Services provides, there are many other algorithms that you can use for data mining. Accordingly, Analysis Services provides a mechanism for "plugging in" algorithms that are created by third parties. As long as the algorithms follow certain standards, you can use them within Analysis Services just as you use the Microsoft algorithms. Plugin algorithms have all the capabilities of algorithms that SQL Server Analysis Services provides.

For a full description of the interfaces that Analysis Services uses to communicate with plugin algorithms, see the samples for creating a custom algorithm and custom model viewer that are published on [CodePlex](#) Web site.

Algorithm Requirements

To plug an algorithm into Analysis Services, you must implement the following COM interfaces:

IDMAgorithm

Implements an algorithm that produces models, and implements the prediction operations of the resulting models.

IDMAgorithmNavigation

Enables browsers to access the content of the models.

IDMPersist

Enables the models that the algorithm trains to be saved and loaded by Analysis Services.

IDMAgorithmMetadata

Describes the capabilities and input parameters of the algorithm.

IDMAgorithmFactory

Creates instances of the objects that implement the algorithm interface, and provides Analysis Services with access to the algorithm-metadata interface.

Analysis Services uses these COM interfaces to communicate with plugin algorithms. Although plugin algorithms that you use must support the Microsoft OLE DB for Data Mining specification, they do not have to support all the data mining options in the specification. You can use the [MINING_SERVICES](#) schema rowset to determine the capabilities of an algorithm. This schema rowset lists the data mining support options for each plugin algorithm provider.

You must register new algorithms before you use them with Analysis Services. To register an algorithm, include the following information in the .ini file of the instance of Analysis Services on which you want to include the algorithms:

- The algorithm name
- ProgID (this is optional and will only be included for plugin algorithms)
- A flag that indicates whether the algorithm is enabled or not

The following code sample illustrates how to register a new algorithm:

```
<ConfigurationSettings>
```

```
...
```

```
<DataMining>
...
<Algorithms>
...
<Sample_Plugin_Algorithm>
<Enabled>1</Enabled>
<ProgID>Microsoft.DataMining.SamplePlugInAlgorithm.Factory</ProgID>
</Sample_Plugin_Algorithm>
...
</Algorithms>
...
</DataMining>
...
</ConfigurationSettings>
```

Mining Structures (Analysis Services - Data Mining)

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The mining structure defines the data from which mining models are built: it specifies the source data view, the number and type of columns, and an optional partition into training and testing sets. A single mining structure can support multiple mining models that share the same domain. The following diagram illustrates the relationship of the data mining structure to the data source, and to its constituent data mining models.

The mining structure in the diagram is based on a data source that contains multiple tables or views, joined on the CustomerID field. One table contains information about customers, such as the geographical region, age, income and gender, while the related nested table contains multiple rows of additional information about each customer, such as products the customer has purchased. The diagram shows that multiple models can be built on one mining structure, and that the models can use different columns from the structure.

Model 1 Uses CustomerID, Income, Age, Region, and filters the data on Region.

Model 2 Uses CustomerID, Income, Age, Region and filters the data on Age.

Model 3 Uses CustomerID, Age, Gender, and the nested table, with no filter.

Because the models use different columns for input, and because two of the models additionally restrict the data that is used in the model by applying a filter, the models might have very different results even though they are based on the same data. Note that the CustomerID column is required in all models because it is the only available column that can be used as the case key.

This section explains the basic architecture of data mining structures: how you define a mining structure, how you populate it with data, and how you use it to create models. For more information about how to manage or export existing data mining structures, see [Management of Data Mining Solutions and Objects](#).

Defining a Mining Structure

Setting up a data mining structure includes the following steps:

- Define a data source.
- Select columns of data to include in the structure (not all columns need to be added to the model) and defining a key.

- Define a key for the structure, including the key for the bested table, if applicable.
- Specify whether the source data should be separate into a training set and testing set. This step is optional.
- Process the structure.

These steps are described in more detail in the following sections.

Data Sources for Mining Structures

When you define a mining structure, you use columns that are available in an existing data source view. A data source view is a shared object that lets you combine multiple data sources and use them as a single source. The original data sources are not visible to client applications, and you can use the properties of the data source view to modify data types, create aggregations, or alias columns.

If you build multiple mining models from the same mining structure, the models can use different columns from the structure. For example, you can create a single structure and then build separate decision tree and clustering models from it, with each model using different columns and predicting different attributes.

Moreover, each model can use the columns from the structure in different ways. For example, your data source view might contain an Income column, which you can bin in different ways for different models.

The data mining structure stores the definition of the data source and the columns in it in the form of *bindings* to the source data. For more information about data source bindings, see [Data Sources and Bindings \(SSAS Multidimensional\)](#). However, note that you can also create a data mining structure without binding it to a specific data source by using the DMX [CREATE MINING STRUCTURE \(DMX\)](#) statement.

Mining Structure Columns

The building blocks of the mining structure are the mining structure columns, which describe the data that the data source contains. These columns contain information such as data type, content type, and how the data is distributed. The mining structure does not contain information about how columns are used for a specific mining model, or about the type of algorithm that is used to build a model; this information is defined in the mining model itself.

A mining structure can also contain nested tables. A nested table represents a one-to-many relationship between the entity of a case and its related attributes. For example, if the information that describes the customer resides in one table, and the customer's purchases reside in another table, you can use nested tables to combine the information into a single case. The customer identifier is the entity, and the purchases are the related attributes. For more information about when to use nested tables, see [Nested Tables \(Analysis Services - Data Mining\)](#).

To create a data mining model in Visual Studio with Analysis Services projects, you must first create a data mining structure. The Data Mining wizard walks you through the process of creating a mining structure, choosing data, and adding a mining model.

If you create a mining model by using Data Mining Extensions (DMX), you can specify the model and the columns in it, and DMX will automatically create the required mining structure. For more information, see [CREATE MINING MODEL \(DMX\)](#).

For more information, see [Mining Structure Columns](#).

Dividing the Data into Training and Testing Sets

When you define the data for the mining structure, you can also specify that some of the data be used for training, and some for testing. Therefore, it is no longer necessary to separate your data in advance of creating a data mining structure. Instead, while you create your model, you can specify that a certain percentage of the data be held out for testing, and the rest used for training, or you can specify a certain number of cases to use as the test data set. The information about the training and testing data sets is cached with the mining structure,

and as a result, the same test set can be used with all models that are based on that structure.

For more information, see [Training and Testing Data Sets](#).

Enabling Drillthrough

You can add columns to the mining structure even if you do not plan to use the column in a specific mining model. This is useful if, for example, you want to retrieve the e-mail addresses of customers in a clustering model, without using the e-mail address during the analysis process. To ignore a column during the analysis and prediction phase, you add it to the structure but do not specify a usage for the column, or set the usage flag to Ignore. Data flagged in this way can still be used in queries if drillthrough has been enabled on the mining model, and if you have the appropriate permissions. For example, you could review the clusters resulting from analysis of all customers, and then use a drillthrough query to get the names and e-mail addresses of customers in a particular cluster, even though those columns of data were not used to build the model.

For more information, see [Drillthrough Queries \(Data Mining\)](#).

Processing Mining Structures

A mining structure is just a metadata container until it is processed. When you process a mining structure, Analysis Services creates a cache that stores statistics about the data, information about how any continuous attributes are discretized, and other information that is later used by mining models. The mining model itself does not store this summary information, but instead references the information that was cached when the mining structure was processed. Therefore, you do not need to reprocess the structure each time you add a new model to an existing structure; you can process just the model.

You can opt to discard this cache after processing, if the cache is very large or you want to remove detailed data. If you do not want the data to be cached, you can change the **CacheMode** property of the mining structure to **ClearAfterProcessing**. This will destroy the cache after any models are processed. Setting the **CacheMode** property to **ClearAfterProcessing** will disable drillthrough from the mining model.

However, after you destroy the cache, you will not be able to add new models to the mining structure. If you add a new mining model to the structure, or change the properties of existing models, you would need to reprocess the mining structure first. For more information, see [Processing Requirements and Considerations \(Data Mining\)](#).

Viewing Mining Structures

You cannot use viewers to browse the data in a mining structure. However, in Visual Studio with Analysis Services projects, you can use the **Mining Structure** tab of Data Mining Designer to view the structure columns and their definitions. For more information, see [Data Mining Designer](#).

If you want to review the data in the mining structure, you can create queries by using Data Mining Extensions (DMX). For example, the statement `SELECT * FROM <structure>.CASES` returns all the data in the mining structure. To retrieve this information, the mining structure must have been processed, and the results of processing must be cached.

The statement `SELECT * FROM <model>.CASES` returns the same columns, but only for the cases in that particular model. For more information, see [SELECT FROM <structure>.CASES](#) and [SELECT FROM <model>.CASES \(DMX\)](#).

Using Data Mining Models with Mining Structures

A data mining model applies a mining model algorithm to the data that is represented by a mining structure. A mining model is an object that belongs to a particular mining structure, and the model inherits all the values of the properties that are defined by the mining structure. The model can use all the columns that the mining structure contains or a subset of the columns. You can add multiple copies of a structure column to a structure. You can also add multiple copies of a structure column to a model, and then assign different names, or *aliases*,

to each structure column in the model. For more information about aliasing structure columns, see [Create an Alias for a Model Column](#) and [Mining Model Properties](#).

For more information about the architecture of data mining models, see [Mining Models \(Analysis Services - Data Mining\)](#).

Mining Structure Columns

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You define the columns in a mining structure when you create the mining structure, by choosing columns of external data and then specifying how the data is to be used for modeling. Therefore, mining structure columns are more than copies of data from a data source: they define how the data from the source is to be used by the mining model. You can assign properties that determine how the data is discretized, properties that describe how the data values are distributed.

Mining structure columns are designed to be flexible and extensible, because each algorithm that you use to build a mining model may use different columns from the structure to interpret the data. Rather than have one set of data for each model, you can use a single mining structure and use the columns in it to customize the data for each model.

Defining Mining Structure Columns

The basic data types and content types that define structure columns are derived from the data source that you use to create the structure. You can change these settings within the mining structure, and you can also set modeling flags and set the distribution for continuous columns.

The definition of a mining structure column must contain the following information:

- **ID:** The unique name of the column, often the same as the name. This cannot be changed after you create the mining structure, whereas the name can be changed.
- **Name:** A name or alias for the column.
- **Content:** An enumeration that describes whether the data is discrete or continuous.
- **Type:** An enumeration that indicates the general data type.
- **Distribution:** An enumeration that describes the expected distribution of values. A distribution is included if the column is continuous.
- **Modeling flags:** An enumeration that indicates how to handle missing values and so forth. Modeling flags can also be defined on the mining model, but the model flags are different than the flags used on structure columns.
- **Bindings:** Properties that specify the source data.

Third-party algorithms may also include custom properties that can be defined on the mining structure column.

For more information about the data mining structure and the data mining model, see [Mining Structures \(Analysis Services - Data Mining\)](#).

[Mining Model Columns](#)

Data Types (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a mining model or a mining structure in Microsoft SQL Server Analysis Services, you must define the data types for each of the columns in the mining structure. The data type tells the analysis engine whether the data in the data source is numerical or text, and how the data should be processed. For example, if your source data contains numerical data, you can specify whether the numbers be treated as integers or by using decimal places.

Analysis Services supports the following data types for mining structure columns:

DATA TYPE	SUPPORTED CONTENT TYPES
Text	Cyclical, Discrete, Discretized, Key Sequence, Ordered, Sequence
Long	Continuous, Cyclical, Discrete, Discretized, Key, Key Sequence, Key Time, Ordered, Sequence, Time Classified
Boolean	Cyclical, Discrete, Ordered
Double	Continuous, Cyclical, Discrete, Discretized, Key, Key Sequence, Key Time, Ordered, Sequence, Time Classified
Date	Continuous, Cyclical, Discrete, Discretized, Key, Key Sequence, Key Time, Ordered

NOTE

The Time and Sequence content types are only supported by third-party algorithms. The Cyclical and Ordered content types are supported, but most algorithms treat them as discrete values and do not perform special processing.

The table also shows the *content types* supported for each data type.

The content type is specific to data mining and lets you customize the way that data is processed or calculated in the mining model. For example, even if your column contains numbers, you might need to model them as discrete values. If the column contains numbers, you can also specify that they be binned, or discretized, or specify that the model handle them as continuous values. Thus, the content type can have a huge effect on the model.. For a list of all the content types, see [Content Types \(Data Mining\)](#).

NOTE

In other machine learning systems, you might encounter the terms *nominal data, factors* or *categories, ordinal data, or sequence data*. In general, these correspond to content types. In SQL Server, the data type specifies only the value type for storage, not its usage in the model.

Specifying a Data Type

If you create the mining model directly by using Data Mining Extensions (DMX), you can define the data type for each column as you define the model, and Analysis Services will create the corresponding mining structure with the specified data types at the same time. If you create the mining model or mining structure by using a wizard, Analysis Services will suggest a data type, or you can choose a data type from a list.

Changing a Data Type

If you change the data type of a column, you must always reprocess the mining structure and any mining models that are based on that structure. Sometimes if you change the data type, that column can no longer be used in a particular model. In that case, Analysis Services will either raise an error when you reprocess the model, or will process the model but leave out that particular column.

Nested Tables (Analysis Services - Data Mining)

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In SQL Server Analysis Services, data must be fed to a data mining algorithm as a series of cases that are contained within a case table. However, not all cases can be described by a single row of data. For example, a case might be derived from two tables: one table that contains customer information, and another table that contains customer purchases. A single customer in the customer information table might have multiple items in the customer purchases table, which makes it difficult to describe the data by using a single row. Analysis Services provides a unique method for handling these cases, by using *nested tables*. The concept of a nested table is demonstrated in the following illustration.

In this diagram, the first table, which is the parent table, contains information about customers, and associates a unique identifier for each customer. The second table, the child table, contains the purchases for each customer. The purchases in the child table are related to the parent table by the unique identifier, the **CustomerKey** column. The third table in the diagram shows the two tables combined.

A nested table is represented in the case table as a special column that has a data type of **TABLE**. For any particular case row, this kind of column contains selected rows from the child table that pertain to the parent table.

The data in a nested table can be used for prediction or for input, or for both. For example, you might have two nested table columns in a model: one nested table column might contain a list of the products that a customer has purchased, while the other nested table column contains information about the customer's hobbies and interests, possibly obtained from a survey. In this scenario, you could use the customer's hobbies and interests as an input for analyzing purchasing behavior, and predicting likely purchases.

Joining Case Tables and Nested Tables

In order to create a nested table, the two source tables must contain a defined relationship so that the items in one table can be related to the other table. In Visual Studio with Analysis Services projects, you can define this relationship in the data source view.

NOTE

The **CustomerKey** field is the relational key that is used to link the case table and the nested table within the data source view definition, and to establish the relationship of the columns within the mining structure. However, typically you should not use this relational key in mining models built on that structure. Usually it is best to omit the relational key column from the mining model if it serves only to join the tables and does not provide information that is interesting for analysis.

You can create nested tables programmatically by either using Data Mining Extensions (DMX) or Analysis Management Objects (AMO), or you can use the Data Mining Wizard and Data Mining Designer in Visual Studio with Analysis Services projects.

Using Nested Table Columns in a Mining Model

In the case table, the key is often a customer ID, a product name, or date in a series: data that uniquely identifies a row in the table. . However, in nested tables, the key is typically not the relational key (or foreign key) but rather the column that represents the attribute that you are modeling.

For example, if the case table contains orders, and the nested table contains items in the order, you would be interested in modeling the relationship between items stored in the nested table across multiple orders, which are stored in the case table. Therefore, although the **Items** nested table is joined to the **Orders** case table by the relational key **OrderID**, you should not use **OrderID** as the nested table key. Instead, you would select the **Items** column as the nested table key, because that column contains the data that you want to model. In most cases, you can safely ignore **OrderID** in the mining model, because the relationship between the case table and the nested table has already been established by the data source view definition.

When you choose a column to use as the nested table key, you must ensure that the values in that column are unique for each case. For example, if the case table represents customers and the nested table represents items purchased by the customer, you must ensure that no item is listed more than one time per customer. If a customer has purchased the same item more than one time, you might want to create a different view that has a column that aggregates the count of purchases for each unique product.

How you decide to handle duplicate values in a nested table depends on the mining model that you are creating and the business problem that you are solving. In some scenarios you might not care how many times a customer has purchased a particular product, but want to check for the existence of at least one purchase. In other scenarios, the quantity and sequence of purchases might be very important.

If the order of items is important, you might need an additional column that indicates the sequence. When you use the sequence clustering algorithm to create a model, you must choose an additional *key sequence* column to represent the order of the items. The key sequence column is a special kind of nested key that is used only in sequence clustering models, and requires a unique numeric data type. For example, integers and dates can both be used as a key sequence column, but all sequence values must be unique. In addition to the key sequence column, a sequence clustering model also has a nested table key that represents the attribute that is being modeled, such as the products that have been purchased.

Using Non-Key Nested Columns from a Nested Table

After you have defined the join between the case table and the nested table, and you have chosen a column that contains interesting and unique attributes to use as the nested table key, you can include other columns from the nested table to use as input to the model. All columns from the nested table can be used for input, prediction and input, or for prediction only.

For example, if the nested table contains the columns **Product**, **ProductQuantity**, and **ProductPrice**, you might choose **Product** as the nested table key, but add **ProductQuantity** to the mining structure to use as input.

Filtering Nested Table Data

In SQL Server 2017, you can create filters on the data that is used to train or test a data mining model. A filter can be used to affect the composition of the model, or to test the model on a subset of cases. Filters can also be applied to nested tables. However, there are limitations on the syntax that can be used with nested tables.

Often when you apply a filter to a nested table you are testing for the existence or nonexistence of an attribute. For example, you can apply a filter that restricts the cases used in the model to only those cases that have a specified value in the nested table. Or, you could restrict the cases used in the model to customers who have not purchased

a particular item.

When you create filters on a nested table, you can also use operators such as greater than or less than. For example, you could restrict the cases used in the model to customers who had purchased at least n units of the target product. The ability to filter on nested table attributes provides great flexibility for customizing models.

For more information about how to create and use model filters, see [Filters for Mining Models \(Analysis Services - Data Mining\)](#).

Column Distributions (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

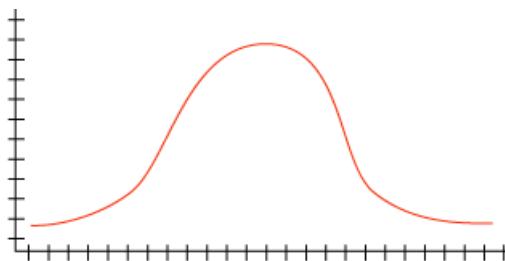

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, you can define column distributions in a mining structure, to affect how algorithms process the data in those columns when you create mining models. For some algorithms, it is useful to define the distribution of any continuous columns before you process the model, if the columns are known to contain common distributions of values. If you do not define the distributions, the resulting mining models may produce less accurate predictions than if the distributions were defined, because the algorithms will have less information from which to interpret the data.

The algorithms that are available in Analysis Services support the following distribution types:

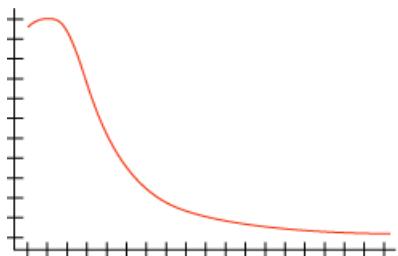

Normal

The values for the continuous column form a histogram with a normal distribution.

Log Normal

The values for the continuous column form a histogram, where the curve is elongated at the upper end and is skewed toward the lower end.

Uniform

The values for the continuous column form a flat curve, in which all values are equally likely.

For more information about the algorithms that Analysis Services provides, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

[Mining Structure Columns](#)

Discretization Methods (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Some algorithms that are used to create data mining models in SQL Server Analysis Services require specific content types in order to function correctly. For example, the Microsoft Naïve Bayes algorithm cannot use continuous columns as input and cannot predict continuous values. Additionally, some columns may contain so many values that the algorithm cannot easily identify interesting patterns in the data from which to create a model.

In these cases, you can discretize the data in the columns to enable the use of the algorithms to produce a mining model. *Discretization* is the process of putting values into buckets so that there are a limited number of possible states. The buckets themselves are treated as ordered and discrete values. You can discretize both numeric and string columns.

There are several methods that you can use to discretize data. If your data mining solution uses relational data, you can control the number of buckets to use for grouping data by setting the value of the [DiscretizationBucketCount](#) property. The default number of buckets is 5.

If your data mining solution uses data from an Online Analytical Processing (OLAP) cube, the data mining algorithm automatically computes the number of buckets to generate by using the following equation, where n is the number of distinct values of data in the column:

$$\text{Number of Buckets} = \sqrt{n}$$

If you do not want Analysis Services to calculate the number of buckets, you can use the [DiscretizationBucketCount](#) property to manually specify the number of buckets.

The following table describes the methods that you can use to discretize data in Analysis Services.

DISCRETIZATION METHOD	DESCRIPTION
AUTOMATIC	Analysis Services determines which discretization method to use.
CLUSTERS	<p>The algorithm divides the data into groups by sampling the training data, initializing to a number of random points, and then running several iterations of the Microsoft Clustering algorithm using the Expectation Maximization (EM) clustering method. The CLUSTERS method is useful because it works on any distribution curve. However, it requires more processing time than the other discretization methods.</p> <p>This method can only be used with numeric columns.</p>

DISCRETIZATION METHOD	DESCRIPTION
EQUAL AREAS	<p>The algorithm divides the data into groups that contain an equal number of values. This method is best used for normal distribution curves, but does not work well if the distribution includes a large number of values that occur in a narrow group in the continuous data. For example, if one-half of the items have a cost of 0, one-half the data will occur under a single point in the curve. In such a distribution, this method breaks the data up in an effort to establish equal discretization into multiple areas. This produces an inaccurate representation of the data.</p>

Remarks

- You can use the **EQUAL AREAS** method to discretize strings.
- The **CLUSTERS** method uses a random sample of 1000 records to discretize data. Use the **EQUAL AREAS** method if you do not want the algorithm to sample data.

Classified Columns (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you define a classified column, you create a relationship between the current column and another column in the mining structure. The data in the mining structure column that you designate as the classified column contains categorical information that describes the values in another column in the mining structure.

For example, suppose you have two columns with numerical data: one column, [Yearly Purchases], contains the total yearly purchases per customer for a specific calendar year, and the other column, [Standard Deviations], contains the standard deviations for those values. In this case you could designate the [Yearly Purchases] column as the classified column, and the model would be able to use this relationship in analysis.

NOTE

The algorithms provided in Analysis Services do not support the use of classified columns; this feature is provided for use in creating custom algorithms.

Defining a Classified Column

The data type of a classified column must be either **Long** or **Double**.

The following list describes the content types that Analysis Services supports for classified columns.

PROBABILITY

The value in the column is the probability of the associated value, and is a number between 0 and 1.

VARIANCE

The value in the column is the variance of the associated value.

STDEV

The value in the column is the standard deviation of the associated value.

PROBABILITY_VARIANCE

The value in the column is the variance of the probability for the associated value.

PROBABILITY_STDEV

The value in the column is the standard deviation of the probability for the associated value.

SUPPORT

The value in the column is the weight, or case replication factor, of the associated value.

Drillthrough on Mining Structures

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Drillthrough means the ability to query either a mining model or a mining structure and get detailed data that is not exposed in the model.

SQL Server 2017 provides two different options for drilling through into case data. You can drill through to the data that were used to build the mining model, or you can drill through to the source data in the mining structure.

Drillthrough to Model Cases vs. Drillthrough to Structure

Drilling through to **model cases** is useful for finding additional details about rules, patterns or clusters in a model.

In contrast, **drillthrough to structure** data is intended to provide access to information that was not made available in the model. For example, if you have the appropriate permissions, you might want to find out which rows of data were used for training the model and which were used for testing.

You can also view attributes of the data that were not used in analysis, provided they have been included in the structure definition. For example, often mining structures support many different kinds of models, and some structure columns might have been excluded from a model because the data type was incompatible or the data was not useful for analysis. For example, you would not use customer contact information in a clustering model, even if the data was included in the structure, but by enabling drillthrough you gain access to this information without running separate queries against the data source.

Enabling Drillthrough to Structure Data

To use drillthrough on the mining structure, the following conditions must be met:

- Drillthrough on the model must also be enabled. By default, drillthrough of both kinds is disabled. To enable drillthrough in the Data Mining Wizard, select the option to enable drillthrough to model cases on the final page of the wizard. You can also add the ability to drillthrough on a model later by changing the **AllowDrillthrough** property.
- If you create the mining structure by using DMX, use the WITH DRILLTHROUGH clause. For more information, see [CREATE MINING STRUCTURE \(DMX\)](#).
- Drillthrough works by retrieving information about the training cases that was cached when you processed the mining structure. Therefore, if you clear the cached data after processing the structure by changing the **MiningStructureCacheMode** property to **ClearAfterProcessing**, drillthrough will not work. To enable drillthrough to structure columns, you must change the **MiningStructureCacheMode** property to **KeepTrainingCases** and then reprocess the structure.
- Verify that both the mining structure and the mining model have the **AllowDrillThrough** property set to **True**. Moreover, you must be a member of a role that has drillthrough permissions on both the structure and the model.

Security Issues for Drillthrough

Drillthrough permissions are set separately on the structure and model. The model permission lets you drill through from the model, even if you do not have permissions on the structure. Drillthrough permissions on the structure provide the additional ability to include structure columns in drillthrough queries from the model, by

using the [StructureColumn \(DMX\)](#) function.

For information about how to create roles and assign permissions in Analysis Services, see [Role Designer \(Analysis Services - Multidimensional Data\)](#).

NOTE

If you enable drillthrough on both the mining structure and the mining model, any user who is a member of a role that has drillthrough permissions on the mining model can also view columns in the mining structure, even if those columns are not included in the mining model. Therefore, to protect sensitive data, you should set up the data source view to mask personal information, and allow drillthrough access on the mining structure only when necessary.

Related Tasks

See the following topics for more information about how to use drillthrough with mining models.

Use drillthrough to structure from the mining model viewers	Use Drillthrough from the Model Viewers

Properties for Mining Structure and Structure Columns

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can set or change the properties for a mining structure and for its associated columns and nested tables by using the **Mining Structure** tab of Data Mining Designer. Properties that you set in this tab are propagated to each mining model that is associated with the structure.

NOTE

If you change the value of any property in the mining structure, even metadata such as a name or description, the mining structure and its models must be reprocessed before you can view or query the model.

Properties of Mining Structures and Mining Structure Columns

The following table describes the properties for the mining structure and the mining structure columns that are specific to data mining, and that you can view or configure in the **Mining Structure** tab. To view or configure these properties, right-click an element in the tree view, and then click **Properties**.

- To view the properties of the structure, click the mining structure heading.
- To view the properties of a column or a nested table, click the column name.

Properties of the Mining Structure

PROPERTY	DESCRIPTION
CacheMode	Specifies whether cases used in training should be cached or discarded after training is completed. Note: This property must be set to KeepTrainingCases to enable drillthrough and holdout.
Collation	Specifies the default collation for the column. If a collation is not specified, the collation of the server is used.
Description	Describes the mining structure. As a best practice, the description should state the purpose and composition of the data in the structure.
ErrorConfiguration (default)	Specifies options for special handling of errors, if any.
HoldoutMaxCases	Specifies the maximum number of structure cases that can be reserved as a test data set. If values are specified for both HoldoutMaxCases and HoldoutPercent , the conditions are combined. Note: To set this property, CacheMode must be set to KeepTrainingCases .

PROPERTY	DESCRIPTION
HoldoutPercent	Specifies the percentage of the structure cases to reserve as a test data set. If values are specified for both HoldoutMaxCases and HoldoutPercent , the conditions are combined. Note: To set this property, CacheMode must be set to KeepTrainingCases .
HoldoutSeed	Specifies a seed to initialize partitioning of the holdout test set, to ensure that the test data set can be re-created. Note: To set this property, CacheMode must be set to KeepTrainingCases .
ID	Displays the unique identifier of the mining structure. The name that you assigned to the mining structure when you created the structure is used as the ID. If you later change the name by typing a new value for the Name property, the new name is used as an alias only; the ID does not change.
Language	Specifies the language for the captions in the mining structure.
Name	Specifies the name or alias of the mining structure. If you change the value for the Name property, the new name is used as a caption or alias only; the identifier for the mining structure does not change.
Source	Displays the name of the data source, and the type of data source.

Properties of the Mining Structure Columns

PROPERTY	DESCRIPTION
ClassifiedColumns	Identifies the column that a classified column describes.
Content	The content type of the column.
Description	Describes the column. As a best practice, the description of the column should provide information about how the data in the column has been derived or altered for data mining.
DiscretizationBucketCount	Displays the number of buckets in the discretized column. Enabled only if the content type is set to Discretized . This property is read-only.
DiscretizationMethod	Displays the method that was used to discretize the column. Enabled only if the content type is set to Discretized . This property is read-only.
Distribution	Specifies the distribution of content in the column.

PROPERTY	DESCRIPTION
ID	Displays the identifier of the column. If you change the value of the Name property of the column, it does not affect the value of the ID property.
IsKey	Indicates whether the column is a key column.
KeyColumns	Contains the definition of a column that is the key or is part of the key for an attribute.
ModelingFlags	Sets additional parameters that are made available by the algorithm.
Name	The name of the column.
NameColumn	Identifies the column that provides the name of the parent element.
Source	Displays the source of the column. For relational data sources, the value is always (none) . For structures based on an OLAP cube, the value is the MDX statement that defines the slice used as the source for the nested table.
SourceMeasureGroup	Displays the source of the measure group. For relational data sources, the value is always (none) . For structures based on an OLAP cube, the value is the MDX statement that defines the slice used as the source for the nested table.
Type	The data type for the content in the column.

For more information about setting or changing properties, see [Mining Structure Tasks and How-tos](#).

Create a New Relational Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Use the Data Mining Wizard to create a new mining structure, using data from a relational database or other source, and then save the structure and any related models to a Microsoft SQL Server Analysis Services database.

To create a relational mining structure

1. In Solution Explorer, right-click the **Mining Structures** folder in an Analysis Services project, and then click **New Mining Structure**.

The Data Mining Wizard opens.

2. On the **Welcome to the Data Mining Wizard** page, click **Next**.
3. On the **Select the Definition Method** page, select **From existing relational database or data warehouse**, and then click **Next**.
4. On the **Select the Data Mining Technique** page, select the data mining algorithm that you want to use, and then click **Next**.

For more information about data mining algorithms, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

5. On the **Select Data Source View** page, under **Available data source views**, click the data source view that you want to use, and then click **Next**.

For more information about creating a data source view, see [Data Source Views in Multidimensional Models](#).

6. On the **Specify Table Types** page, under **Input tables**, select a case table and a nested table.
7. On the **Specify the Training Data** page, under **Mining model structure**, select the key, input, and predictable columns.

After you select the predictable column, you can click the **Suggest** button to open the **Suggest Related Columns** dialog box. You can accept the suggested columns by clicking **OK** in this dialog box to include the selected columns in the mining structure, or you can change the selections in the **Input** column first, and then click **OK**. To ignore the suggestions, click **Cancel**.

8. Click **Next**.
9. On the **Specify Columns' Content and Data Type** page, under **Mining model structure**, you can adjust the content type and data type for each column.

NOTE

You can click **Detect** to automatically detect whether a column contains continuous or discrete data. After you click this button, the column content and data types will be updated in the **Content Type** and **Data Type** columns. For more information about content types and data types, see [Content Types \(Data Mining\)](#) and [Data Types \(Data Mining\)](#).

10. Click **Next**.
11. On the **Completing the Wizard** page, provide a name for the mining structure and the related initial mining model that will be created, and then click **Finish**.

See Also

[Mining Structure Tasks and How-tos](#)

Create a New OLAP Mining Structure

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can use the Data Mining Wizard in Microsoft SQL Server Analysis Services to create a mining structure that uses data from a multidimensional model. Mining models that are based on OLAP cubes can use the column and values in fact tables, dimensions, and measure groups as attributes for analysis.

To create a new OLAP mining structure

1. In Solution Explorer in Visual Studio with Analysis Services projects, right-click the **Mining Structures** folder in an Analysis Services project, and then click **New Mining Structure** to open the Data Mining Wizard.
2. On the **Welcome to the Data Mining Wizard** page, click **Next**.
3. On the **Select the Definition Method** page, select **From existing cube**, and then click **Next**.

If you get an error with the message, Unable to retrieve a list of supported data mining algorithms, open the **Project Properties** dialog box and verify that you have specified the name of an Analysis Services instance that supports multidimensional models. You cannot create mining models on an instance of Analysis Services that supports tabular modeling.

4. On the **Create the Data Mining Structure** page, decide whether you will create a mining structure only, or a mining structure plus one related mining model. Generally it is easier to create a mining model at the same time, so that you can be prompted to include necessary columns.

If you will create a mining model, select the data mining algorithm that you want to use, and then click **Next**. For more information about how to choose an algorithm, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

5. On the **Select the Source Cube Dimension** page, under **Select a Source Cube Dimension**, locate the dimension that contains the majority of your case data.

For example, if you are trying to identify customer groupings, you might choose the Customer dimension; if you are trying to analyze purchases across transactions, you might choose the Internet Sales Order Details dimension. You are not restricted to using only the data in this dimension, but it should contain important attributes to use in analysis.

Click **Next**.

6. On the **Select the Case Key** page, under **Attributes**, select the attribute that will be the key of the mining structure, and then click **Next**.

Typically the attribute that you use as key for the mining structure is also a key for the dimension and will be pre-selected.

7. On the **Select Case Level Columns** page, under **Related Attributes and Measures**, select the attributes and measures that contain values you want to add to the mining structure as case data. Click **Next**.
8. On the **Specify Mining Model Column Usage** page, under **Mining model structure**, first set the predictable column, and then choose columns to use as inputs.
 - Select the checkbox in the leftmost column to include the data in the mining structure. You can include columns in the structure that you will use for reference, but not use them for analysis.

- Select the checkbox in the **Input** column to use the attribute as a variable in analysis.
- Select the checkbox in the **Predict** column only for predictable attributes.

Note that columns you have designated as keys cannot be used for input or prediction.

Click **Next**.

9. On the **Specify Mining Model Column Usage** page, you can also add and remove nested tables to the mining structure, using **Add Nested Tables** and **Nested Tables**.

In an OLAP mining model, a nested table is another set of data within the cube that has a one-to-many relationship with the dimension that represents the case attributes. Therefore, when the dialog box opens, it pre-selects measure groups that are already related to the dimension you selected as the case table. At this point, you would choose a different dimension that contains additional information useful for analysis.

For example, if you are analyzing customers, you would use the [Customer] dimension as the case table. For the nested table, you might add the reason customers cited when making a purchase, which is included in the [Sales Reason] dimension.

If you add nested data, you must specify two additional columns:

- The key of the nested table: This should be pre-selected on the page, **Select Nested Table Key**.
- The attributes or attributes to use for analysis: The page, **Select Nested Table Columns**, provides a list of measures and attributes in the nested table selection.
 - For each attribute that you include in the model, check the box in the left column.
 - If you want to use the attribute for analysis only, check **Input**.
 - If you want to include the column as one of the predictable attributes for the model, select **Predict**.
 - Any item that you include in the structure but do not specify as an input or predictable attribute is added to the structure with the flag **Ignore**; this means that the data is processed when you build the model but is not used in analysis, and is available only for drillthrough. This can be handy if you want to include details such as customer names but don't want to use them in analysis.

Click **Finish** to close the part of the wizard that works with nested tables. You can repeat the process to add multiple nested columns.

10. On the **Specify Columns' Content and Data Type** page, under **Mining model structure**, set the content type and data type for each column.

NOTE

OLAP mining models do not support using the **Detect** feature to automatically detect whether a column contains continuous or discrete data.

Click **Next**.

11. On the **Slice Source Cube** page, you can filter the data that is used to create the mining structure.

Slicing the cube lets you restrict the data that is used to build the model. For example, you could build separate models for each region by slicing on the Geography hierarchy and

- **Dimension:** Choose a related dimension from the dropdown list.

- **Hierarchy:** Select the level of the dimension hierarchy at which you want to apply the filter. For example, if you are slicing by the [Geography] dimension, you would choose a hierarchy level such as [Region Country Name].
 - **Operator:** Choose an operator from the list.
 - **Filter Expression:** Type a value or expression to serve as the filter condition, or use the dropdown list to select a value from the list of members at the specified level of the hierarchy.
- For example, if you selected [Geography] as the dimension and [Region Country Name] as the hierarchy level, the dropdown list contains all the valid countries that you can use as a filter condition. You can make multiple selections. As a result, the data in the mining structure will be limited to cube data from these geographical areas.
- **Parameters:** Ignore this check box. This dialog box supports multiple cube filtering scenarios and this option is not relevant to building a mining structure.

Click **Next**.

12. On the **Split data into training and testing sets** page, specify a percentage of the mining structure data to reserve for testing, or specify the maximum number of test cases. Click **Next**.
If you specify both values, the limits are combined to use whichever is lowest.
13. On the **Completing the Wizard** page, provide a name for the new OLAP mining structure and the initial mining model.
14. Click **Finish**.

15. On the **Completing the Wizard** page, you also have the option to create a mining model dimension and/or a cube using the mining model dimension. These options are supported only for models built using the following algorithms:

- Microsoft Clustering algorithm
- Microsoft Decision Trees algorithm
- Microsoft Association Rules algorithm

Create mining model dimension: Select this check box and provide a type name for the mining model dimension. When you use this option, a new dimension is created within the original cube that was used to build the mining structure. You can use this dimension to drill down and conduct further analysis. Because the dimension is located within the cube, the dimension is automatically mapped to the case data dimension.

Create cube using mining model dimension: Select this check box, and provide a name for the new cube. When you use this option, a new cube is created that contains both the existing dimensions that were used in building the structure, and the new data mining dimension that contains the results from the model.

[Mining Structure Tasks and How-tos](#)

Add Columns to a Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Use Data Mining Designer in Visual Studio with Analysis Services projects to add columns to a mining structure after you have defined it in the Data Mining Wizard. You can add any column that exists in the data source view that was used to define the mining structure.

NOTE

You can add multiple copies of columns to a mining structure; however, you should avoid using more than one instance of the column within the same model, to avoid false correlations between the source and the derived column.

To add a column to a mining structure

1. Select the **Mining Structure** tab in Data Mining Designer.
2. Right-click the mining structure and select **Add a Column**.

The **Select a Column** dialog box opens.

3. Under **Source table**, select the table in the data source view where the column resides.
4. Under **Source column**, select the column that you want to add to the mining structure.
5. Click **OK**.

NOTE

If you add a column that already exists, a copy will be included in the structure, and the name appended with a "1". You can change the name of the copied column to something more descriptive by typing a new name in the **Name** property of the mining structure column.

[Mining Structure Tasks and How-tos](#)

Remove Columns from a Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can use Data Mining Designer to remove columns from a mining structure after the structure has already been created. Reasons to remove a mining structure column might include the following:

- The mining structure contains multiple copies of a column and you want to avoid the use of duplicate data in a model.
- The data should be protected, but drillthrough has been enabled.
- The data is unused in modeling and should not be processed.

Deleting a column from the mining structure does not change the column in the data source view or in the external data; only metadata is deleted. However, when you change the columns used in a mining structure, you must reprocess the structure and any models based on it.

To remove a column from the mining structure

1. Select the **Mining Structure** tab in Data Mining Designer.
2. Expand the tree for the mining structure, to show all the columns.
3. Right-click the column that you want to delete, and then select **Delete**.
4. In the **Delete Objects** dialog box, click **OK**.

[Mining Structure Tasks and How-tos](#)

Add a Nested Table to a Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Use Data Mining Designer to add a nested table to a mining structure after it has been created by the Data Mining Wizard.

To add a nested table to a mining structure

1. Select the **Mining Structure** tab in Data Mining Designer.
2. Right-click the mining structure to which you want to add a table column.
3. Select **Add a Nested Table**.

The **Select a Nested Table Key Column** dialog box opens.

4. Under **Nested table**, select the table that you want to nest in the mining structure.
5. Under **Source column**, select the key column for the nested table.
6. Click **OK**.

A new table column that contains the key column is added to the mining structure. For information about how to add additional columns, see [Add Columns to a Mining Structure](#).

[Mining Structure Tasks and How-tos](#)

Change the Properties of a Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

There are two kinds of properties on a mining structure, both of which can be modified:

- Properties of the mining structure that affect the entire structure
- Properties on individual columns in the structure

Note that some properties are dependent on other property settings. For example, you cannot set properties that control binning behavior (such as [DiscretizationMethod](#) or [DiscretizationBucketCount](#)) until you have set the data type of the column to **Discretized**.

For more information about mining structure properties, see [Mining Structure Columns](#).

To change the properties of a mining structure

1. On the **Mining Structure** tab in Data Mining Designer, right-click either the mining structure or a column in the mining structure, and then select **Properties**.

The **Properties** window opens on the right side of the screen, if it was not already visible.

2. In the **Properties** window, select the value that corresponds to the property that you want to change, and then enter the new value.

The new value will take effect when you select a different element in the designer.

Process a Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Before you can browse or work with the mining models that are associated with a mining structure, you have to deploy the Analysis Services project and process the mining structure and mining models. Also, if you make a change to the mining structure or mining models, you will be prompted to redeploy and process them. Processing the structure in the **Mining Structure** tab of Data Mining Designer in Visual Studio with Analysis Services projects processes all the associated models.

You can process a mining structure by using these tools:

- Visual Studio with Analysis Services projects
- SQL Server Management Studio
- XMLA: Process command

For information about how to process individual models, see [Process a Mining Model](#).

To process a mining structure and all associated mining models using SQL Server Data Tools

1. Select **Process Mining Structure and All Models** from the **Mining Model** menu item in Visual Studio with Analysis Services projects.

If you made changes to the structure, you will be prompted to redeploy the structure before processing the models. Click **Yes**.

2. Click **Run** in the **Processing Mining Structure - <structure>** dialog box.

The **Process Progress** dialog box opens to display the details of model processing.

3. Click **Close** in the **Process Progress** dialog box after the models have completed processing.
4. Click **Close** in the **Processing Mining Structure - <structure>** dialog box.

[Mining Structure Tasks and How-tos](#)

Mining Models (Analysis Services - Data Mining)

7/16/2019 • 10 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A *mining model* is created by applying an algorithm to data, but it is more than an algorithm or a metadata container: it is a set of data, statistics, and patterns that can be applied to new data to generate predictions and make inferences about relationships.

This section explains what a data mining model is and what it can be used for: the basic architecture of models and structures, the properties of mining models, and ways to create and work with mining models.

Mining Model Architecture

[Defining Data Mining Models](#)

[Mining Model Properties](#)

[Mining Model Columns](#)

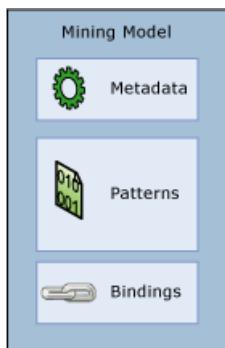

[Processing Mining Models](#)

[Viewing and Querying Mining Models](#)

Mining Model Architecture

A data mining model gets data from a mining structure and then analyzes that data by using a data mining algorithm. The mining structure and mining model are separate objects. The mining structure stores information that defines the data source. A mining model stores information derived from statistical processing of the data, such as the patterns found as a result of analysis.

A mining model is empty until the data provided by the mining structure has been processed and analyzed. After a mining model has been processed, it contains metadata, results, and bindings back to the mining structure.

The metadata specifies the name of the model and the server where it is stored, as well as a definition of the model, including the columns from the mining structure that were used in building the model, the definitions of any filters that were applied when processing the model, and the algorithm that was used to analyze the data. All these choices—the data columns and their data types, filters, and algorithm—have a powerful influence on the results of analysis.

For example, you can use the same data to create multiple models, using perhaps a clustering algorithm, decision tree algorithm, and Naïve Bayes algorithm. Each model type creates different set of patterns, itemsets, rules, or formulas, which you can use for making predictions. Generally each algorithm analyses the data in a different way, so the *content* of the resulting model is also organized in different structures. In one type of model, the data

and patterns might be grouped in *clusters*; in another type of model, data might be organized into trees, branches, and the rules that divide and define them.

The model is also affected by the data that you train it on: even models trained on the same mining structure can yield different results if you filter the data differently or use different seeds during analysis. However, the actual data is not stored in the model-only summary statistics are stored, with the actual data residing in the mining structure. If you have created filters on the data when you trained the model, the filter definitions are saved with the model object as well.

The model does contain a set of bindings, which point back to the data cached in the mining structure. If the data has been cached in the structure and has not been cleared after processing, these bindings enable you to drill through from the results to the cases that support the results. However, the actual data is stored in the structure cache, not in the model.

[Mining Model Architecture](#)

Defining Data Mining Models

You create a data mining model by following these general steps:

- Create the underlying mining structure and include the columns of data that might be needed.
- Select the algorithm that is best suited to the analytical task.
- Choose the columns from the structure to use in the model, and specify how they should be used—which column contains the outcome you want to predict, which columns are for input only, and so forth.
- Optionally, set parameters to fine-tune the processing by the algorithm.
- Populate the model with data by *processing* the structure and model.

Analysis Services provides the following tools to help you manage your mining models:

- The Data Mining Wizard helps you create a structure and related mining model. This is the easiest method to use. The wizard automatically creates the required mining structure and helps you with the configuration of the important settings.
- A DMX CREATE MODEL statement can be used to define a model. The required structure is automatically created as part of the process; therefore, you cannot reuse an existing structure with this method. Use this method if you already know exactly which model you want to create, or if you want to script models.
- A DMX ALTER STRUCTURE ADD MODEL statement can be used to add a new mining model to an existing structure. Use this method if you want to experiment with different models that are based on the same data set.

You can also create mining models programmatically, by using AMO or XML/A, or by using other clients such as the Data Mining Client for Excel. For more information, see the following topics:

[Mining Model Architecture](#)

Mining Model Properties

Each mining model has properties that define the model and its metadata. These include the name, description, the date the model was last processed, permissions on the model, and any filters on the data that is used for training.

Each mining model also has properties that are derived from the mining structure, and that describe the columns of data used by the model. If any column used by the model is a nested table, the column can also have a separate filter applied.

In addition, each mining model contains two special properties: [Algorithm](#) and [Usage](#).

- **Algorithm property** Specifies the algorithm that is used to create the model. The algorithms that are available depend on the provider that you are using. For a list of the algorithms that are included with SQL Server Analysis Services, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#). The **Algorithm** property applies to the mining model and can be set only one time for each model. You can change the algorithm later but some columns in the mining model might become invalid if they are not supported by the algorithm that you choose. You must always reprocess the model following a change to this property.
- **Usage property** Defines how each column is used by the model. You can define the column usage as **Input**, **Predict**, **Predict Only**, or **Key**. The **Usage** property applies to individual mining model columns and must be set individually for every column that is included in a model. If the structure contains a column that you do not use in the model, the usage is set to **Ignore**. Examples of data that you might include in the mining structure but not use in analysis might be customer names or e-mail addresses. This way you can query them later without having to include them during the analysis phase.

You can change the value of mining model properties after you create a mining model. However, any change, even to the name of the mining model, requires that you reprocess the model. After you reprocess the model, you might see different results.

[Mining Model Architecture](#)

Mining Model Columns

The mining model contains columns of data that are obtained from the columns defined in the mining structure. You can choose which columns from the mining structure to use in the model, and you can create copies of the mining structure columns and then rename them or change their usage. As part of the model building process, you must also define the usage of the column by the model. That includes such information as whether the column is a key, whether it is used for prediction, or whether it can be ignored by the algorithm.

While you are building a model, rather than automatically adding every column of data that is available, it is recommended that you review the data in the structure carefully and include in the model only those columns that make sense for analysis. For example, you should avoid including multiple columns that repeat the same data, and you should avoid using columns that have mostly unique values. If you think a column should not be used, you do not need to delete it from the mining structure or mining model; instead, you can just set a flag on the column that specifies that it should be ignored when building the model. This means that the column will remain in the mining structure, but will not be used in the mining model. If you have enabled drillthrough from the model to the mining structure, you can retrieve the information from the column later.

Depending on which algorithm you choose, some columns in the mining structure might be incompatible with certain model types, or might give you poor results. For example, if your data contains continuous numeric data, such as an Income column, and your model requires discrete values, you might need to convert the data to discrete ranges or remove it from the model. In some cases the algorithm will automatically convert or bin the data for you, but the results might not always be what you want or expect. Consider making additional copies of the column and trying out different models. You can also set flags on the individual columns to indicate where special processing is required. For example, if your data contains nulls, you can use a modeling flag to control handling. If you want a particular column to be considered as a regressor in a model you can do that with a modeling flag.

After you have created the model, you can make changes such as adding or removing columns, or changing the name of the model. However, any change, even only to the model metadata, requires that you reprocess the model.

[Mining Model Architecture](#)

Processing Mining Models

A data mining model is an empty object until it is processed. When you process a model, the data that is cached by the structure is passed through a filter, if one has been defined in the model, and is analyzed by the algorithm. The algorithm computes a set of summary statistics that describes the data, identifies the rules and patterns within the data, and then uses these rules and patterns to populate the model.

After it has been processed, the mining model contains a wealth of information about the data and the patterns found through analysis, including statistics, rules, and regression formulas. You can use the custom viewers to browse this information, or you can create data mining queries to retrieve this information and use it for analysis and presentation.

[Mining Model Architecture](#)

Viewing and Querying Mining Models

After you have processed a model, you can explore it by using the custom viewers that are provided in Visual Studio with Analysis Services projects and SQL Server Management Studio. For

You can also create queries against the mining model either to make predictions, or to retrieve model metadata or the patterns created by the model. You create queries by using Data Mining Extensions (DMX).

Mining Model Columns

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A data mining model applies a mining model algorithm to the data that is represented by a mining structure. Like the mining structure, the mining model contains columns. A mining model is contained within the mining structure, and inherits all the values of the properties that are defined by the mining structure. The model can use all the columns that the mining structure contains or a subset of the columns.

You can define two additional pieces of information on a mining model column: usage, and modeling flags.

- **Usage** is a property that defines how the model uses the column. Columns can be used as input columns, key columns, or predictable columns.
- **Modeling flags** provide the algorithm with additional information about the data that is defined in the case table, so that the algorithm can build a more accurate model. You can define modeling flags programmatically by using the Data Mining Extensions (DMX) language, or in **Data Mining Designer** in Visual Studio with Analysis Services projects.

The following list describes the modeling flags that you can define on a mining model column.

MODEL_EXISTENCE_ONLY

Indicates that the presence of the attribute is more important than the values that are in the attribute column. For example, consider a case table that contains a list of order items that are associated with a particular customer. The table data includes the product type, ID, and cost of each item. For modeling purposes, the fact that the customer purchased a particular order item may be more important than the cost of the order item itself. In this case, the cost column should be marked as **MODEL_EXISTENCE_ONLY**.

REGRESSOR

Indicates that the algorithm can use the specified column in the regression formula of regression algorithms. This flag is supported by the Microsoft Decision Trees and Microsoft Time Series algorithms.

For more information about setting the usage property and defining modeling flags programmatically with DMX, see [CREATE MINING MODEL \(DMX\)](#). For more information about setting the usage property and defining modeling flags in Visual Studio with Analysis Services projects, see [Moving Data Mining Objects](#).

Content Types (Data Mining)

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, you can define both the physical data type for a column in a mining structure, and a logical content type for the column when used in a model.

The *data type* determines how algorithms process the data in those columns when you create mining models. Defining the data type of a column gives the algorithm information about the type of data in the columns, and how to process the data. Each data type in Analysis Services supports one or more content types for data mining.

The *content type* describes the behavior of the content that the column contains. For example, if the content in a column repeats in a specific interval, such as days of the week, you can specify the content type of that column as cyclical.

Some algorithms require specific data types and specific content types to be able to function correctly. For example, the Microsoft Naïve Bayes algorithm cannot use continuous columns as input, and cannot predict continuous values. Some content types, such as Key Sequence, are used only by a specific algorithm. For a list of the algorithms and the content types that each supports, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

The following list describes the content types that are used in data mining, and identifies the data types that support each type.

Discrete

Discrete means that the column contains a finite number of values with no continuum between values. For example, a gender column is a typical discrete attribute column, in that the data represents a specific number of categories.

The values in a discrete attribute column cannot imply ordering, even if the values are numeric. Moreover, even if the values used for the discrete column are numeric, fractional values cannot be calculated. Telephone area codes are a good example of discrete data that is numeric.

The **Discrete** content type is supported by all data mining data types.

Continuous

Continuous means that the column contains values that represent numeric data on a scale that allows interim values. Unlike a discrete column, which represents finite, countable data, a continuous column represents scalable measurements, and it is possible for the data to contain an infinite number of fractional values. A column of temperatures is an example of a continuous attribute column.

When a column contains continuous numeric data, and you know how the data should be distributed, you can potentially improve the accuracy of the analysis by specifying the expected distribution of values. You specify the column distribution at the level of the mining structure. Therefore, the setting applies to all models that are based on the structure. For more information, see [Column Distributions \(Data Mining\)](#).

The **Continuous** content type is supported by the following data types: **Date**, **Double**, and **Long**.

Discretized

Discretization is the process of putting values of a continuous set of data into buckets so that there are a limited number of possible values. You can discretize only numeric data.

Thus, the *discretized* content type indicates that the column contains values that represent groups, or buckets, of values that are derived from a continuous column. The buckets are treated as ordered and discrete values.

You can discretize your data manually, to ensure that you get the buckets you want, or you can use the discretization methods provided in SQL Server Analysis Services. Some algorithms perform discretization automatically. For more information, see [Change the Discretization of a Column in a Mining Model](#).

The **Discretized** content type is supported by the following data types: **Date**, **Double**, **Long**, and **Text**.

Key

The *key* content type means that the column uniquely identifies a row. In a case table, typically the key column is a numeric or text identifier. You set the content type to **key** to indicate that the column should not be used for analysis, only for tracking records.

Nested tables also have keys, but the usage of the nested table key is a little different. You set the content type to **key** in a nested table if the column is the attribute that you want to analyze. The values in the nested table key must be unique for each case but there can be duplicates across the entire set of cases.

For example, if you are analyzing the products that customers purchase, you would set content type to key for the **CustomerID** column in the case table, and set content type to key again for the **PurchasedProducts** column in the nested table.

NOTE

Nested tables are available only if you use data from an external data source that has been defined as an Analysis services data source view.

This content type is supported by the following data types: **Date**, **Double**, **Long**, and **Text**.

Key Sequence

The *key sequence* content type can only be used in sequence clustering models. When you set content type to **key sequence**, it indicates that the column contains values that represent a sequence of events. The values are ordered, but do not have to be an equal distance apart.

This content type is supported by the following data types: **Double**, **Long**, **Text**, and **Date**.

Key Time

The *key time* content type can only be used in time series models. When you set content type to **key time**, it indicates that the values are ordered and represent a time scale.

This content type is supported by the following data types: **Double**, **Long**, and **Date**.

Table

The *table* content type indicates that the column contains another data table, with one or more columns and one or more rows. For any particular row in the case table, this column can contain multiple values, all related to the parent case record. For example, if the main case table contains a listing of customers, you could have several columns that contain nested tables, such as a **ProductsPurchased** column, where the nested table lists

products bought by this customer in the past, and a **Hobbies** column that lists the interests of the customer.

The data type of this column is always **Table**.

Cyclical

The *cyclical* content type means that the column contains values that represent a cyclical ordered set. For example, the numbered days of the week is a cyclical ordered set, because day number one follows day number seven.

Cyclical columns are considered both ordered and discrete in terms of content type.

This content type is supported by all the data mining data types in Analysis Services. However, most algorithms treat cyclical values as discrete values and do not perform special processing.

Ordered

The *Ordered* content type also indicates that the column contains values that define a sequence or order. However, in this content type the values used for ordering do not imply any distance or magnitude relationship between values in the set. For example, if an ordered attribute column contains information about skill levels in rank order from one to five, there is no implied information in the distance between skill levels; a skill level of five is not necessarily five times better than a skill level of one.

Ordered attribute columns are considered to be discrete in terms of content type.

This content type is supported by all the data mining data types in Analysis Services. However, however, most algorithms treat ordered values as discrete values and do not perform special processing.

Classified

In addition to the preceding content types that are in common use with all models, for some data types you can use classified columns to define content types. For more information about classified columns, see [Classified Columns \(Data Mining\)](#).

Mining Model Properties

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Mining models have the following kinds of properties:

- Properties that are inherited from the mining structure that define the data type and content type of the data used by the model;
- Properties that are related to the algorithm used to create the mining model, including any customer parameters;
- Properties that define a filter on the model used to train the model.

The properties of a mining model are initially defined when you create the model; however, you can alter most properties later, including the algorithm parameters, filters, and column usage properties. You change properties by using the **Mining Models** tab of Data Mining Designer, or by using AMO or XMLA.

Whenever you change any property of a model, you must reprocess the model for the changes to be reflected in the model. Reprocessing is required even if the change only involves metadata, such as adding a column alias or description.

Properties of Models

The following table describes the properties that are specific to mining models. Additionally, there are properties that you can set on individual columns in the mining

PROPERTY	DESCRIPTION
Algorithm	Sets the algorithm type for the mining model.
AlgorithmParameters	Sets values for algorithm parameters that are available for each algorithm type.
Filter	Sets a filter that is applied to the data that is used for training and testing the mining model. The filter definition is stored with the model and can be used optionally when you create prediction queries, or when you test the accuracy of the model. The model filter is not optional when training the model.
Name	Sets the name of the mining model.
AllowDrillThrough	Specifies whether drill through is enabled on the mining model.

Properties of Model Columns

You can set the following data mining-specific properties for each column in a mining model. You can set these properties to a different value for each mining model in a mining structure.

PROPERTY	DESCRIPTION
Description	Describes the purpose of the mining column.
Name	Sets the name of the mining model column. You can type a new name, to provide an alias for the mining model column.
ModelingFlags	Sets any algorithm-specific flags for the column.
SourceColumnID	Indicates the name of the mining structure column on which the model column is based. This property is read-only.
Usage	Sets how the column will be used by the mining model.

Missing Values (Analysis Services - Data Mining)

7/16/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Handling *missing values* correctly is an important part of effective modeling. This section explains what missing values are, and describes the features provided in Analysis Services to work with missing values when building data mining structures and mining models.

Definition of Missing Values in Data Mining

A missing value can signify a number of different things. Perhaps the field was not applicable, the event did not happen, or the data was not available. It could be that the person who entered the data did not know the right value, or did not care if a field was not filled in.

However, there are many data mining scenarios in which missing values provide important information. The meaning of the missing values depends largely on context. For example, a missing value for the date in a list of invoices has a meaning substantially different from the lack of a date in column that indicates an employee hire date. Generally, Analysis Services treats missing values as informative and adjusts the probabilities to incorporate the missing values into its calculations. By doing so, you can ensure that models are balanced and do not weight existing cases too heavily.

Therefore, Analysis Services provides two distinctly different mechanisms for managing and calculating missing values. The first method controls the handling of nulls at the level of the mining structure. The second method differs in implementation for each algorithm, but generally defines how missing values are processed and counted in models that permit null values.

Specifying Handling of Nulls

In your data source, missing values might be represented in many ways: as nulls, as empty cells in a spreadsheet, as the value N/A or some other code, or as an artificial value such as 9999. However, for purposes of data mining, only nulls are considered missing values. If your data contains placeholder values instead of nulls, they can affect the results of the model, so you should replace them with nulls or infer correct values if possible. There are a variety of tools that you can use to infer and fill in appropriate values, such as the Lookup transformation or the Data Profiler task in SQL Server Integration Services, or the Fill By Example tool provided in the Data Mining Add-Ins for Excel.

If the task that you are modeling specifies that a column must never have missing values, you should apply the **NOT_NULL** modeling flag to the column when you define the mining structure. This flag indicates that processing should fail if a case does not have an appropriate value. If this error occurs when processing a model, you can log the error and take steps to correct the data that is supplied to the model.

Calculation of the Missing State

To the data mining algorithm, missing values are informative. In case tables, **Missing** is a valid state like any other. Moreover, a data mining model can use other values to predict whether a value is missing. In other words, the fact that a value is missing is not an error.

When you create a mining model, a **Missing** state is automatically added to the model for all discrete columns. For example, if the input column [Gender] contains two possible values, Male and Female, a third value is automatically added to represent the **Missing** value, and the histogram that shows the distribution of all values

for the column always includes a count of the cases with **Missing** values. If the Gender column is not missing any values, the histogram shows that the Missing state is found in 0 cases.

The rationale for including the **Missing** state by default becomes clear when you consider that your data might not have examples of all possible values, and you would not want the model to exclude the possibility just because there was no example in the data. For example, if sales data for a store showed that all customers who purchased a certain product happened to be women, you would not want to create a model that predicts that only women could purchase the product. Instead, Analysis Services adds a placeholder for the extra unknown value, called **Missing**, as a way of accommodating possible other states.

For example, the following table shows the distribution of values for the (All) node in the decision tree model created for the Bike Buyer tutorial. In the example scenario, the [Bike Buyer] column is the predictable attribute, where 1 indicates "Yes" and 0 indicates "No".

VALUE	CASES
0	9296
1	9098
Missing	0

This distribution shows that about half of the customers have purchased a bike, and half have not. This particular data set is very clean; therefore, every case has a value in the [Bike Buyer] column, and the count of **Missing** values is 0. However, if any case had a null in the [Bike Buyer] field, Analysis Services would count that row as a case with a **Missing** value.

If the input is a continuous column, the model tabulates two possible states for the attribute: **Existing** and **Missing**. In other words, either the column contains a value of some numeric data type, or it contains no value. For cases that have a value, the model calculates mean, standard deviation, and other meaningful statistics. For cases that have no value, the model provides a count of the **Missing** values and adjusts predictions accordingly. The method for adjusting the prediction differs depending on the algorithm and is described in the following section.

NOTE

For attributes in a nested table, missing values are not informative. For example, if a customer has not purchased a product, the nested **Products** table would not have a row corresponding to that product, and the mining model would not create an attribute for the missing product. However, if you are interested in customers who have not purchased certain products, you can create a model that is filtered on the non-existence of the products in the nested table, by using a NOT EXISTS statement in the model filter. For more information, see [Apply a Filter to a Mining Model](#).

Adjusting Probability for Missing States

In addition to counting values, Analysis Services calculates the probability of any value across the data set. The same is true for the **Missing** value. For example, the following table shows the probabilities for the cases in the previous example:

VALUE	CASES	PROBABILITY
0	9296	50.55%
1	9098	49.42%

Value	Cases	Probability
Missing	0	0.03%

It may seem odd that the probability of the **Missing** value is calculated as 0.03%, when the number of cases is 0. In fact, this behavior is by design, and represents an adjustment that lets the model handle unknown values gracefully.

In general, probability is calculated as the favorable cases divided by all possible cases. In this example, the algorithm computes the sum of the cases that meet a particular condition (`[Bike Buyer] = 1`, or `[Bike Buyer] = 0`), and divides that number by the total count of rows. However, to account for the **Missing** cases, 1 is added to the number of all possible cases. As a result, the probability for the unknown case is no longer zero, but a very small number, indicating that the state is merely improbable, not impossible.

The addition of the small **Missing** value does not change the outcome of the predictor; however, it enables better modeling in scenarios where the historical data does not include all possible outcomes.

NOTE

Data mining providers differ in the way they handle missing values. For example, some providers assume that missing data in a nested column is sparse representation, but that missing data in a non-nested column is missing at random.

If you are certain that all outcomes are specified in your data and want to prevent probabilities from being adjusted, you should set the NOT_NULL modeling flag on the column in the mining structure.

NOTE

Each algorithm, including custom algorithms that you may have obtained from a third-party plug-in, can handle missing values differently.

Special Handling of Missing Values in Decision Tree Models

The Microsoft Decision Trees algorithm calculates probabilities for missing values differently than in other algorithms. Instead of just adding 1 to the total number of cases, the decision trees algorithm adjusts for the **Missing** state by using a slightly different formula.

In a decision tree model, the probability of the **Missing** state is calculated as follows:

$$\text{StateProbability} = (\text{NodePriorProbability}) * (\text{StateSupport} + 1) / (\text{NodeSupport} + \text{TotalStates})$$

The Decision Trees algorithm provides an additional adjustment that helps the algorithm compensate for the presence of filters on the model, which may result in many states to be excluded during training.

In SQL Server 2017, if a state is present during training but just happens to have zero support in a certain node, the standard adjustment is made. However, if a state is never encountered during training, the algorithm sets the probability to exactly zero. This adjustment applies not only to the **Missing** state, but also to other states that exist in the training data but have zero support as result of model filtering.

This additional adjustment results in the following formula:

$$\text{StateProbability} = 0.0 \text{ if that state has 0 support in the training set}$$

$$\text{ELSE } \text{StateProbability} = (\text{NodePriorProbability}) * (\text{StateSupport} + 1) / (\text{NodeSupport} + \text{TotalStatesWithNonZeroSupport})$$

The net effect of this adjustment is to maintain the stability of the tree.

[Modeling Flags \(Data Mining\)](#)

Feature Selection (Data Mining)

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Feature selection is an important part of machine learning. Feature selection refers to the process of reducing the inputs for processing and analysis, or of finding the most meaningful inputs. A related term, *feature engineering* (or *feature extraction*), refers to the process of extracting useful information or features from existing data.

Why Do Feature Selection?

Feature selection is critical to building a good model for several reasons. One is that feature selection implies some degree of *cardinality reduction*, to impose a cutoff on the number of attributes that can be considered when building a model. Data almost always contains more information than is needed to build the model, or the wrong kind of information. For example, you might have a dataset with 500 columns that describe the characteristics of customers; however, if the data in some of the columns is very sparse you would gain very little benefit from adding them to the model, and if some of the columns duplicate each other, using both columns could affect the model.

Not only does feature selection improve the quality of the model, it also makes the process of modeling more efficient. If you use unneeded columns while building a model, more CPU and memory are required during the training process, and more storage space is required for the completed model. Even if resources were not an issue, you would still want to perform feature selection and identify the best columns, because unneeded columns can degrade the quality of the model in several ways:

- Noisy or redundant data makes it more difficult to discover meaningful patterns.
- If the data set is high-dimensional, most data mining algorithms require a much larger training data set.

During the process of feature selection, either the analyst or the modeling tool or algorithm actively selects or discards attributes based on their usefulness for analysis. The analyst might perform feature engineering to add features, and remove or modify existing data, while the machine learning algorithm typically scores columns and validates their usefulness in the model.

In short, feature selection helps solve two problems: having too much data that is of little value, or having too little data that is of high value. Your goal in feature selection should be to identify the minimum number of columns from the data source that are significant in building a model.

How Feature Selection Works in SQL Server Data Mining

Feature selection is always performed before the model is trained. With some algorithms, feature selection techniques are "built-in" so that irrelevant columns are excluded and the best features are automatically discovered. Each algorithm has its own set of default techniques for intelligently applying feature reduction. However, you can also manually set parameters to influence feature selection behavior.

During automatic feature selection, a score is calculated for each attribute, and only the attributes that have the best scores are selected for the model. You can also adjust the threshold for the top scores. SQL Server Data Mining provides multiple methods for calculating these scores, and the exact method that is applied in any model depends on these factors:

- The algorithm used in your model
- The data type of the attribute
- Any parameters that you may have set on your model

Feature selection is applied to inputs, predictable attributes, or to states in a column. When scoring for feature selection is complete, only the attributes and states that the algorithm selects are included in the model-building process and can be used for prediction. If you choose a predictable attribute that does not meet the threshold for feature selection the attribute can still be used for prediction, but the predictions will be based solely on the global statistics that exist in the model.

NOTE

Feature selection affects only the columns that are used in the model, and has no effect on storage of the mining structure. The columns that you leave out of the mining model are still available in the structure, and data in the mining structure columns will be cached.

Feature Selection Scores

SQL Server Data Mining supports these popular and well-established methods for scoring attributes. The specific method used in any particular algorithm or data set depends on the data types, and the column usage.

- The *interestingness* score is used to rank and sort attributes in columns that contain nonbinary continuous numeric data.
- *Shannon's entropy* and two *Bayesian* scores are available for columns that contain discrete and discretized data. However, if the model contains any continuous columns, the interestingness score will be used to assess all input columns, to ensure consistency.

Interestingness score

A feature is interesting if it tells you some useful piece of information. However, *interestingness* can be measured in many ways. *Novelty* might be valuable for outlier detection, but the ability to discriminate between closely related items, or *discriminating weight*, might be more interesting for classification.

The measure of interestingness that is used in SQL Server Data Mining is *entropy-based*, meaning that attributes with random distributions have higher entropy and lower information gain; therefore, such attributes are less interesting. The entropy for any particular attribute is compared to the entropy of all other attributes, as follows:

$$\text{Interestingness(Attribute)} = - (m - \text{Entropy(Attribute)}) * (m - \text{Entropy(Attribute)})$$

Central entropy, or *m*, means the entropy of the entire feature set. By subtracting the entropy of the target attribute from the central entropy, you can assess how much information the attribute provides.

This score is used by default whenever the column contains nonbinary continuous numeric data.

Shannon's Entropy

Shannon's entropy measures the uncertainty of a random variable for a particular outcome. For example, the entropy of a coin toss can be represented as a function of the probability of it coming up heads.

Analysis Services uses the following formula to calculate Shannon's entropy:

$$H(X) = -\sum P(x_i) \log(P(x_i))$$

This scoring method is available for discrete and discretized attributes.

Bayesian with K2 Prior

SQL Server Data Mining provides two feature selection scores that are based on Bayesian networks. A Bayesian network is a *directed* or *acyclic* graph of states and transitions between states, meaning that some states are always prior to the current state, some states are posterior, and the graph does not repeat or loop. By definition, Bayesian networks allow the use of prior knowledge. However, the question of which prior states to use in calculating probabilities of later states is important for algorithm design, performance, and accuracy.

The K2 algorithm for learning from a Bayesian network was developed by Cooper and Herskovits and is often used in data mining. It is scalable and can analyze multiple variables, but requires ordering on variables used as input. For more information, see [Learning Bayesian Networks](#) by Chickering, Geiger, and Heckerman.

This scoring method is available for discrete and discretized attributes.

Bayesian Dirichlet Equivalent with Uniform Prior

The Bayesian Dirichlet Equivalent (BDE) score also uses Bayesian analysis to evaluate a network given a dataset. The BDE scoring method was developed by Heckerman and is based on the BD metric developed by Cooper and Herskovits. The Dirichlet distribution is a multinomial distribution that describes the conditional probability of each variable in the network, and has many properties that are useful for learning.

The Bayesian Dirichlet Equivalent with Uniform Prior (BDEU) method assumes a special case of the Dirichlet distribution, in which a mathematical constant is used to create a fixed or uniform distribution of prior states. The BDE score also assumes likelihood equivalence, which means that the data cannot be expected to discriminate equivalent structures. In other words, if the score for If A Then B is the same as the score for If B Then A, the structures cannot be distinguished based on the data, and causation cannot be inferred.

For more information about Bayesian networks and the implementation of these scoring methods, see [Learning Bayesian Networks](#).

Feature Selection Methods per Algorithm

The following table lists the algorithms that support feature selection, the feature selection methods used by the algorithm, and the parameters that you set to control feature selection behavior:

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Naive Bayes	Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	The Microsoft Naïve Bayes algorithm accepts only discrete or discretized attributes; therefore, it cannot use the interestingness score. For more information about this algorithm, see Microsoft Naïve Bayes Algorithm Technical Reference .
Decision trees	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	If any columns contain non-binary continuous values, the interestingness score is used for all columns, to ensure consistency. Otherwise, the default feature selection method is used, or the method that you specified when you created the model. For more information about this algorithm, see Microsoft Decision Trees Algorithm Technical Reference .

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Neural network	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	The Microsoft Neural Networks algorithm can use both Bayesian and entropy-based methods, as long as the data contains continuous columns. For more information about this algorithm, see Microsoft Neural Network Algorithm Technical Reference .
Logistic regression	Interestingness score Shannon's Entropy Bayesian with K2 Prior Bayesian Dirichlet with uniform prior (default)	Although the Microsoft Logistic Regression algorithm is based on the Microsoft Neural Network algorithm, you cannot customize logistic regression models to control feature selection behavior; therefore, feature selection always default to the method that is most appropriate for the attribute. If all attributes are discrete or discretized, the default is BDEU. For more information about this algorithm, see Microsoft Logistic Regression Algorithm Technical Reference .
Clustering	Interestingness score	The Microsoft Clustering algorithm can use discrete or discretized data. However, because the score of each attribute is calculated as a distance and is represented as a continuous number, the interestingness score must be used. For more information about this algorithm, see Microsoft Clustering Algorithm Technical Reference .
Linear regression	Interestingness score	The Microsoft Linear Regression algorithm can only use the interestingness score, because it only supports continuous columns. For more information about this algorithm, see Microsoft Linear Regression Algorithm Technical Reference .

ALGORITHM	METHOD OF ANALYSIS	COMMENTS
Association rules Sequence clustering	Not used	<p>Feature selection is not invoked with these algorithms.</p> <p>However, you can control the behavior of the algorithm and reduce the size of input data if necessary by setting the value of the parameters <code>MINIMUM_SUPPORT</code> and <code>MINIMUM_PROBABILITY</code>.</p> <p>For more information, see Microsoft Association Algorithm Technical Reference and Microsoft Sequence Clustering Algorithm Technical Reference.</p>
Time series	Not used	<p>Feature selection does not apply to time series models.</p> <p>For more information about this algorithm, see Microsoft Time Series Algorithm Technical Reference.</p>

Feature Selection Parameters

In algorithms that support feature selection, you can control when feature selection is turned on by using the following parameters. Each algorithm has a default value for the number of inputs that are allowed, but you can override this default and specify the number of attributes. This section lists the parameters that are provided for managing feature selection.

MAXIMUM_INPUT_ATTRIBUTES

If a model contains more columns than the number that is specified in the `MAXIMUM_INPUT_ATTRIBUTES` parameter, the algorithm ignores any columns that it calculates to be uninteresting.

MAXIMUM_OUTPUT_ATTRIBUTES

Similarly, if a model contains more predictable columns than the number that is specified in the `MAXIMUM_OUTPUT_ATTRIBUTES` parameter, the algorithm ignores any columns that it calculates to be uninteresting.

MAXIMUM_STATES

If a model contains more cases than are specified in the `MAXIMUM_STATES` parameter, the least popular states are grouped together and treated as missing. If any one of these parameters is set to 0, feature selection is turned off, affecting processing time and performance.

In addition to these methods for feature selection, you can improve the ability of the algorithm to identify or promote meaningful attributes by setting *modeling flags* on the model or by setting *distribution flags* on the structure. For more information about these concepts, see [Modeling Flags \(Data Mining\)](#) and [Column Distributions \(Data Mining\)](#).

[Customize Mining Models and Structure](#)

Modeling Flags (Data Mining)

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can use modeling flags in SQL Server Analysis Services to provide additional information to a data mining algorithm about the data that is defined in a case table. The algorithm can use this information to build a more accurate data mining model.

Some modeling flags are defined at the level of the mining structure, whereas others are defined at the level of the mining model column. For example, the **NOT NULL** modeling flag is used with mining structure columns. You can define additional modeling flags on the mining model columns, depending on the algorithm you use to create the model.

NOTE

Third-party plug-ins might have other modeling flags, in addition to those pre-defined by Analysis Services.

List of Modeling Flags

The following list describes the modeling flags that are supported in Analysis Services. For information about modeling flags that are supported by specific algorithms, see the technical reference topic for the algorithm that was used to create the model.

NOT NULL

Indicates that the values for the attribute column should never contain a null value. An error will result if Analysis Services encounters a null value for this attribute column during the model training process.

MODEL_EXISTENCE_ONLY

Indicates that the column will be treated as having two states: **Missing** and **Existing**. If the value is **NULL**, it is treated as Missing. The MODEL_EXISTENCE_ONLY flag is applied to the predictable attribute and is supported by most algorithms.

In effect, setting the MODEL_EXISTENCE_ONLY flag to **True** changes the representation of the values such that there are only two states: **Missing** and **Existing**. All the non-missing states are combined into a single **Existing** value.

A typical use for this modeling flag would be in attributes for which the **NULL** state has an implicit meaning, and the explicit value of the **NOT NULL** state might not be as important as the fact that the column has any value. For example, a [DateContractSigned] column might be **NULL** if a contract was never signed and **NOT NULL** if the contract was signed. Therefore, if the purpose of the model is to predict whether a contract will be signed, you can use the MODEL_EXISTENCE_ONLY flag to ignore the exact date value in the **NOT NULL** cases and distinguish only between cases where a contract is **Missing** or **Existing**.

NOTE

Missing is a special state used by the algorithm, and differs from the text value "Missing" in a column. For more information, see [Missing Values \(Analysis Services - Data Mining\)](#).

REGRESSOR

Indicates that the column is a candidate for used as a regressor during processing. This flag is defined on a

mining model column, and can only be applied to columns that have a continuous numeric data type. For more information about the use of this flag, see the section in this topic, [Uses of the REGRESSOR Modeling Flag](#).

Viewing and Changing Modeling Flags

You can view the modeling flags associated with a mining structure column or model column in Data Mining Designer by viewing the properties of the structure or model.

To determine which modeling flags have been applied to the current mining structure, you can create a query against the data mining schema rowset that returns the modeling flags for just the structure columns, by using a query like the following:

```
SELECT COLUMN_NAME, MODELING_FLAG  
FROM $system.DMSCHEMA_MINING_STRUCTURE_COLUMNS  
WHERE STRUCTURE_NAME = '<structure name>'
```

You can add or change the modeling flags used in a model by using the Data Mining Designer and editing the properties of the associated columns. Such changes require that the structure or model be reprocessed.

You can specify modeling flags in a new mining structure or mining model by using DMX, or by using AMO or XMLA scripts. However, you cannot change the modeling flags used in an existing mining model and structure by using DMX. You must create a new mining model by using the syntax,

```
ALTER MINING STRUCTURE....ADD MINING MODEL .
```

Uses of the REGRESSOR Modeling Flag

When you set the REGRESSOR modeling flag on a column, you are indicating to the algorithm that the column contains potential regressors. The actual regressors that are used in the model are determined by the algorithm. A potential regressor can be discarded if it does not model the predictable attribute.

When you build a model by using the Data Mining wizard, all continuous input columns are flagged as possible regressors. Therefore, even if you do not explicitly set the REGRESSOR flag on a column, the column might be used as a regressor in the model.

You can determine the regressors that were actually used in the processed model by performing a query against the schema rowset for the mining model, as shown in the following example:

```
SELECT COLUMN_NAME, MODELING_FLAG  
FROM $system.DMSCHEMA_MINING_COLUMNS  
WHERE MODEL_NAME = '<model name>'
```

Note If you modify a mining model and change the content type of a column from continuous to discrete, you must manually change the flag on the mining column and then reprocess the model.

Regressors in Linear Regression Models

Linear regression models are based on the Microsoft Decision Trees algorithm. Even if you do not use the Microsoft Linear Regression algorithm, any decision tree model can contain a tree or nodes that represents a regression on a continuous attribute.

Therefore, in these models you do not need to specify that a continuous column represents a regressor. The Microsoft Decision Trees algorithm will partition the dataset into regions with meaningful patterns even if you do not set the REGRESSOR flag on the column. The difference is that when you set the modeling flag, the algorithm will try to find regression equations of the following form to fit the patterns in the nodes of the tree.

$a*C1 + b*C2 + \dots$

Then, the sum of the residuals is calculated, and if the deviation is too great, a split is forced in the tree.

For example, if you are predicting customer purchasing behavior using **Income** as an attribute, and set the REGRESSOR modeling flag on the column, the algorithm would first try to fit the **Income** values by using a standard regression formula. If the deviation is too great, the regression formula is abandoned and the tree would be split on some other attribute. The decision tree algorithm would then try fit a regressor for income in each of the branches after the split.

You can use the FORCE_REGRESSOR parameter to guarantee that the algorithm will use a particular regressor. This parameter can be used with the Decision Trees algorithm and Linear Regression algorithm.

Mining Model Content (Analysis Services - Data Mining)

7/16/2019 • 22 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

After you have designed and processed a mining model using data from the underlying mining structure, the mining model is complete and contains *mining model content*. You can use this content to make predictions or analyze your data.

Mining model content includes metadata about the model, statistics about the data, and patterns discovered by the mining algorithm. Depending on the algorithm that was used, the model content may include regression formulas, the definitions of rules and itemsets, or weights and other statistics.

Regardless of the algorithm that was used, mining model content is presented in a standard structure. You can browse the structure in the Microsoft Generic Content Tree Viewer, provided in Visual Studio with Analysis Services projects, and then switch to one of the custom viewers to see how the information is interpreted and displayed graphically for each model type. You can also create queries against the mining model content by using any client that supports the MINING_MODEL_CONTENT schema rowset. For more information, see [Data Mining Query Tasks and How-tos](#).

This section describes the basic structure of the content provided for all kinds of mining models. It describes the node types that are common to all mining model content, and provides guidance on how to interpret the information.

[Structure of Mining Model Content](#)

[Nodes in the Model Content](#)

[Mining Model Content by Algorithm Type](#)

[Tools for Viewing Mining Model Content](#)

[Tools for Querying Mining Model Content](#)

Structure of Mining Model Content

The content of each model is presented as a series of *nodes*. A node is an object within a mining model that contains metadata and information about a portion of the model. Nodes are arranged in a hierarchy. The exact arrangement of nodes in the hierarchy, and the meaning of the hierarchy, depends on the algorithm that you used. For example, if you create a decision trees model, the model can contain multiple trees, all connected to the model root; if you create a neural network model, the model may contain one or more networks, plus a statistics node.

The first node in each model is called the *root node*, or the *model parent* node. Every model has a root node (NODE_TYPE = 1). The root node typically contains some metadata about the model, and the number of child nodes, but little additional information about the patterns discovered by the model.

Depending on which algorithm you used to create the model, the root node has a varying number of child nodes. Child nodes have different meanings and contain different content, depending on the algorithm and the depth and complexity of the data.

Nodes in Mining Model Content

In a mining model, a node is a general-purpose container that stores a piece of information about all or part of the model. The structure of each node is always the same, and contains the columns defined by the data mining schema rowset. For more information, see [DMSchema_Minining_Model_Content Rowset](#).

Each node includes metadata about the node, including an identifier that is unique within each model, the ID of the parent node, and the number of child nodes that the node has. The metadata identifies the model to which the node belongs, and the database catalog where that particular model is stored. Additional content provided in the node differs depending on the type of algorithm you used to create the model, and might include the following:

- Count of cases in the training data that supports a particular predicted value.
- Statistics, such as mean, standard deviation, or variance.
- Coefficients and formulas.
- Definition of rules and lateral pointers.
- XML fragments that describe a portion of the model.

List of Mining Content Node Types

The following table lists the different types of nodes that are output in data mining models. Because each algorithm processes information differently, each model generates only a few specific kinds of nodes. If you change the algorithm, the type of nodes may change. Also, if you reprocess the model, the content of each node may change.

NOTE

If you use a different data mining service, or if you create your own plug-in algorithms, additional custom node types may be available.

NODE_TYPE_ID	NODE_LABEL	NODE_CONTENTS
1	Model	Metadata and root content node. Applies to all model types.
2	Tree	Root node of a classification tree. Applies to decision tree models.
3	Interior	Interior split node in a tree. Applies to decision tree models.
4	Distribution	Terminal node of a tree. Applies to decision tree models.
5	Cluster	Cluster detected by the algorithm. Applies to clustering models and sequence clustering models.
6	Unknown	Unknown node type.

NODE_TYPE_ID	NODE_LABEL	NODE_CONTENTS
7	ItemSet	Itemset detected by the algorithm. Applies to association models or sequence clustering models.
8	AssociationRule	Association rule detected by the algorithm. Applies to association models or sequence clustering models.
9	PredictableAttribute	Predictable attribute. Applies to all model types.
10	InputAttribute	Input attribute. Applies to decision trees and Naïve Bayes models.
11	InputAttributeState	Statistics about the states of an input attribute. Applies to decision trees and Naïve Bayes models.
13	Sequence	Top node for a Markov model component of a sequence cluster. Applies to sequence clustering models.
14	Transition	Markov transition matrix. Applies to sequence clustering models.
15	TimeSeries	Non-root node of a time series tree. Applies to time series models only.
16	TsTree	Root node of a time series tree that corresponds to a predictable time series. Applies to time series models, and only if the model was created using the MIXED parameter.
17	NNetSubnetwork	One sub-network. Applies to neural network models.
18	NNetInputLayer	Group that contains the nodes of the input layer. Applies to neural network models.
19	NNetHiddenLayer	Groups that contains the nodes that describe the hidden layer. Applies to neural network models.
21	NNetOutputLayer	Groups that contains the nodes of the output layer. Applies to neural network models.
21	NNetInputNode	Node in the input layer that matches an input attribute with the corresponding states. Applies to neural network models.

NODE_TYPE_ID	NODE_LABEL	NODE_CONTENTS
22	NNetHiddenNode	Node in the hidden layer. Applies to neural network models.
23	NNetOutputNode	Node in the output layer. This node will usually match an output attribute and the corresponding states. Applies to neural network models.
24	NNetMarginalNode	Marginal statistics about the training set. Applies to neural network models.
25	RegressionTreeRoot	Root of a regression tree. Applies to linear regression models and to decision trees models that contains continuous input attributes.
26	NaiveBayesMarginalStatNode	Marginal statistics about the training set. Applies to Naïve Bayes models.
27	ArimaRoot	Root node of an ARIMA model. Applies to only those time series models that use the ARIMA algorithm.
28	ArimaPeriodicStructure	A periodic structure in an ARIMA model. Applies to only those time series models that use the ARIMA algorithm.
29	ArimaAutoRegressive	Autoregressive coefficient for a single term in an ARIMA model. Applies to only those time series models that use the ARIMA algorithm.
30	ArimaMovingAverage	Moving average coefficient for a single term in an ARIMA model. Applies to only those time series models that use the ARIMA algorithm.
1000	CustomBase	Starting point for custom node types. Custom node types must be integers greater in value than this constant. Applies to models created by using custom plug-in algorithms.

Node ID, Name, Caption and Description

The root node of any model always has the unique ID (**NODE_UNIQUE_NAME**) of 0. All node IDs are assigned automatically by Analysis Services and cannot be modified.

The root node for each model also contains some basic metadata about the model. This metadata includes the Analysis Services database where the model is stored (**MODEL_CATALOG**), the schema

(**MODEL_SCHEMA**), and the name of the model (**MODEL_NAME**). However, this information is repeated in all the nodes of the model, so you do not need to query the root node to get this metadata.

In addition to a name used as the unique identifier, each node has a *name* (**NODE_NAME**). This name is automatically created by the algorithm for display purposes and cannot be edited.

NOTE

The Microsoft Clustering algorithm allows users to assign friendly names to each cluster. However, these friendly names are not persisted on the server, and if you reprocess the model, the algorithm will generate new cluster names.

The *caption* and *description* for each node are automatically generated by the algorithm, and serve as labels to help you understand the content of the node. The text generated for each field depends on the model type. In some cases, the name, caption, and description may contain exactly the same string, but in some models, the description may contain additional information. See the topic about the individual model type for details of the implementation.

NOTE

Analysis Services server supports the renaming of nodes only if you build models by using a custom plug-in algorithm that implements renaming,. To enable renaming, you must override the methods when you create the plug-in algorithm.

Node Parents, Node Children, and Node Cardinality

The relationship between parent and child nodes in a tree structure is determined by the value of the PARENT_UNIQUE_NAME column. This value is stored in the child node and tells you the ID of the parent node. Some examples follow of how this information might be used:

- A PARENT_UNIQUE_NAME that is NULL means that the node is the top node of the model.
- If the value of PARENT_UNIQUE_NAME is 0, the node must be a direct descendant of the top node in the model. This is because the ID of the root node is always 0.
- You can use functions within a Data Mining Extensions (DMX) query to find descendants or parents of a particular node. For more information about using functions in queries, see [Data Mining Queries](#).

Cardinality refers to the number of items in a set. In the context of a processed mining model, cardinality tells you the number of children in a particular node. For example, if a decision tree model has a node for [Yearly Income], and that node has two child nodes, one for the condition [Yearly Income] = High and one for the condition, [Yearly Income] = Low, the value of CHILDREN_CARDINALITY for the [Yearly Income] node would be 2.

NOTE

In Analysis Services, only the immediate child nodes are counted when calculating the cardinality of a node. However, if you create a custom plug-in algorithm, you can overload CHILDREN_CARDINALITY to count cardinality differently. This may be useful, for example, if you wanted to count the total number of descendants, not just the immediate children.

Although cardinality is counted in the same way for all models, how you interpret or use the cardinality value differs depending on the model type. For example, in a clustering model, the cardinality of the top node tells you the total number of clusters that were found. In other types of models, cardinality may

always have a set value depending on the node type. For more information about how to interpret cardinality, see the topic about the individual model type.

NOTE

Some models, such as those created by the Microsoft Neural Network algorithm, additionally contain a special node type that provides descriptive statistics about the training data for the entire model. By definition, these nodes never have child nodes.

Node Distribution

The NODE DISTRIBUTION column contains a nested table that in many nodes provides important and detailed information about the patterns discovered by the algorithm. The exact statistics provided in this table change depending on the model type, the position of the node in the tree, and whether the predictable attribute is a continuous numeric value or a discrete value; however, they can include the minimum and maximum values of an attribute, weights assigned to values, the number of cases in a node, coefficients used in a regression formula, and statistical measures such as standard deviation and variance. For more information about how to interpret node distribution, see the topic for the specific type of model type that you are working with.

NOTE

The NODE DISTRIBUTION table may be empty, depending on the node type. For example, some nodes serve only to organize a collection of child nodes, and it is the child nodes that contain the detailed statistics.

The nested table, NODE DISTRIBUTION, always contains the following columns. The content of each column varies depending on the model type. For more information about specific model types, see [Mining Model Content by Algorithm Type](#).

ATTRIBUTE_NAME

Content varies by algorithm. Can be the name of a column, such as a predictable attribute, a rule, an itemset, or a piece of information internal to the algorithm, such as part of a formula.

This column can also contain an attribute-value pair.

ATTRIBUTE_VALUE

Value of the attribute named in ATTRIBUTE_NAME.

If the attribute name is a column, then in the most straightforward case, the ATTRIBUTE_VALUE contains one of the discrete values for that column.

Depending on how the algorithm processes values, the ATTRIBUTE_VALUE can also contain a flag that tells you whether a value exists for the attribute (**Existing**), or whether the value is null (**Missing**).

For example, if your model is set up to find customers who have purchased a particular item at least once, the ATTRIBUTE_NAME column might contain the attribute-value pair that defines the item of interest, such as `Model = 'Water bottle'`, and the ATTRIBUTE_VALUE column would contain only the keyword **Existing** or **Missing**.

SUPPORT

Count of the cases that have this attribute-value pair, or that contain this itemset or rule.

In general, for each node, the support value tells you how many cases in the training set are included in the current node. In most model types, support represents an exact count of cases. Support values are useful because you can view the distribution of data within your training cases without having to query the training data. The Analysis Services server also uses these stored values to calculate stored probability

versus prior probability, to determine whether inference is strong or weak.

For example, in a classification tree, the support value indicates the number of cases that have the described combination of attributes.

In a decision tree, the sum of support at each level of a tree sums to the support of its parent node. For example, if a model containing 1200 cases is divided equally by gender, and then subdivided equally by three values for Income-Low, Medium, and High-the child nodes of node (2), which are nodes (4), (5) and (6), always sum to the same number of cases as node (2).

NODE ID AND NODE ATTRIBUTES	SUPPORT COUNT
(1) Model root	1200
(2) Gender = Male	600
(3) Gender = Female	600
(4) Gender = Male and Income = High	200
(5) Gender = Male and Income = Medium	200
(6) Gender = Male and Income = Low	200
(7) Gender = Female and Income = High	200
(8) Gender = Female and Income = Medium	200
(9) Gender = Female and Income = Low	200

For a clustering model, the number for support can be weighted to include the probabilities of belonging to multiple clusters. Multiple cluster membership is the default clustering method. In this scenario, because each case does not necessarily belong to one and only one cluster, support in these models might not add up to 100 percent across all clusters.

PROBABILITY

Indicates the probability for this specific node within the entire model.

Generally, probability represents support for this particular value, divided by the total count of cases within the node (NODE_SUPPORT).

However, probability is adjusted slightly to eliminate bias caused by missing values in the data.

For example, if the current values for [Total Children] are 'One' and 'Two', you want to avoid creating a model that predicts that it is impossible to have no children, or to have three children. To ensure that missing values are improbable, but not impossible, the algorithm always adds 1 to the count of actual values for any attribute.

Example:

Probability of [Total Children = One] = [Count of cases where Total Children = One] + 1/[Count of all cases] + 3

Probability of [Total Children = Two] = [Count of cases where Total Children = Two] + 1/[Count of all cases] + 3

NOTE

The adjustment of 3 is calculated by adding 1 to the total number of existing values, n.

After adjustment, the probabilities for all values still add up to 1. The probability for the value with no data (in this example, [Total Children = 'Zero', 'Three', or some other value]), starts at a very low non-zero level, and rises slowly as more cases are added.

VARIANCE

Indicates the variance of the values within the node. By definition, variance is always 0 for discrete values. If the model supports continuous values, variance is computed as σ (sigma), using the denominator n, or the number of cases in the node.

There are two definitions in general use to represent standard deviation (**StDev**). One method for calculating standard deviation takes into account bias, and another method computes standard deviation without using bias. In general, Microsoft data mining algorithms do not use bias when computing standard deviation.

The value that appears in the NODE DISTRIBUTION table is the actual value for all discrete and discretized attributes, and the mean for continuous values.

VALUE_TYPE

Indicates the data type of the value or an attribute, and the usage of the value. Certain value types apply only to certain model types:

VALUE_TYPE_ID	VALUE_LABEL	VALUE_TYPE_NAME
1	Missing	Indicates that the case data did not contain a value for this attribute. The Missing state is calculated separately from attributes that have values.
2	Existing	Indicates that the case data contains a value for this attribute.
3	Continuous	Indicates that the value of the attribute is a continuous numeric value and therefore can be represented by a mean, together with variance and standard deviation.
4	Discrete	Indicates a value, either numeric or text, that is treated as discrete. Note Discrete values can also be missing; however, they are handled differently when making calculations. For information, see Missing Values (Analysis Services - Data Mining) .
5	Discretized	Indicates that the attribute contains numeric values that have been discretized. The value will be a formatted string that describes the discretization buckets.

Value_Type ID	Value Label	Value Type Name
6	Existing	Indicates that the attribute has continuous numeric values and that values have been supplied in the data, vs. values that are missing or inferred.
7	Coefficient	<p>Indicates a numeric value that represents a coefficient.</p> <p>A coefficient is a value that is applied when calculating the value of the dependent variable. For example, if your model creates a regression formula that predicts income based on age, the coefficient is used in the formula that relates age to income.</p>
8	Score gain	Indicates a numeric value that represents score gain for an attribute.
9	Statistics	Indicates a numeric value that represents a statistic for a regressor.
10	Node unique name	<p>Indicates that the value should not be handled not as numeric or string, but as the unique identifier of another content node in a model.</p> <p>For example, in a neural network model, the IDs provide pointers from nodes in the output layer to nodes in the hidden layer, and from nodes in the hidden layer to nodes in the input layer.</p>
11	Intercept	Indicates a numeric value that represents the intercept in a regression formula.
12	Periodicity	<p>Indicates that the value denotes a periodic structure in a model.</p> <p>Applies only to time series models that contain an ARIMA model.</p> <p>Note: The Microsoft Time Series algorithm automatically detects periodic structures based on the training data. As a result, the periodicities in the final model may include periodicity values that you did not provide as a parameter when creating the model.</p>

Value_Type_ID	Value_Label	Value_Type_Name
13	Autoregressive order	Indicates that the value represents the number of autoregressive series. Applies to time series models that use the ARIMA algorithm.
14	Moving average order	Represents a value that represents the number of moving averages in a series. Applies to time series models that use the ARIMA algorithm.
15	Difference order	Indicates that the value represents a value that indicates how many times the series is differentiated. Applies to time series models that use the ARIMA algorithm.
16	Boolean	Represents a Boolean type.
17	Other	Represents a custom value defined by the algorithm.
18	Prerendered string	Represents a custom value that the algorithm renders as a string. No formatting was applied by the object model.

The value types are derived from the ADMOMD.NET enumeration. For more information, see [Microsoft.AnalysisServices.AdomdServer.MiningValueType](#).

Node Score

The meaning of the node score differs depending on the model type, and can be specific to the node type as well. For information about how NODE_SCORE is calculated for each model and node type, see [Mining Model Content by Algorithm Type](#).

Node Probability and Marginal Probability

The mining model schema rowset includes the columns NODE_PROBABILITY and MARGINAL_PROBABILITY for all model types. These columns contain values only in nodes where a probability value is meaningful. For example, the root node of a model never contains a probability score.

In those nodes that do provide probability scores, the node probability and marginal probabilities represent different calculations.

- **Marginal probability** is the probability of reaching the node from its parent.
- **Node probability** is the probability of reaching the node from the root.
- **Node probability** is always less than or equal to **marginal probability**.

For example, if the population of all customers in a decision tree is split equally by gender (and no values are missing), the probability of the child nodes should be .5. However, suppose that each of the nodes for gender is divided equally by income levels-High, Medium, and Low. In this case the MARGINAL_PROBABILITY score for each child node should always be .33 but the NODE_PROBABILITY

value will be the product of all probabilities leading to that node and thus always less than the MARGINAL_PROBABILITY value.

LEVEL OF NODE/ATTRIBUTE AND VALUE	MARGINAL PROBABILITY	NODE PROBABILITY
Model root	1	1
All target customers		
Target customers split by gender	.5	.5
Target customers split by gender, and split again three ways by income	.33	.5 * .33 = .165

Node Rule and Marginal Rule

The mining model schema rowset also includes the columns NODE_RULE and MARGINAL_RULE for all model types. These columns contain XML fragments that can be used to serialize a model, or to represent some part of the model structure. These columns may be blank for some nodes, if a value would be meaningless.

Two kinds of XML rules are provided, similar to the two kinds of probability values. The XML fragment in MARGINAL_RULE defines the attribute and value for the current node, whereas the XML fragment in NODE_RULE describes the path to the current node from the model root.

Mining Model Content by Algorithm Type

Each algorithm stores different types of information as part of its content schema. For example, the Microsoft Clustering Algorithm generates many child nodes, each of which represents a possible cluster. Each cluster node contains rules that describe characteristics shared by items in the cluster. In contrast, the Microsoft Linear Regression algorithm does not contain any child nodes; instead, the parent node for the model contains the equation that describes the linear relationship discovered by analysis.

The following table provides links to topics for each type of algorithm.

- **Model content topics:** Explain the meaning of each node type for each algorithm type, and provide guidance about which nodes are of most interest in a particular model type.
- **Querying topics:** Provide examples of queries against a particular model type and guidance on how to interpret the results.

ALGORITHM OR MODEL TYPE	MODEL CONTENT	QUERYING MINING MODELS
Association rules models	Mining Model Content for Association Models (Analysis Services - Data Mining)	Association Model Query Examples
Clustering models	Mining Model Content for Decision Tree Models (Analysis Services - Data Mining)	Clustering Model Query Examples
Decision trees model	Mining Model Content for Decision Tree Models (Analysis Services - Data Mining)	Decision Trees Model Query Examples

ALGORITHM OR MODEL TYPE	MODEL CONTENT	QUERYING MINING MODELS
Linear regression models	Mining Model Content for Linear Regression Models (Analysis Services - Data Mining)	Linear Regression Model Query Examples
Logistic regression models	Mining Model Content for Logistic Regression Models (Analysis Services - Data Mining)	Linear Regression Model Query Examples
Naïve Bayes models	Mining Model Content for Naïve Bayes Models (Analysis Services - Data Mining)	Naïve Bayes Model Query Examples
Neural network models	Mining Model Content for Neural Network Models (Analysis Services - Data Mining)	Neural Network Model Query Examples
Sequence clustering	Mining Model Content for Sequence Clustering Models (Analysis Services - Data Mining)	Sequence Clustering Model Query Examples
Time series models	Mining Model Content for Time Series Models (Analysis Services - Data Mining)	Time Series Model Query Examples

Tools for Viewing Mining Model Content

When you browse or explore a model in Visual Studio with Analysis Services projects, you can view the information in the **Microsoft Generic Content Tree Viewer**, which is available in both Visual Studio with Analysis Services projects and SQL Server Management Studio.

The Microsoft Generic Content Viewer displays the columns, rules, properties, attributes, nodes, and other content from the model by using the same information that is available in the content schema rowset of the mining model. The content schema rowset is a generic framework for presenting detailed information about the content of a data mining model. You can view model content in any client that supports hierarchical rowsets. The viewer in Visual Studio with Analysis Services projects presents this information in an HTML table viewer that represents all models in a consistent format, making it easier to understand the structure of the models that you create. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#).

Tools for Querying Mining Model Content

To retrieve mining model content, you must create a query against the data mining model.

The easiest way to create a content query is to execute the following DMX statement in SQL Server Management Studio:

```
SELECT * FROM [<mining model name>].CONTENT
```

For more information, see [Data Mining Queries](#).

You can also query the mining model content by using the data mining schema rowsets. A schema rowset is a standard structure that clients use to discover, browse, and query information about mining structures and models. You can query the schema rowsets by using XMLA, Transact-SQL, or DMX statements.

In SQL Server 2017, you can also access the information in the data mining schema rowsets by opening a connection to the Analysis Services instance and querying the system tables. For more information, see [Data Mining Schema Rowsets \(SSAs\)](#).

Drillthrough on Mining Models

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Drillthrough means the ability to query either a mining model or a mining structure and get detailed data that is not exposed in the model.

SQL Server 2017 provides two different options for drilling through into case data. You can drill through to the cases that were used to build the data, or you can drill through to the cases in the mining structure.

Drillthrough to Model Cases vs. Drillthrough to Structure

Drilling through to **model cases** is useful for finding additional details about rules, patterns or clusters in a model. For example, you would not use customer contact information for analysis in a clustering model, even if the data was available, by using drillthrough, you can gain access to that information from the model.

In contrast, **drillthrough to structure** data is intended to provide access to information that was not made available in the model. For example, some structure columns might have been excluded from a model because the data type was incompatible or the data was not useful for analysis.

Enabling Drillthrough on a Model

To use drillthrough on a mining model, the following conditions must be met:

- It is possible to configure drillthrough on just the model cases and not on the mining structure, but not vice versa. In other words, drillthrough must be enabled on the mining model to permit drillthrough to the mining structure.
- Drillthrough on both model and structure is disabled by default. If you use the Data Mining Wizard, the option to enable drillthrough to the model cases is on the final page of the wizard.
- You can add the ability to drill through on an existing mining model, but if you do, the model must be reprocessed before you can drill through to the data.
- Drillthrough will not work unless the cache that was created during the training process has been preserved. For more information about the properties that control caching, see [Drillthrough on Mining Structures](#).

Models that Support Drillthrough

If a mining model has been configured to allow drillthrough, and if you have the appropriate permissions, when you browse the model, you can click on a node in the appropriate viewer and retrieve detailed information about the cases in that particular node.

Not all models support drillthrough; it depends on the algorithm that was used to create the model. The following table lists the types of models that do not support drillthrough, or support drillthrough with limitations. If the model type is not listed here, drillthrough is supported.

ALGORITHM NAME	SUPPORT FOR DRILLTHROUGH
----------------	--------------------------

ALGORITHM NAME	SUPPORT FOR DRILLTHROUGH
Microsoft Naïve Bayes algorithm	<p>Not supported.</p> <p>These algorithms do not assign cases to specific nodes in the content.</p>
Microsoft Neural Network algorithm	<p>Not supported.</p> <p>These algorithms do not assign cases to specific nodes in the content.</p>
Microsoft Logistic Regression algorithm	<p>Not supported.</p> <p>These algorithms do not assign cases to specific nodes in the content.</p>
Microsoft Linear Regression algorithm	<p>Supported.</p> <p>However, because the model creates a single node, All, drillthrough returns all the training cases for the model. If the training set is large, loading the results may take a very long time.</p>
Microsoft Time Series algorithm	<p>Supported.</p> <p>However, you cannot drill through to structure or case data by using the Mining Model Viewer in Data Mining Designer. You must create a DMX query instead.</p> <p>Also, you cannot drill through to specific nodes, or write a DMX query to retrieve cases in specific nodes of a time series model. You can retrieve case data from either the model or the structure by using other criteria, such as date or attribute values.</p> <p>If you wish to view details of the ARTXP and ARIMA nodes created by the Microsoft Time Series algorithm, it might be easier to use the Microsoft Generic Content Tree Viewer (Data Mining).</p>

Filters for Mining Models (Analysis Services - Data Mining)

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Data-based model filtering helps you create mining models that use subsets of data in a mining structure. Filtering gives you flexibility when you design your mining structures and data sources, because you can create a single mining structure, based on a comprehensive data source view. You can then create filters to use only a part of that data for training and testing a variety of models, instead of building a different structure and related model for each subset of data.

For example, you define the data source view on the Customers table and related tables. Next, you define a single mining structure that includes all the fields you need. Finally, you create a model that is filtered on a particular customer attribute, such as Region. You can then easily make a copy of that model, and change just the filter condition to generate a new model based on a different region.

Some real-life scenarios where you might benefit from this feature include the following:

- Creating separate models for discrete values such as gender, regions, and so forth. For example, a clothing store might use customer demographics to build separate models by gender, even though the sales data comes from a single data source for all customers.
- Experimenting with models by creating and then testing multiple groupings of the same data, such as ages 20-30 vs. ages 20-40 vs. ages 20-25.
- Specifying complex filters on nested table contents, such as requiring that a case be included in the model only if the customer has purchased at least two of a particular item.

This section explains how to build, use, and manage filters on mining models.

Creating Model Filters

You can create and apply filters in the following ways:

- Using the **Mining Models** tab in Data Mining Designer to build conditions with the help of filter editor dialog boxes.
- Typing a filter expression directly into the **Filter** property of the mining model.
- Setting filter conditions on a model programmatically, by using AMO.

Creating Model Filters using Data Mining Designer

You filter a model in Data Mining Designer by changing the **Filter** property of the mining model. You can either type a filter expression directly into the **Properties** pane, or you can open a filter dialog box to build conditions.

There are two filter dialog boxes. The first lets you create conditions that are applied to the case table. If the data source contains multiple tables, first you select a table, and then you select a column and specify operators and conditions that apply to that column. You can link multiple conditions by using **AND/OR** operators. The operators that are available for defining values depend on whether the column contains discrete or continuous values. For example, with continuous values, you can use **greater than** and **less than** operators. However, for discrete values, you can only use **= (equal to)**, **!= (not equal to)**, and **is null** operators.

NOTE

The **LIKE** keyword is not supported. If you want to include multiple discrete attributes, you must create separate conditions and link them by using the **OR** operator.

If the conditions are complex, you can use the second filter dialog box to work with one table at a time. When you close the second filter dialog box, the expression is evaluated and then combined with filter conditions that have been set on other columns in the case table.

Creating Filters on Nested Tables

If the data source view contains nested tables, you can use the second filter dialog box to build conditions on the rows in the nested tables.

For example, if your case table is related to customers, and the nested table shows the products that a customer has purchased, you can create a filter for customers who have purchased particular items by using the following syntax in the nested table filter: `[ProductName]='Water Bottle' OR ProductName='Water Bottle Cage'`.

You can also filter on the existence of a particular value in the nested table by using the **EXISTS** or **NOT EXISTS** keywords and a subquery. This lets you create conditions such as

`EXISTS (SELECT * FROM Products WHERE ProductName='Water Bottle')`. The `EXISTS SELECT(<subquery>)` returns **true** if the nested table contains at least one row that includes the value, `Water Bottle`.

You can combine conditions on the case table with conditions on the nested table. For example, the following syntax includes a condition on the case table (`Age > 30`), a subquery on the nested table (

`EXISTS (SELECT * FROM Products)`), and multiple conditions on the nested table (
`WHERE ProductName='Milk' AND Quantity>2`).

`(Age > 30 AND EXISTS (SELECT * FROM Products WHERE ProductName='Milk' AND Quantity>2))`

When you have finished building the filter, the filter text is evaluated by Analysis Services, translated to a DMX expression, and then saved with the model.

For instructions on how to use the filter dialog boxes in Visual Studio with Analysis Services projects, see [Apply a Filter to a Mining Model](#).

Managing Mining Model Filters

Data-based model filtering greatly simplifies the task of managing mining structures and mining models, because you can easily create multiple models that are based on the same structure. You can also quickly make copies of existing mining models and then change only the filter condition. However, filters can lead to some confusion.

Here are some frequently asked questions about how to manage and interpret filters on mining models:

How can I tell whether a filter is being used?

There are multiple ways to determine whether a filter is applied to a model:

- In the designer, click the **Mining Models** tab, open **Properties**, and view the **Filter** property of the mining model.
- The DMV, **DMSchema_Minining_Models**, outputs a column that contains the text of the filter. You can use the following query on a DMV to return the names of models and their filters:

```
SELECT MODEL_NAME, [FILTER]
FROM $SYSTEM.DMSCHEMA_MINING_MODELS
```

- You can get the value of the Filter property of the MiningModel object in AMO, or inspect the Filter element in XMLA.

You might also establish a naming convention for models to reflect the contents of the filter. This can make it easier to tell related models apart.

How can I save a filter?

The filter expression is saved as a script that is stored with the associated mining model or nested table. If you delete the filter text, it can only be restored by manually re-creating the filter expression. Therefore, if you create complex filter expressions, you should create a backup copy of the filter text.

Why can't I see any effects from the filter?

Whenever you change or add a filter expression, you must reprocess the structure and model before you can view the effects of the filter.

Why do I see filtered attributes in prediction query results?

When you apply a filter to a model, it affects only the selection of cases used for training the model. The filter does not affect the attributes known to the model, or change or suppress data that is present in the data source. As a result, queries against the model can return predictions for other types of cases, and dropdown lists of values used by the model might show attribute values excluded by the filter.

For example, suppose you train the [Bike Buyer] model using only cases involving women aged 20-30. You can still run a prediction query that predicts the probability of a man buying a bike, or predict the outcome for a woman aged 30-40. That is because the attributes and values present in the data source define what is theoretically possible, while the cases define the occurrences used for training. However, these queries would return very small probabilities, because the training data does not contain any cases with the target values.

If you need to completely hide or anonymize attribute values in the model, there are various options:

- Filter the incoming data as part of the definition of the data source view, or in the relational data source.
- Mask or encode the attribute value.
- Collapse excluded values into a category as part of the mining structure definition.

Model Filter Syntax and Examples (Analysis Services - Data Mining)

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This section provides detailed information about the syntax for model filters, together with sample expressions.

Filter syntax

[Filters on case attributes](#)

[Filters on nested table attributes](#)

[Filters on multiple nested table attributes](#)

[Filters attributes missing in nested table](#)

[Filters on multiple nested table values](#)

[Filters on nested table attributes and EXISTS](#)

[Filter combinations](#)

[Filters on dates](#)

Filter Syntax

Filter expressions generally are equivalent to the content of a WHERE clause. You can connect multiple conditions by using the logical operators **AND**, **OR**, and **NOT**.

In nested tables, you can also use the **EXISTS** and **NOT EXISTS** operators. An **EXISTS** condition evaluates to **true** if the subquery returns at least one row. This is useful in cases where you want to restrict the model to cases that contain a particular value in the nested table: for example, customers who have purchased an item at least once.

A **NOT EXISTS** condition evaluates to **true** if the condition specified in the subquery does not exist. An example is when you want to restrict the model to customers who have never purchased a particular item.

The general syntax is as follows:

```
<filter> ::= <predicate list> | ( <predicate list> )
<predicate list> ::= <predicate> | [<logical_operator> <predicate list>]
<logical_operator> ::= AND | OR
<predicate> ::= NOT <predicate> | ( <predicate> ) <avPredicate> | <nestedTablePredicate> | ( <predicate> )
<avPredicate> ::= <columnName> <operator> <scalar> | <columnName> IS [NOT] NULL
<operator> ::= = | != | <> | > | >= | < | <=
<nestedTablePredicate> ::= EXISTS ( <subquery> )
<subquery> ::= SELECT * FROM <columnName>[ WHERE <predicate list> ]
```

filter

Contains one or more predicates, connected by logical operators.

predicate list

One or more valid filter expressions, separated by logical operators.

columnName

The name of a mining structure column.

logical operator

AND, OR, NOT

avPredicate

Filter expression that can be applied to scalar mining structure column only. An *avPredicate* expression can be used in both model filters or nested table filters.

An expression that uses any of the following operators can only be applied to a continuous column. :

- < (less than)
- > (greater than)
- >= (greater than or equal to)
- <= (less than or equal to)

NOTE

Regardless of the data type, these operators cannot be applied to a column that has the type **Discrete**, **Discretized**, or **Key**.

An expression that uses any of the following operators can be applied to a continuous, discrete, discretized, or key column:

- = (equals)
- != (not equal to)
- **IS NULL**

If the argument, *avPredicate*, applies to a discretized column, the value used in the filter can be any value in a specific bucket.

In other words, you do not define the condition as `AgeDisc = '25-35'`, but instead compute and then use a value from that interval.

Example: `AgeDisc = 27` means any value in the same interval as 27, which in this case is 25-35.

nestedTablePredicate

Filter expression that applies to a nested table. Can be used in model filters only.

The sub-query argument of the argument, *nestedTablePredicate*, can only apply to a table mining structure column

subquery

A SELECT statement followed by a valid predicate or list of predicates.

All the predicates must be of the type described in *avPredicates*. Furthermore, the predicates can refer only to columns that are included in the current nested table, identified by the argument, *columnName*.

Limitations on Filter Syntax

The following restrictions apply to filters:

- A filter can contain only simple predicates. These include mathematical operators, scalars, and column names.
- User-defined functions are not supported in the filter syntax.

- Non-Boolean operators, such as the plus or minus signs, are not supported in the filter syntax.

Examples of Filters

The following examples demonstrate the use of filters applied to a mining model. If you create the filter expression by using Visual Studio with Analysis Services projects, in the **Property** window and the **Expression** pane of the filter dialog box, you would see only the string that appears after the WITH FILTER keywords. Here, the definition of the mining structure is included to make it easier to understand the column type and usage.

Example 1: Typical Case-Level Filtering

This example shows a simple filter that restricts the cases used in the model to customers whose occupation is architect and whose age is over 30.

```
ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_1
(
CustomerId,
Age,
Occupation,
MaritalStatus PREDICT
)
WITH FILTER (Age > 30 AND Occupation='Architect')
```

Example 2: Case-Level Filtering using Nested Table Attributes

If your mining structure contains nested tables, you can either filter on the existence of a value in a nested table, or filter on nested table rows that contain a specific value. This example restricts the cases used for the model to customers over the age of 30 who made at least one purchase that included milk.

As this example shows, it is not necessary that the filter use only columns that are included in the model. The nested table **Products** is part of the mining structure, but is not included in the mining model. However, you can still filter on values and attributes in the nested table. To view the details of these cases, drillthrough must be enabled.

```
ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_2
(
CustomerId,
Age,
Occupation,
MaritalStatus PREDICT
)
WITH DRILLTHROUGH,
FILTER (Age > 30 AND EXISTS (SELECT * FROM Products WHERE ProductName='Milk'))
)
```

Example 3: Case-Level Filtering on Multiple Nested Table Attributes

This example shows a three-part filter: a condition applies to the case table, another condition to an attribute in the nested table, and another condition on a specific value in one of the nested table columns.

The first condition in the filter, `Age > 30`, applies to a column in the case table. The remaining conditions apply to the nested table.

The second condition, `EXISTS (SELECT * FROM Products WHERE ProductName='Milk')`, checks for the presence of at least one purchase in the nested table that included milk. The third condition, `Quantity>=2`, means that the customer must have purchased at least two units of milk in a single transaction.

```

ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_3
(
CustomerId,
Age,
Occupation,
MaritalStatus PREDICT,
Products PREDICT
(
ProductName KEY,
Quantity
)
)
FILTER (Age > 30 AND EXISTS (SELECT * FROM Products WHERE ProductName='Milk' AND Quantity >= 2)
)

```

Example 4: Case-Level Filtering On Absence of Nested Table Attributes

This example shows how to limit cases to customer who did not purchase a specific item, by filtering on the absence of an attribute in the nested table. In this example, the model is trained using customers over the age of 30 who have never bought milk.

```

ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_4
(
CustomerId,
Age,
Occupation,
MaritalStatus PREDICT,
Products PREDICT
(
ProductName
)
)
FILTER (Age > 30 AND NOT EXISTS (SELECT * FROM Products WHERE ProductName='Milk') )

```

Example 5: Filtering on Multiple Nested Table Values

The purpose of the example is to show nested table filtering. The nested table filter is applied after the case filter, and only restricts nested table rows.

This model could contain multiple cases with empty nested tables because EXISTS is not specified.

```

ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_5
(
CustomerId,
Age,
Occupation,
MaritalStatus PREDICT,
Products PREDICT
(
ProductName KEY,
Quantity
) WITH FILTER(ProductName='Milk' OR ProductName='bottled water')
)
WITH DRILLTHROUGH

```

Example 6: Filtering on Nested Table Attributes and EXISTS

In this example, the filter on the nested table restricts the rows to those that contain either milk or bottled water. Then, the cases in the model are restricted by using an **EXISTS** statement. This makes sure that the nested table is not empty.

```

ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_6
(
CustomerId,
Age,
Occupation,
MaritalStatus PREDICT,
Products PREDICT
(
ProductName KEY,
Quantity
) WITH FILTER(ProductName='Milk' OR ProductName='bottled water')
)
FILTER (EXISTS (Products))

```

Example 7: Complex Filter Combinations

The scenario for this model resembles that of Example 4, but is far more complex. The nested table, **ProductsOnSale**, has the filter condition `(OnSale)` meaning that the value of **OnSale** must be **true** for the product listed in **ProductName**. Here, **OnSale** is a structure column.

The second part of the filter, for **ProductsNotOnSale**, repeats this syntax, but filters on products for which the value of **OnSale** is **not true** `(!OnSale)`.

Finally, the conditions are combined and one additional restriction is added to the case table. The result is to predict purchases of products in the **ProductsNotOnSale** list, based on the cases that are included in the **ProductsOnSale** list, for all customers over the age of 25.

```

ALTER MINING STRUCTURE MyStructure ADD MINING MODEL MyModel_7
(
CustomerId,
Age,
Occupation,
MaritalStatus,
ProductsOnSale
(
ProductName KEY
) WITH FILTER(OnSale),
ProductsNotOnSale PREDICT ONLY
(
ProductName KEY
) WITH FILTER(!OnSale)
)
WITH DRILLTHROUGH,
FILTER (EXISTS (ProductsOnSale) AND EXISTS(ProductsNotOnSale) AND Age > 25)

```

Example 8: Filtering on Dates

You can filter input columns on dates, as you would any other data. Dates contained in a column of type date/time

are continuous values; therefore, you can specify a date range by using operators such as greater than (>) or less than (<). If your data source does not represent dates by a Continuous data type, but as discrete or text values, you cannot filter on a date range, but must specify individual discrete values.

However, you cannot create a filter on the date column in a time series model if the date column used for the filter is also the key column for the model. That is because, in time series models and sequence clustering models, the date column might be handled as type **KeyTime** or **KeySequence**.

If you need to filter on continuous dates in a time series model, you can create a copy of the column in the mining structure, and filter the model on the new column.

For example, the following expression represents a filter on a date column of type **Continuous** that has been added to the Forecasting model.

```
= [DateCopy] > '12:31:2003:00:00:00'
```

NOTE

Note that any extra columns that you add to the model might affect the results. Therefore, if you do not want the column to be used in computation of the series, you should add the column only to the mining structure, and not to the model. You can also set the model flag on the column to **PredictOnly** or to **Ignore**. For more information, see [Modeling Flags \(Data Mining\)](#).

For other model types, you can use dates as input criteria or filter criteria just like you would in any other column. However, if you need to use a specific level of granularity that is not supported by a **Continuous** data type, you can create a derived value in the data source by using expressions to extract the unit to use in filtering and analysis.

WARNING

When you specify a dates as filter criteria, you must use the following format, regardless of the date format for the current OS: `mm/dd/yyyy`. Any other format results in an error.

For example, if you want to filter your call center results to show only weekends, you can create an expression in the data source view that extracts the weekday name for each date, and then use that weekday name value for input or as a discrete value in filtering. Just remember that repeating values can affect the model, so you should use only one of the columns, not the date column plus the derived value.

Add a Mining Model to an Existing Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can add more mining models to a mining structure, after you add the initial model. Each model must contain columns that exist in the structure, but you can define the usage of the columns differently for each mining model. For more information about how to define mining models columns, see [Mining Model Columns](#).

To add a mining model to the structure

1. From the **Mining Model** menu item in Visual Studio with Analysis Services projects, select **New Mining Model**.

The **New Mining Model** dialog box opens.

2. Under **Model name**, enter a name for the new mining model.
3. Under **Algorithm name**, select the algorithm that the mining model will be built from.
4. Click **OK**.

A new mining model appears in the **Mining Models** tab. The model uses the default columns that exist in the structure. For information about how to modify the columns, see [Change the Properties of a Mining Model](#).

[Mining Model Tasks and How-tos](#)

Delete a Mining Model from a Mining Structure

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can delete mining models by using Data Mining Designer, by using SQL Server Management Studio, or by using DMX statements.

Delete a mining model using SQL Server Data Tools

1. Select the **Mining Models** tab in Visual Studio with Analysis Services projects.
2. Right-click the model that you want to delete, and select **Delete**.

The **Delete Objects** dialog box opens.

3. Click **OK**.

Delete a mining model using SQL Server Management Studio

1. In SQL Server Management Studio, open the Analysis Services database that contains the model.
2. Expand **Mining Structures**, and then expand **Mining Models**.
3. Right-click the model you want to delete, and select **Delete**.

Deleting the model does not delete the training data, only the metadata and any patterns created when you trained the model.

Delete a mining model using DMX

- [DROP MINING MODEL \(DMX\)](#)

[Mining Model Tasks and How-tos](#)

Exclude a Column from a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a new mining model, you may not want to use all the columns that exist in the mining structure on which the model is based. For example, you might have added a customer name column for drillthrough, but don't want to use it for modeling. Or, you might decide to create multiple copies of a column with different discretizations, and use only one of the copies in each model, and ignore the rest. You could also selectively add input columns in several different models to see how the added variable affects the output column.

You do not need to create a new mining structure for each combination of columns; instead, you can simply flag a column as not being used in a particular model.

To exclude a column from a mining model

1. In the **Mining Models** tab of Data Mining Designer in Visual Studio with Analysis Services projects, select the cell that corresponds to the column you want to exclude, under the appropriate mining model.
2. Select **Ignore** from the drop-down list box.

See Also

[Mining Model Tasks and How-tos](#)

Create an Alias for a Model Column

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In SQL Server 2017, you can create an alias for a model column. This might be useful when the mining structure name is too long to easily work with, or when you want to rename the column to be more descriptive of its contents or usage in the model. For example, if you make a copy of a structure column and then discretize the column differently for a particular model, you can rename the column to reflect the content more accurately.

To create an alias for a model column, you use the **Properties** pane and set the **Name** property of the column.

On the **Mining Models** tab of Data Mining Designer, the alias appears enclosed in parentheses next to the column usage label.

For information about how to set the properties of a mining model, see [Mining Model Columns](#).

To add an alias to a mining model column

1. In the **Mining Models** tab in Data Mining Designer, right-click the cell in the mining model for the mining column that you want to change, and then select **Properties**.
2. In the **Properties** window on the right side of the screen, click the cell next to the Name property and delete the current value. Type a new name for the column.

[Mining Model Tasks and How-tos](#)

[Mining Model Properties](#)

Change the Discretization of a Column in a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services automatically discretizes values—that is to say, it bins data in numeric column—in certain scenarios. For example, if your data contains continuous numeric data and you create a decision tree model, each column of continuous data will be automatically binned, depending on the distribution of the data. If you want to control how the data is discretized, you must change the properties on the mining structure column that control how the data is used in the model.

For general information about how to set the properties in a mining model, see [Mining Model Columns](#).

To display the properties for a mining model column

1. In the **Mining Models** tab in Data Mining Designer, right-click the column header that contains the name of the mining model, or the row in the grid that contains the name of the mining algorithm, and then select **Properties**.

The **Properties** window displays the properties that are associated with the mining model as a whole.

2. In the **Structure** column near the left side of the screen, click the column that contains the continuous numeric data you want to discretize.

The **Properties** window changes to display just the properties associated with that column.

To change the discretization method

1. In the **Mining Properties** window, click the text box next to **Content**, and select **Discretized** from the dropdown list.

The **DiscretizationBucketCount** and **DiscretizationMethod** properties are now enabled.

2. In the **Properties** window, click the text box next to **DiscretizationMethod** and select one of the following values: **Automatic**, **EqualAreas**, or **Cluster**.

NOTE

If the column usage is set to **Ignore**, the **Properties** window for the column is blank.

The new value will take effect when you select a different element in the designer.

3. In the **Properties** window, click the text box next to **DiscretizationBucketCount** and type a numeric value.

NOTE

If you change these properties, the structure must be reprocessed, along with any models that you want to use the new setting.

See Also

[Mining Model Tasks and How-tos](#)

View or Change Modeling Flags (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Modeling flags are properties that you set on a mining structure column or mining model columns to control how the algorithm processes the data during analysis.

In Data Mining Designer, you can view and modify the modeling flags associated with a mining structure or mining column by viewing the properties of the structure or model. You can also set modeling flags by using DMX, AMO, or XMLA.

This procedure describes how to change the modeling flags in the designer.

View or change the modeling flag for a structure column or model column

1. In SQL Server Design Studio, open Solution Explorer, and then double-click the mining structure.
2. To set the NOT NULL modeling flag, click the **Mining Structure** tab. To set the REGRESSOR or MODEL_EXISTENCE_ONLY flags, click the **Mining Model** tab.
3. Right-click the column you want to view or change, and select **Properties**.
4. To add a new modeling flag, click the text box next to the **ModelingFlags** property, and select the check box or check boxes for the modeling flags you want to use.

Modeling flags are displayed only if they are appropriate for the column data type.

NOTE

After you change a modeling flag, you must reprocess the model.

Get the modeling flags used in the model

- In SQL Server Management Studio, open a DMX Query window, and type a query like the following:

```
SELECT COLUMN_NAME, CONTENT_TYPE, MODELING_FLAG  
FROM $system.DMSCHEMA_MINING_COLUMNS  
WHERE MODEL_NAME = 'Forecasting'
```

[Modeling Flags \(Data Mining\)](#)

Specify a Column to Use as Regressor in a Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A linear regression model represents the value of the predictable attribute as the result of a formula that combines the inputs in such a way that the data is fitted as closely as possible to an estimated regression line. The algorithm accepts only numeric values as inputs, and automatically detects the inputs that provide the best fit.

However, you can specify that a column be included as a regressor by adding the FORCE_REGRESSOR parameter to the model and specifying the regressors to use. You might want to do this in cases where the attribute has meaning even if the effect is too small to be detected by the model, or when you want to ensure that the attribute is included in the formula.

The following procedure describes how to create a simple linear regression model, using the same sample data that is used for the [neural networks tutorial](#). The model is not necessarily robust, but demonstrates how to use the Data Mining Designer to customize a linear regression model.

How to create a simple linear regression model

1. In Visual Studio with Analysis Services projects, in **Solution Explorer**, expand **Mining Structures**.
2. Double-click Call Center.dmm to open it in the designer.
3. From the **Mining Model** menu, select **New Mining Model**.
4. For the algorithm, select **Microsoft Linear Regression**. For the name, type **Call Center Regression**.
5. In the **Mining Models** tab, change the column usage as follows. All columns not in the following list should be set to **Ignore**, if they are not already.

FactCallCenterID**Key**

ServiceGrade**PredictOnly**

Total Operators**Input**

AverageTimePerIssue**Input**

6. From the **Mining Model** menu, select **Set Model Parameters**.

7. For the parameter, FORCE_REGRESSOR, in the **Value** column, type the column names enclosed in brackets and separated by a comma, as follows:

```
[Average Time Per Issue],[Total Operators]
```

NOTE

The algorithm will automatically detect which columns are the best regressors. You only need to force regressors when you want to ensure that a column is included in the final formula.

8. From the **Mining Model** menu, select **Process Model**.

In the viewer, the model is represented a single node containing the regression formula. You can view the formula in the **Mining Legend**, or you can extract the coefficients for the formula by using queries.

[Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#)

Change the Properties of a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Some mining model properties apply to the model as a whole, and other model properties apply to individual columns. Examples of properties that apply to the entire model would be the **Drillthrough** property, which specifies whether the case data should be available for querying, and the **Description** property. Properties that apply to the column include **Usage** and **ModelingFlags**, which control how data in the column is used within the model.

The following model properties have advanced editors that you can use to create expressions or configure complex model properties. The following properties provide:

- **Filter** property: Opens the [Data Set Filter or Model Filter Dialog Box](#).
- **AlgorithmParameters** property: Opens the [Algorithm Parameters Dialog Box \(Mining Models View\)](#).

For information about how to set the properties in a mining model, see [Mining Model Columns](#).

To change the properties of a mining model

1. In the **Mining Models** tab in Data Mining Designer, right-click either the column header that contains the name of the mining model, or the row in the grid that contains the name of the mining algorithm, and then select **Properties**.
2. In the **Properties** window on the right side of the screen, highlight the value that corresponds to the property that you want to change, and enter the new value.

The new value will take effect when you select a different element in the designer.

To change the properties of a mining model column

1. In the **Mining Models** tab in Data Mining Designer, right-click the cell in the grid at the intersection of the mining structure column and the mining model, and then select **Properties**.
2. In the **Properties** window on the right side of the screen, highlight the value that corresponds to the property that you want to change, and enter the new value.

NOTE

If the column usage is set to **Ignore**, the **Properties** window for the column is blank.

The new value will take effect when you select a different element in the designer.

[Mining Model Tasks and How-tos](#)

Apply a Filter to a Mining Model

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If your mining structure contains a nested table, you can apply a filter to the case table, the nested table, or both.

The following procedure demonstrates how to create both kinds of filters: case filters, and filters on the nested table rows.

The condition on the case table restricts customers to those with income between 30000 and 40000. The condition on the nested table restricts the customers to those who did not purchase a particular item.

The complete filter condition created in this example is as follows:

```
[Income] > '30000'  
AND [Income] < '40000'  
AND EXISTS (SELECT * FROM [<nested table name>]  
WHERE [Model] <> 'Water Bottle' )
```

To create a case filter on a mining model

1. In Visual Studio with Analysis Services projects, in Solution Explorer, click the mining structure that contains the mining model you want to filter.

2. Click the **Mining Models** tab.

3. Select the model, and right-click to open the shortcut menu.

-or-

Select the model. Then, on the **Mining Model** menu, select **Set Model Filter**.

4. In the **Model Filter** dialog box, click the top row in the grid, in the **Mining Structure Column** text box.

5. If the data source contains a single flat table, the drop-down list displays only the names of the columns in that table.

If the mining structure contains multiple tables, the list shows the names of the source tables. The column names do not display until a table has been selected.

If the mining structure contains a case table and a nested table, the drop-down list shows columns from the case table, and the name of the nested table.

6. Select a column from the drop-down list.

The icon at the left side of the text box changes to indicate that the selected item is a table or a column.

7. Click the **Operator** text box and select an operator from the list. The valid operators change depending on the data type of the column you selected.

8. Click the **Value** text box, and type a value in the box.

For example, select **Income** as the column, select the greater than operator (>), and then type **30000**.

9. Click the next row in the grid.

The filter condition that you created is automatically added to the Expression text box. For example,

```
[Income] > '30000'
```

10. Click the **AND/OR** text box in the next row of the grid to add a condition.

For example, to create a BETWEEN condition, select **AND** from the drop-down list of logical operands.

11. Select an operator and type a value as described in Steps 7 and 8.

For example, select **Income** as the column again, select the less than operator (<), and then type **40000**.

12. Click the next row in the grid.

13. The filter condition in the Expression text box is automatically updated to include the new condition. The completed expression is as follows:

```
[Income] > '30000' AND [Income] < '40000'
```

To add a filter on the nested table in a mining model

1. In the **<name>Model Filter** Dialog box, click an empty row in the grid under **Mining Structure Column**.

2. Select the name of the nested table from the drop-down list.

The icon at the left side of the text box changes to indicate that the selected item is the name of a table.

3. Click the **Operator** text box and select **Contains** or **Not Contains**.

These are the only conditions available for the nested table in the **Model Filter** dialog box, because you are restricting the case table to only those cases that contain a certain value in the nested table. You will set the value for the condition on the nested table in the next step.

4. Click the **Value** box, and then click the (...) button to build an expression.

The **<name>Filter** dialog box opens. This dialog box can set conditions only on the current table, which in this case is the nested table.

5. Click the **Mining Structure Column** box and select a column name from the dropdown lists of nested table columns.

6. Click **Operator** and select an operator from the list of valid operators for the column.

7. Click **Value** and type a value.

For example, for **Mining Structure Column**, select **Model**. For **Operator**, select **<>**, and type the value **Water Bottle**. This condition creates the following filter expression:

```
EXISTS (SELECT * FROM [<nested table name>] WHERE [Model] <> 'Water Bottle' )
```

NOTE

Because the number of nested table attributes is potentially unlimited, Analysis Services does not supply a list of possible values from which to select. You must type the exact value. Also, you cannot use a LIKE operator in a nested table.

1. Add more conditions as necessary, combining the conditions by selecting **AND** or **OR** in the **AND/OR** box at the left side of the **Conditions** grid. Click **OK**.
2. In the **Model Filter** dialog box, review the conditions that you created by using the **Filter** dialog box. The conditions for the nested table are appended to the conditions for the case table, and the complete set of filter conditions is displayed in the **Expression** text box.
3. Optionally, click **Edit Query** to manually change the filter expression.

NOTE

If you change any part of a filter expression manually, the grid will be disabled and thereafter you must work with the filter expression in text edit mode only. To restore grid editing mode, you must clear the filter expression and start over.

[Filters for Mining Models \(Analysis Services - Data Mining\)](#)

[Mining Model Tasks and How-tos](#)

[Delete a Filter from a Mining Model](#)

Delete a Filter from a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create a filter on a mining model, you can create models on a subset of the data in the data source view. Filters are also useful for testing the accuracy of the model on a subset of the original data.

However, you must delete the filter if you want to view the complete set of cases again. This procedure describes how to remove conditions on a filter, or delete the filter completely.

To delete a condition from a filter on a mining model

1. In Visual Studio with Analysis Services projects, in Solution Explorer, click the mining structure that contains the mining model you want to filter.
2. Click the **Mining Models** tab.
3. Select the model, and right-click to open the shortcut menu.

-or-

Select the model. On the **Mining Model** menu, select **Set Model Filter**.

4. In the **Model Filter** dialog box, right-click the row in the grid that contains the condition you want to delete.
5. Select **Delete**.

To clear the filter on a mining model in the Filter Editor dialog box

- In the **Filter Editor** dialog box, right-click any row in the grid, and select **Delete All**.

Working with Model Filters Using the Properties Window

If you want to delete the whole filter, you do not need to open the filter editor dialog boxes. The filter conditions that you created are available in the **Filter** property of the mining model.

NOTE

You can view the properties of a mining model in Visual Studio with Analysis Services projects, but not in SQL Server Management Studio.

To clear the filter on a mining model in Solution Explorer

1. In Solution Explorer, click the mining model that contains the filter.
2. In the **Properties** window, right-click the filter text in the **Filter** property, and select **Select All**.
3. Press the Backspace or Delete key.

[Drill Through to Case Data from a Mining Model](#)

[Mining Model Tasks and How-tos](#)

[Filters for Mining Models \(Analysis Services - Data Mining\)](#)

Enable Drillthrough for a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If you have enabled drillthrough for a mining model, when you browse the model you can retrieve detailed information about the cases that were used to create the model. To view this information, you must have the necessary permissions, and the structure must have already been processed.

Permissions For a user to drill through to either model data or structure data, the user must be a member of a role that has [AllowDrillThrough](#) permissions on the mining model or mining structure. Drillthrough permissions are set separately on the structure and model.

- Drillthrough permissions on the model enable you to drill through from the model, even if you do not have permissions on the structure.
- Drillthrough permissions on the structure provide the additional ability to include structure columns in drillthrough queries from the model, by using the [StructureColumn \(DMX\)](#) function. You can also query the training and test cases in the structure by using the SELECT... FROM <structure>.CASES syntax.

Caching of training cases Drillthrough works by retrieving information about the training cases in the mining structure. This information is cached when the structure is processed. Therefore, if you choose to clear all cached data by changing the [MiningStructureCacheMode](#) property to **ClearAfterProcessing**, drillthrough will not work.

NOTE

If the training cases have not been cached, you must change the [MiningStructureCacheMode](#) property to **KeepTrainingCases** and then reprocess the model before you can view the case data.

For more information, see [Drillthrough Queries \(Data Mining\)](#).

To enable drillthrough on a mining model

1. In Visual Studio with Analysis Services projects, on the **Mining Models** tab of Data Mining Designer, right-click the name of the mining model on which you want to enable drillthrough, and select **Properties**.
2. In the **Properties** windows, click **AllowDrillthrough**, and select **True**.
3. In the **Mining Models** tab, right-click the model, and select **Process Model**.

To enable caching for a mining structure

1. In Visual Studio with Analysis Services projects, on the **Mining Structure** tab of Data Mining Designer, right-click the name of the mining structure.
2. Open the **Properties** window.
3. In the **Properties** window, locate the **CacheMode** property, and select **KeepTrainingCases** from the list.
4. On the **Database** menu, select **Process**.

See Also

[Drillthrough Queries \(Data Mining\)](#)

View or Change Algorithm Parameters

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can change the parameters provided with the algorithms that you use to build data mining models to customize the results of the model.

The algorithm parameters provided in Microsoft SQL Server Analysis Services change much more than just properties on the model: they can be used to fundamentally alter the way that data is processed, grouped, and displayed. For example, you can use algorithm parameters to do the following:

- Change the method of analysis, such as the clustering method.
- Control feature selection behavior.
- Specify the size of itemsets or the probability of rules.
- Control branching and depth of decision trees.
- Specify a seed value or the size of the internal holdout set used for model creation.

The parameters provided for each algorithm vary greatly; for a list of the parameters that you can set for each algorithm, see the technical reference topics in this section: [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

Change an algorithm parameter

1. On the **Mining Models** tab of Data Mining Designer in Visual Studio with Analysis Services projects, right-click the algorithm type of the mining model for which you want to tune the algorithm, and select **Set Algorithm Parameters**.

The **Algorithm Parameters** dialog box opens.

2. In the **Value** column, set a new value for the algorithm that you want to change.

If you do not enter a value in the **Value** column, Analysis Services uses the default parameter value. The **Range** column describes the possible values that you can enter.

3. Click **OK**.

The algorithm parameter is set with the new value. The parameter change will not be reflected in the mining model until you reprocess the model.

View the parameters used in an existing model

1. In SQL Server Management Studio, open a DMX Query window.
2. Type a query like this one:

```
select MINING_PARAMETERS  
from $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = '<model name>'
```

See Also

Process a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In the Mining Models tab of Data Mining Designer in Visual Studio with Analysis Services projects, you can either process a specific mining model that is associated with a mining structure or you can process all the models that are associated with the structure.

You can process a mining model by using the following tools:

- Visual Studio with Analysis Services projects
- SQL Server Management Studio

You can also use an XMLA Process command. For more information, see [Tools and Approaches for Processing \(Analysis Services\)](#).

Process a single mining model using SQL Server Data Tools

1. On the **Mining Models** tab of Data Mining Designer, select a mining model from the one or more columns of models in the grid.
2. On the **Mining Model** menu, select **Process Model**.

If you made changes to the mining structure, you will be prompted to redeploy the structure before processing the model. Click **Yes**.

3. In the **Processing Mining Model - <model>** dialog box, click **Run**.

The **Process Progress** dialog box opens to show the details of model processing.

4. After the model has successfully completed processing, click **Close** in the **Process Progress** dialog box.
5. Click **Close** in the **Processing Mining Model - <model>** dialog box.

Only the mining structure and the selected mining model have been processed.

Process all mining models that are associated with a mining structure

1. On the **Mining Models** tab of Data Mining Designer, select **Process Mining Structure and All Models** from the **Mining Model** menu.
2. If you made changes to the mining structure, you will be prompted to redeploy the structure before processing the models. Click **Yes**.
3. In the **Processing Mining Structure - <structure>** dialog box, click **Run**.
4. The **Process Progress** dialog box opens to show the details of model processing.
5. After the models have successfully completed processing, click **Close** in the **Process Progress** dialog box.
6. Click **Close** in the **Processing <model>** dialog box.

The mining structure and all the associated mining models have been processed.

Make a Copy of a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Creating a copy of a mining model is useful when you want to quickly create several mining models that are based on the same data. After you copy the model, you can then edit the new copy by changing parameters or adding a filter.

For example, if you have a *Customers* table that is linked to a table of purchases, you could create copies to generate separate mining models for each customer demographic, filtering on attributes such as age or region.

For information about how to copy the content of the model (such as the graphical representation or the model patterns) to the Clipboard for use in other programs, see [Copy a View of a Mining Model](#).

To create a related mining model

1. In Visual Studio with Analysis Services projects, in Solution Explorer, click the mining structure that contains the mining model.
2. Click the **Mining Models** tab.
3. Select the model, and right-click to open the shortcut menu.

-or-

Select the model. On the **Mining Model** menu, select **New Mining Model**.

4. Type a name for the new mining model, and select an algorithm. Click **OK**.

To edit the filter on the copied mining model

1. Select the mining model.
2. In the **Properties** window, click the text box for the **Filter** property, and then click the build (...) button.
3. Change the filter conditions.

For more information about how to use the filter editor dialog boxes, see [Apply a Filter to a Mining Model](#).

4. In the **Properties** window, in the **AlgorithmParameters** text box, click **Set algorithm parameters**, and change algorithm parameters, if desired.
5. Click **OK**.

- [Delete a Filter from a Mining Model](#)

Create a Data Mining Dimension

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If your mining structure is based on an OLAP cube, you can create a dimension that contains the content of the mining model. You can then incorporate the dimension back into the source cube.

You can also browse the dimension, use it to explore the model results, or query the dimension using MDX.

To create a data mining dimension

1. In Data Mining Designer in Visual Studio with Analysis Services projects, select either the **Mining Structure** tab or the **Mining Models** tab.
2. From the **Mining Model** menu, select **Create a Data Mining Dimension**.

The **Create Data Mining Dimension** dialog box opens.

3. In the **Model name** list of the **Create Data Mining Dimension** dialog box, select an OLAP mining model.
4. In the **Dimension name** box, enter a name for the new data mining dimension.
5. If you want to create a cube that includes the new data mining dimension, select **Create cube**. After you select **Create cube**, you can enter a new name for the cube.
6. Click **OK**.

The data mining dimension is created and is added to the **Dimensions** folder in Solution Explorer. If you selected **Create cube**, a new cube is also created and is added to the **Cubes** folder.

[Mining Structure Tasks and How-tos](#)

Testing and Validation (Data Mining)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Validation is the process of assessing how well your mining models perform against real data. It is important that you validate your mining models by understanding their quality and characteristics before you deploy them into a production environment.

This section introduces some basic concepts related to model quality, and describes the strategies for model validation that are provided in Microsoft Analysis Services. For an overview of how model validation fits into the larger data mining process, see [Data Mining Solutions](#).

Methods for Testing and Validation of Data Mining Models

There are many approaches for assessing the quality and characteristics of a data mining model.

- Use various measures of statistical validity to determine whether there are problems in the data or in the model.
- Separate the data into training and testing sets to test the accuracy of predictions.
- Ask business experts to review the results of the data mining model to determine whether the discovered patterns have meaning in the targeted business scenario

All of these methods are useful in data mining methodology and are used iteratively as you create, test, and refine models to answer a specific problem. No single comprehensive rule can tell you when a model is good enough, or when you have enough data.

Definition of Criteria for Validating Data Mining Models

Measures of data mining generally fall into the categories of accuracy, reliability, and usefulness.

Accuracy is a measure of how well the model correlates an outcome with the attributes in the data that has been provided. There are various measures of accuracy, but all measures of accuracy are dependent on the data that is used. In reality, values might be missing or approximate, or the data might have been changed by multiple processes. Particularly in the phase of exploration and development, you might decide to accept a certain amount of error in the data, especially if the data is fairly uniform in its characteristics. For example, a model that predicts sales for a particular store based on past sales can be strongly correlated and very accurate, even if that store consistently used the wrong accounting method. Therefore, measurements of accuracy must be balanced by assessments of reliability.

Reliability assesses the way that a data mining model performs on different data sets. A data mining model is reliable if it generates the same type of predictions or finds the same general kinds of patterns regardless of the test data that is supplied. For example, the model that you generate for the store that used the wrong accounting method would not generalize well to other stores, and therefore would not be reliable.

Usefulness includes various metrics that tell you whether the model provides useful information. For example, a data mining model that correlates store location with sales might be both accurate and reliable, but might not be useful, because you cannot generalize that result by adding more stores at the same location. Moreover, it does not answer the fundamental business question of why certain locations have more sales. You might also find that a model that appears successful in fact is meaningless, because it is based on cross-correlations in the data.

Tools for Testing and Validation of Mining Models

Analysis Services supports multiple approaches to validation of data mining solutions, supporting all phases of the data mining test methodology.

- Partitioning data into testing and training sets.
- Filtering models to train and test different combinations of the same source data.
- Measuring *lift* and *gain*. A *lift chart* is a method of visualizing the improvement that you get from using a data mining model, when you compare it to random guessing.
- Performing *cross-validation* of data sets
- Generating *classification matrices*. These charts sort good and bad guesses into a table so that you can quickly and easily gauge how accurately the model predicts the target value.
- Creating *scatter plots* to assess the fit of a regression formula.
- Creating *profit charts* that associate financial gain or costs with the use of a mining model, so that you can assess the value of the recommendations.

These metrics do not aim to answer the question of whether the data mining model answers your business question; rather, these metrics provide objective measurements that you can use to assess the reliability of your data for predictive analytics, and to guide your decision of whether to use a particular iterate on the development process.

The topics in this section provide an overview of each method and walk you through the process of measuring the accuracy of models that you build using SQL Server Data Mining.

Training and Testing Data Sets

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Separating data into training and testing sets is an important part of evaluating data mining models. Typically, when you separate a data set into a training set and testing set, most of the data is used for training, and a smaller portion of the data is used for testing. Analysis Services randomly samples the data to help ensure that the testing and training sets are similar. By using similar data for training and testing, you can minimize the effects of data discrepancies and better understand the characteristics of the model.

After a model has been processed by using the training set, you test the model by making predictions against the test set. Because the data in the testing set already contains known values for the attribute that you want to predict, it is easy to determine whether the model's guesses are correct.

Creating Test and Training Sets for Data Mining Structures

In SQL Server 2017, you separate the original data set at the level of the mining structure. The information about the size of the training and testing data sets, and which row belongs to which set, is stored with the structure, and all the models that are based on that structure can use the sets for training and testing.

You can define a testing data set on a mining structure in the following ways:

- Using the Data Mining Wizard to divide the mining structure when you create it.
- Modifying structure properties in the **Mining Structure** tab of the Data Mining Designer.
- Creating and modifying structures programmatically by using Analysis Management Objects (AMO) or XML Data Definition Language (DDL).

Using the Data Mining Wizard to Divide a Mining Structure

By default, after you have defined the data sources for a mining structure, the Data Mining Wizard will divide the data into two sets: one with 70 percent of the source data, for training the model, and one with 30 percent of the source data, for testing the model. This default was chosen because a 70-30 ratio is often used in data mining, but with Analysis Services you can change this ratio to suit your requirements.

You can also configure the wizard to set a maximum number of training cases, or you can combine the limits to allow a maximum percentage of cases up to a specified maximum number of cases. When you specify both a maximum percentage of cases and a maximum number of cases, Analysis Services uses the smaller of the two limits as the size of the test set. For example, if you specify 30 percent holdout for the testing cases, and the maximum number of test cases as 1000, the size of the test set will never exceed 1000 cases. This can be useful if you want to ensure that the size of your test set stays consistent even if more training data is added to the model.

If you use the same data source view for different mining structures, and want to ensure that the data is divided in roughly the same way for all mining structures and their models, you should specify the seed that is used to initialize random sampling. When you specify a value for **HoldoutSeed**, Analysis Services will use that value to begin sampling. Otherwise, sampling uses a hashing algorithm on the name of the mining structure to create the seed value.

NOTE

If you create a copy of the mining structure by using the **EXPORT** and **IMPORT** statements, the new mining structure will have the same training and testing data sets, because the export process creates a new ID but uses the same name.

However, if two mining structures use the same underlying data source but have different names, the sets that are created for each mining structure will be different.

Modifying Structure Properties to Create a Test Data Set

If you create and process a mining structure, and then later decide that you want to set aside a test data set, you can modify the properties of the mining structure. To change the way that data is partitioned, edit the following properties:

PROPERTY	DESCRIPTION
HoldoutMaxCases	Specifies the maximum number of cases to include in the testing set.
HoldoutMaxPercent	Specifies the number of cases to include in the testing set as a percentage of the complete data set. To have no data set, you would specify 0.
HoldoutSeed	Specifies an integer value to use as seed when randomly selecting data for the partitions. This value does not affect the number of cases in the training set; instead, it ensures that the partition can be repeated.

If you add or change a test data set to an existing structure, you must reprocess the structure and all associated models. Also, because dividing the source data causes the model to be trained on a different subset of the data, you might see different results from your model.

Specifying Holdout Programmatically

You can define testing and training data sets on a mining structure by using DMX statements, AMO, or XML DDL. The ALTER MINING STRUCTURE statement does not support the use of holdout parameters.

- **DMX** In the Data Mining Extensions (DMX) language, the CREATE MINING STRUCTURE statement has been extended to include a WITH HOLDOUT clause..
- **ASSL** You can either create a new mining structure, or add a testing data set to an existing mining structure, by using the Analysis Services Scripting Language (ASSL)..
- **AMO** You can also view and modify holdout data sets by using AMO..

You can view information about the holdout data set in an existing mining structure by querying the data mining schema rowset. You can do this by making a DISCOVER ROWSET call, or you can use a DMX query.

Retrieving Information about Holdout Data

By default, all information about the training and test data sets is cached, so that you can use existing data to train and then test new models. You can also define filters to apply to the cached holdout data so that you can evaluate the model on subsets of the data.

The way that cases are divided into training and testing data sets depends on the way that you configure holdout, and the data that you provide. If you want to determine the number of cases used for training or for testing, or if you want to find additional details about the cases included in the training and test sets, you can query the model structure by creating a DMX query. For example, the following query returns the cases that were used in the training set of the model.

```
SELECT * from <structure>.CASES WHERE IsTrainingCase()
```

To retrieve only the test cases, and additionally filter the test cases on one of the columns in the mining structure, use the following syntax:

```
SELECT * from <structure>.CASES WHERE IsTestCase() AND <structure column name> = '<value>'
```

Limitations on the Use of Holdout Data

- To use holdout, the **MiningStructureCacheMode** property of the mining structure must be set to the default value, **KeepTrainingCases**. If you change the **CacheMode** property to **ClearAfterProcessing**, and then reprocess the mining structure, the partition will be lost.
- You cannot remove data from a time series model; therefore, you cannot separate the source data into training and testing sets. If you begin to create a mining structure and model and choose the Microsoft Time Series algorithm, the option to create a holdout data set is disabled. Use of holdout data is also disabled if the mining structure contains a KEY TIME column at either the case or nested table level.
- It is possible to inadvertently configure the holdout data set such that the complete data set is used for testing, and no data remains for training. However, if you do so, Analysis Services will raise an error so that you can correct the problem. Analysis Services also warns you when the structure is processed if more than 50 percent of the data has been held out for testing.
- In most cases, the default holdout value of 30 provides a good balance between training and testing data. There is no simple way to determine how large the data set should be to provide sufficient training, or how sparse the training set can be and still avoid overfitting. However, after you have built a model, you can use cross-validation to assess the data set with respect to a particular model.
- In addition to the properties listed in the previous table, a read-only property, **HoldoutActualSize**, is provided in AMO and XML DDL. However, because the actual size of a partition cannot be determined accurately until after the structure has been processed, you should check whether the model has been processed before you retrieve the value of the **HoldoutActualSize** property.

Lift Chart (Analysis Services - Data Mining)

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A *lift chart* graphically represents the improvement that a mining model provides when compared against a random guess, and measures the change in terms of a *lift* score. By comparing the lift scores for different models, you can determine which model is best. You can also determine the point at which the model's predictions become less useful. For example, by reviewing the lift chart, you might realize that a promotional campaign is likely to be effective against only 30% of your customers, and use that figure to limit the scope of the campaign.

In SQL Server Data Mining, the lift chart can compare the accuracy of multiple models that have the same predictable attribute. You can also assess the accuracy of prediction either for a single outcome (a single value of the predictable attribute), or for all outcomes (all values of the specified attribute).

A profit chart is a related chart type that contains the same information as a lift chart, but also displays the projected increase in profit that is associated with using each model.

Understanding the Lift Chart

It can be hard to understand lift charts in the abstract. Therefore, to illustrate the use of the lift chart tools and the information in the chart, this section presents a scenario in which a lift chart is used to estimate the response to a targeted mailing campaign.

The marketing department in this scenario knows that a 10 percent response rate is more or less typical of mailing campaigns. They have a list of 10,000 potential customers stored in a table in the database. Based on the typical response rate, they could normally expect only about 1,000 of the potential customers to respond. However, the money budgeted for the project is not enough to reach all 10,000 customers in the database, and they want to improve their response rate. Assume for this scenario that their budget allows them to mail an advertisement to only 5,000 customers. The marketing department has two options:

- Randomly select 5,000 customers to target.
- Use a mining model to target the 5,000 customers who are most likely to respond.

By using a lift chart, you can compare the expected results of both options. For example, if the company randomly selected 5,000 customers, they might expect to receive only 500 responses, based on the typical response rate. This scenario is what the *random* line in the lift chart represents. However, if the marketing department used a mining model to target their mailing, they could expect a better response rate because the model would identify those customers who are most likely to respond. If the model were perfect, it would create predictions that are never wrong, and the company could expect to receive 1,000 responses by sending the mailing just to the 1,000 potential customers recommended by the model. This scenario is what the *ideal* line in the lift chart represents.

The reality is that the mining model most likely falls between these two extremes; between a random guess and a perfect prediction. Any improvement from the random guess is considered to be lift.

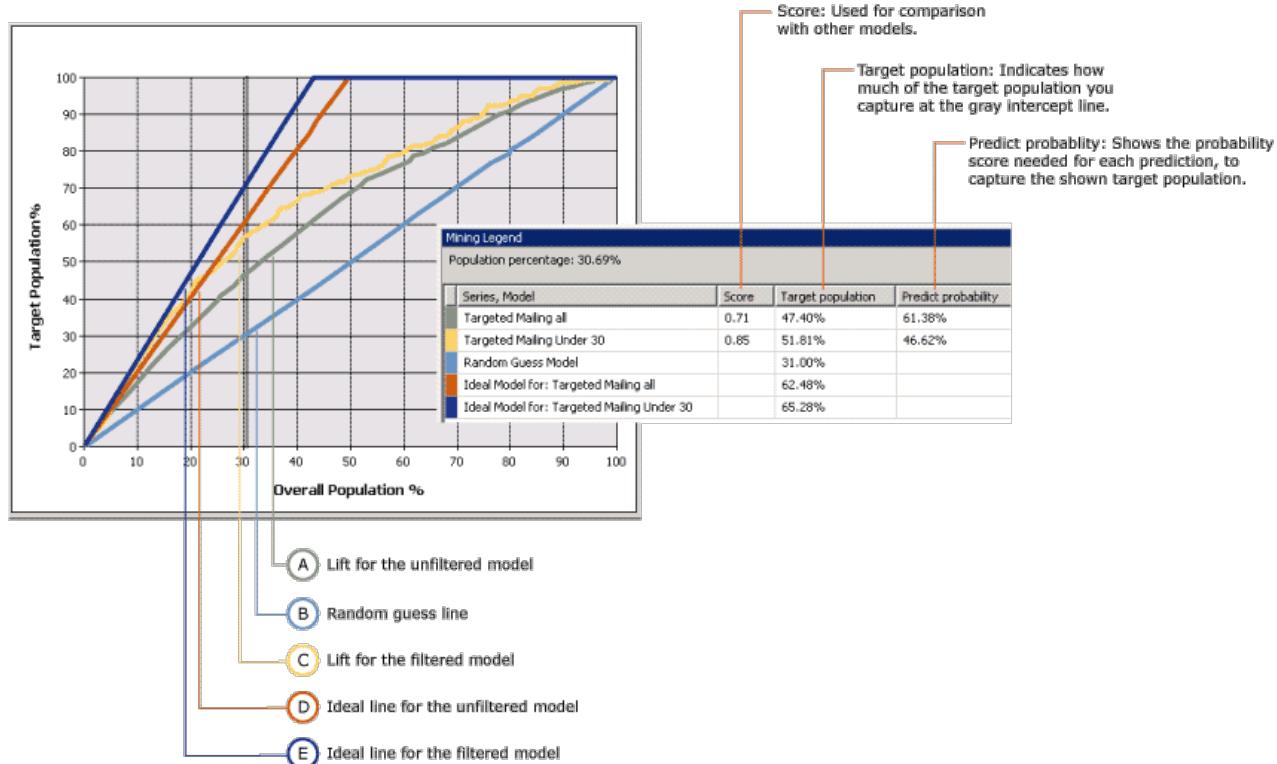

When you create a lift chart, you can target a specific value and measure lift only for that outcome, or you can create a general assessment of the model that measures lifts for all possible outcomes. These selections affect the final chart, as described in the following sections.

[Back to Top](#)

Lift Chart with Target Value

The following chart shows a lift chart for the **Targeted Mailing** model that you create in the [Basic Data Mining Tutorial](#). In this chart, the target attribute is [Bike Buyer] and the target value is 1, meaning that the customer is predicted to buy a bike. The lift chart thus shows the improvement the model provides when identifying these potential customers.

This chart contains multiple models based on the same data. One of these models has been customized to target specific customers. You can customize a model by adding filters on the data used to train the mode. This filter restricts the cases used in both training and evaluation to customers who are under the age of 30. Notice that one effect of filtering is that the basic model and the filtered model use different data sets, and therefore the number of cases used for evaluation in the lift chart is different as well. This point is important to remember when you interpret the prediction results and other statistics.

The x-axis of the chart represents the percentage of the test dataset that is used to compare the predictions. The y-axis of the chart represents the percentage of predicted values.

The diagonal straight line, shown here in blue, appears in every chart. It represents the results of random guessing, and is the baseline against which to evaluate lift. For each model that you add to a lift chart, you get two additional lines: one line shows the ideal results for the training data set if you could create a model that always predicted perfectly, and the second line shows the actual lift, or improvement in results, for the model.

In this example, the ideal line for the filtered model is shown in dark blue, and the line for actual lift in yellow. You can tell from the chart that the ideal line peaks at around 40 percent, meaning that if you had a perfect model, you could reach 100 percent of your targeted customers by sending a mailing to only 40% of the total population. The actual lift for the filtered model when you target 40 percent of the population is between 60 and 70 percent, meaning you could reach 60-70 percent of your targeted customers by sending the mailing to 40 percent of the total customer population.

The **Mining Legend** contains the actual values at any point on the curves. You can change the place that is measured by clicking the vertical gray bar and moving it. In the chart, the gray line has been moved to 30 percent, because this is the point where both the filtered and unfiltered models appear to be most effective, and after this point the amount of lift declines.

The **Mining Legend** also contains scores and statistics that help you interpret the chart. These results represent the accuracy of the model at the gray line, which in this scenario is positioned to include 30 percent of the overall test cases.

Series and Model	Score	Target Population	Predict Probability
Targeted mailing all	0.71	47.40%	61.38%
Targeted mailing under 30	0.85	51.81%	46.62%
Random guess model		31.00%	
Ideal model for: Targeted mailing all		62.48%	
Ideal model for: Targeted mailing under 30		65.28%	

[Back to Top](#)

Interpreting the Results

From these results, you can see that, when measured at 30 percent of all cases, the general model, [Targeted mailing all], can predict the bike buying behavior of 47.40% of the target population. In other words, if you sent out a targeted mailing to only 30 percent of the customers in your database, you could reach slightly less than half of your target audience. If you used the filtered model, you could get slightly better results, and reach about 51 percent of your targeted customers.

The value for **Predict probability** represents the threshold required to include a customer among the "likely to buy" cases. For each case, the model estimates the accuracy of each prediction and stores that value, which you can use to filter out or to target customers. For example, to identify the customers from the basic model who are likely buyers, you would use a query to retrieve cases with a Predict probability of at least 61 percent. To get the customers targeted by the filtered model, you would create query that retrieved cases that met all the criteria: age and a **PredictProbability** value of at least 46 percent.

It is interesting to compare the models. The filtered model appears to capture more potential customers, but when you target customers with a prediction probability score of 46 percent, you also have a 53 percent chance of sending a mailing to someone who will not buy a bike. Therefore, if you were deciding which model is better, you would want to balance the greater precision and smaller target size of the filtered model against the selectiveness of the basic model.

The value for **Score** helps you compare models by calculating the effectiveness of the model across a normalized population. A higher score is better, so in this case you might decide that targeting customers under 30 is the most effective strategy, despite the lower prediction probability.

How is the Score Calculated?

The score is calculated as the geometric mean score of all the points constituting a scatter plot in which the x-axis contains the actual values, the y-axis contains the predicted value, and each point has an associated probability.

The statistical meaning of any individual point score is the predictive lift for the model measured at that point. The average of all points constitutes the score for the model.

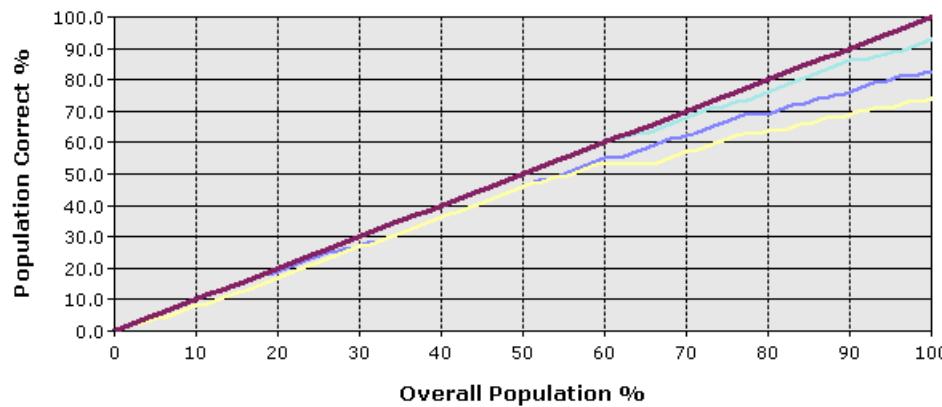

[Back to Top](#)

Lift Chart for Model with No Target Value

If you do not specify the state of the predictable column, you create the type of chart shown in the following diagram. This chart shows how the model performs for all states of the predictable attribute. For example, this chart would tell you how well the model predicts both customers who are likely to buy a bike, and those who are unlikely to buy a bike.

The x-axis is the same as in the chart with the predictable column specified, but the y-axis now represents the

percentage of predictions that are correct. Therefore, the ideal line is the diagonal line, which shows that at 50 percent of the data, the model correctly predicts 50% of the cases, the maximum that can be expected.

You can click in the chart to move the vertical gray bar, and the **Mining Legend** displays the percentage of cases overall, and the percentage of cases that were predicted correctly. For example, if you position the gray slider bar at the 50 percent mark, the **Mining Legend** displays the following accuracy scores. These figures are based on the TM_Decision Tree model created in the Basic Data Mining Tutorial.

SERIES, MODEL	SCORE	TARGET POPULATION	PREDICT PROBABILITY
TM_Decision Tree	0.77	40.50%	72.91%
Ideal model	1.00	50.00%	100%

This table tells you that, at 50 percent of the population, the model that you created correctly predicts 40 percent of the cases. You might consider this a reasonably accurate model. However, remember that this particular model predicts all values of the predictable attribute. Therefore, the model might be accurate in predicting that 90 percent of customers will not buy a bike.

[Back to Top](#)

Restrictions on Lift Charts

Lift charts require that the predictable attribute be a discrete value. In other words, you cannot use lift charts to measure the accuracy of models that predict continuous numeric values.

The prediction accuracy for all discrete values of the predictable attribute is shown in a single line. If you want to see prediction accuracy lines for any individual value of the predictable attribute, you must create a separate lift chart for each targeted value.

You can add multiple models to a lift chart, as long as the models all have the same predictable attribute. Models that do not share the attribute will be unavailable for selection in the **Input** tab.

You cannot display time series models in a lift chart or profit chart. A common practice for measuring the accuracy of time series predictions is to reserve a portion of historical data and compare that data to the predictions. For more information, see [Microsoft Time Series Algorithm](#).

[Testing and Validation \(Data Mining\)](#)

Profit Chart (Analysis Services - Data Mining)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A profit chart displays the estimated profitability associated with using a mining model. For example, let's assume your model predicts which customers a company should contact in a business scenario. In that case, you would add to the profit chart information about the cost of conducting the targeted mailing campaign. Then, in the completed chart, you can see the estimated profit if customers are correctly targeted, as compared to randomly contacting customers.

Build a Profit Chart

A profit chart is similar to a lift chart. You start by creating a lift chart, and then add in the cost and profit information.

To build a profit chart, you must have an existing model.

For this example, we used the Targeted Mailing decision tree model. The model identifies customers who are likely to buy a bike. You can apply the **Profit Chart** to determine how many of your customers to target to maximize your profit.

If you don't have the sample model, you can create it using the [Basic Data Mining Tutorial](#).

1. Open the mining accuracy chart builder.

- In SQL Server Management Studio, right-click the model, and select **View Lift Chart**.
- In SQL Server Data Tools, open the project in which you created the model, and click the **Mining Accuracy Chart** tab.

2. In **the Input Selection** tab, select the model and choose the predictable attribute value.

For this particular scenario, you are interested only in the profitability of accurately predicting one value: [Bike Buyer] = 1.

However, there are other scenarios in which you are equally interested in predicting false values correctly. For example, the cost of a false positive on a medical diagnostic test can be significant and needs to be factored into the profitability of the prediction, as does the cost of false negatives. In such scenarios, you would measure all outcomes.

3. Select a data set for testing. For this example, select the testing data set.

4. Now click the **Lift Chart** tab.

A lift chart is automatically generated.

5. To change this to a profit chart, select **Profit Chart** from the **Chart type** list.

6. As soon as you choose profit chart as the chart type, the **Profit Chart Setting** dialog box automatically opens.

This dialog box helps you specify the costs and benefits associated with a targeted mailing campaign. For the chart shown in these examples, we used the following values:

SETTING	VALUE	COMMENTS
Population	20,000	<p>Set the value for the total target population</p> <p>Your database might contain many customers, but to save on mailing expenses you might choose to target only the 20,000 customers who are most likely to respond. You can get this list by running a prediction query and sorting by the probability output by the predictive model.</p>
Fixed cost	500	<p>Enter the one-time cost of setting up a targeted mailing campaign for 20,000 people. This might include printing, or the cost of setting up an e-mail campaign.</p>
Individual cost	3	<p>Enter the per-unit cost for the targeted mailing campaign.</p> <p>This amount will be multiplied by a number equal to or less than 20000, depending on how many customers the model predicts are good prospects.</p>
Revenue per individual	400	<p>Enter a value that represents the amount of profit or income that can be expected from a successful result. In this case, we'll assume that mailing a catalog results in purchase of accessories or bikes averaging \$400.</p> <p>This amount will be used to project the total profit associated with high probability cases.</p>

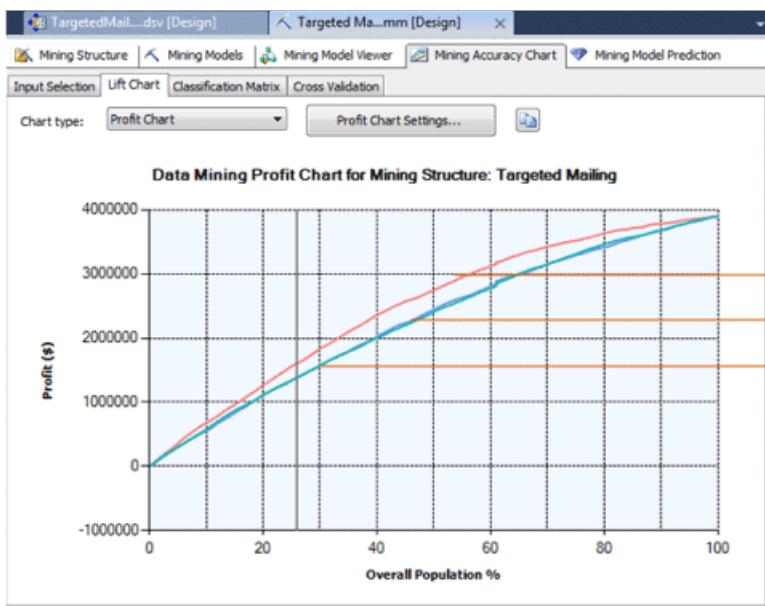

7. After you have set the required parameters, click **OK**.

8. The chart updates to show the profit curve.

Understanding the Profit Chart

The following diagram shows the chart that was based on these parameters. The Y-axis of the chart represents the profit, while the X-axis represents the percentage of the customers who were contacted by the targeted mailing campaign.

As shown here, you can use a profit chart to compare multiple models, as long as they all predict the same discrete attribute.

Notice the gray vertical line in the chart. As you click and drag the line, the ToolTip display the percentage of the target population that is included under the curve at that point.

The **Mining Legend** is also updated as you drag the line, to display the percentage value, a profit score, and the predict probability that is associated with the population percentage at the vertical gray line.

For example, if you were using this model to decide who to send your promotional material to, you might decide to target 25% of the population, based on the predict probabilities. However, the area under the profit curve of the chart is greatest between 40 and 70 percent, indicating that by mailing to more people, you can maximize your return, even if a smaller overall percentage responds.

Saving Charts

When you create an accuracy chart or profit chart, no objects are created on the server. Instead, queries are executed against an existing model and the results are rendered in the viewer. If you need to save the results, you must copy either the chart or the results to Excel or another file.

Classification Matrix (Analysis Services - Data Mining)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A *classification matrix* sorts all cases from the model into categories, by determining whether the predicted value matched the actual value. All the cases in each category are then counted, and the totals are displayed in the matrix. The classification matrix is a standard tool for evaluation of statistical models and is sometimes referred to as a *confusion matrix*.

The chart that is created when you choose the **Classification Matrix** option compares actual to predicted values for each predicted state that you specify. The rows in the matrix represent the predicted values for the model, whereas the columns represent the actual values. The categories used in analysis are *false positive*, *true positive*, *false negative*, and *true negative*.

A classification matrix is an important tool for assessing the results of prediction because it makes it easy to understand and account for the effects of wrong predictions. By viewing the amount and percentages in each cell of this matrix, you can quickly see how often the model predicted accurately.

This section explains how to create a classification matrix and how to interpret the results.

Understanding the Classification Matrix

Consider the model that you created as part of the Basic Data Mining Tutorial. The [TM_DecisionTree] model is used to help create a targeted mailing campaign, and can be used to predict which customers are most likely to buy a bike. To test this expected usefulness of this model, you use a data set for which the values of the outcome attribute, [Bike Buyer], are already known. Typically, you would use the testing data set that you set aside when you created the mining structure that is used for training the model.

There are only two possible outcomes: yes (the customer is likely to buy a bike), and no (the customer will likely not purchase a bike). Therefore, the resulting classification matrix is relatively simple.

Interpreting the Results

The following table shows the classification matrix for the TM_DecisionTree model. Remember that for this predictable attribute, 0 means No and 1 means Yes.

PREDICTED	0 (ACTUAL)	1 (ACTUAL)
0	362	144
1	121	373

The first result cell, which contains the value 362, indicates the number of *true positives* for the value 0. Because 0 indicates that the customer did not purchase a bike, this statistic tells you that model predicted the correct value for non bike-buyers in 362 cases.

The cell directly underneath that one, which contains the value 121, tells you the number of *false positives*, or how many times the model predicted that someone would buy a bike when actually they did not.

The cell that contains the value 144 indicates the number of *false positives* for the value 1. Because 1 means that the customer did purchase a bike, this statistic tells you that in 144 cases, the model predicted someone would not

buy a bike when in fact they did.

Finally, the cell that contains the value 373 indicates the number of true positives for the target value of 1. In other words, in 373 cases the model correctly predicted that someone would buy a bike.

By summing the values in cells that are diagonally adjacent, you can determine the overall accuracy of the model. One diagonal tells you the total number of accurate predictions, and the other diagonal tells you the total number of erroneous predictions.

Using Multiple Predictable Values

The [Bike Buyer] case is especially easy to interpret because there are only two possible values. When the predictable attribute has multiple possible values, the classification matrix adds a new column for each possible actual value and then counts the number of matches for each predicted value. The following table shows the results on a different model, where three values (0, 1, 2) are possible.

PREDICTED	0 (ACTUAL)	1 (ACTUAL)	2 (ACTUAL)
0	111	3	5
1	2	123	17
2	19	0	20

Although the addition of more columns makes the report look more complex, the additional detail can be very useful when you want to assess the cumulative cost of making the wrong prediction. To create sums on the diagonals or to compare the results for different combinations of rows, you can click the **Copy** button provided in the **Classification Matrix** tab and paste the report into Excel. Alternatively, you can use a client such as the Data Mining Client for Excel, which supports SQL Server 2005 (9.x) and later versions, to create a classification report directly in Excel that includes both counts and percentages. For more information, see [SQL Server Data Mining](#).

Restrictions on the Classification Matrix

A classification matrix can be used only with discrete predictable attributes.

Although you can add multiple models when selecting models on the **Input Selection** tab of the **Mining Accuracy Chart** designer, the **Classification Matrix** tab will display a separate matrix for each model.

Scatter Plot (Analysis Services - Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

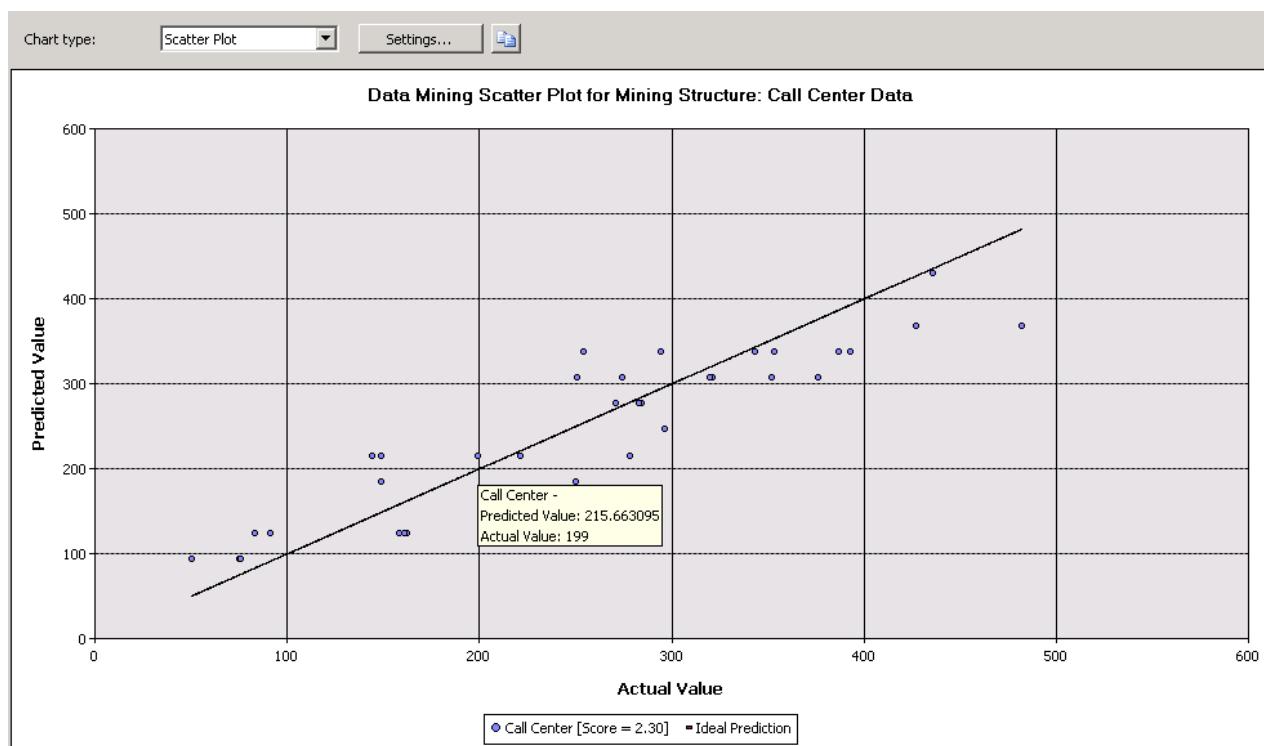

A *scatter plot* graphs the actual values in your data against the values predicted by the model. The scatter plot displays the actual values along the X-axis, and displays the predicted values along the Y-axis. It also displays a line that illustrates the perfect prediction, where the predicted value exactly matches the actual value. The distance of a point from this ideal 45-degree angle line indicates how well or how poorly the prediction performed.

Understanding the Scatter Plot

Consider a model in which the marketing department predicts daily sales based on the number of clicks on a link sent in a promotional e-mail. Because both the number of clicks and the amount of sales are continuous numeric values, you can graph the number of clicks as the independent variable and the sales as the dependent variable. When you do so, the straight line shows the expected linear relationship, and the points scattered around that line show how the actual data diverges from the expected. This analysis tells you at a glance how closely a set of results is correlated with a particular input, and how much variation there is from the ideal model.

Interpreting the Results

The following diagram shows an example of a scatter plot, created for the scenario just described.

You can pause the mouse on any point scattered around the line to view the predicted and actual values in a tooltip. There is no **Mining Legend** for a scatter plot; however, the chart itself contains a legend that displays the score associated with the model. For more information about interpreting the score, see [Mining Model Content for Linear Regression Models \(Analysis Services - Data Mining\)](#).

You can copy the visual representation of the chart to the Clipboard, but not the underlying data or the formula. If you want to view the regression formula for the line, you can create a content query against the model. For more information, see [Linear Regression Model Query Examples](#).

Restrictions on Scatter Plots

A scatter plot can only be created if the model that you choose on the **Input Selection** tab contains a continuous predictable attribute. You do not have to make any additional selections; the scatter plot chart type is automatically displayed in the **Lift Chart** tab based on model and attribute type.

Although time series models predict continuous numbers, you cannot measure the accuracy of a time series model by using a scatter plot. There are other methods that you can use, such as reserving a portion of the historical data. For more information, see [Time Series Model Query Examples](#).

Cross-Validation (Analysis Services - Data Mining)

7/16/2019 • 11 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Cross-validation is a standard tool in analytics and is an important feature for helping you develop and fine-tune data mining models. You use cross-validation after you have created a mining structure and related mining models to ascertain the validity of the model. Cross-validation has the following applications:

- Validating the robustness of a particular mining model.
- Evaluating multiple models from a single statement.
- Building multiple models and then identifying the best model based on statistics.

This section describes how to use the cross-validation features provided for data mining, and how to interpret the results of cross-validation for either a single model or for multiple models based on a single data set.

Overview of Cross-Validation Process

Cross-validation consists of two phases, training and result generation. These phases include the following steps:

- You select a target mining structure.
- You specify the models you want to test. This step is optional; you can test just the mining structure as well.
- You specify the parameters for testing the trained models.
 - The predictable attribute, predicted value, and accuracy threshold.
 - The number of folds into which to partition the structure or model data.
- Analysis Services creates and trains as many models as there are folds.
- Analysis Services returns a set of accuracy metrics for each fold in each model, or for the data set as a whole.

Configuring Cross-Validation

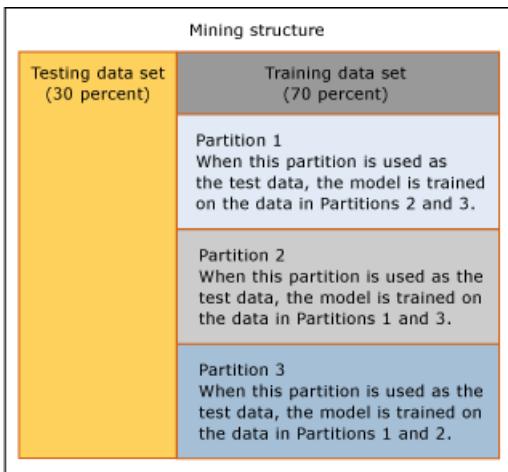

You can customize the way that cross-validation works to control the number of cross-sections, the models that are tested, and the accuracy bar for predictions. If you use the cross-validation stored procedures, you can also specify the data set that is used for validating the models. This wealth of choices means that you can easily produce many sets of different results that must then be compared and analyzed.

This section provides information to help you configure cross-validation appropriately.

Setting the Number of Partitions

When you specify the number of partitions, you determine how many temporary models will be created. For each partition, a cross-section of the data is flagged for use as the test set, and a new model is created by training on the remaining data not in the partition. This process is repeated until Analysis Services has created and tested the specified number of models. The data that you specified as being available for cross-validation is distributed evenly among all partitions.

The example in the diagram illustrates the usage of data if three folds are specified.

In the scenario in the diagram, the mining structure contains a holdout data set that is used for testing, but the test data set has not been included for cross-validation. As a result, all the data in the training data set, 70 percent of the data in the mining structure, is used for cross-validation. The cross-validation report shows the total number of cases used in each partition.

You can also specify the amount of data that is used during cross-validation, by specifying the number of overall cases to use. The cases are distributed evenly across all folds.

For mining structures stored in an instance of SQL Server Analysis Services, the maximum value that you can set for the number of folds is 256, or the number of cases, whichever is less. If you are using a session mining structure, the maximum number of folds is 10.

NOTE

As you increase the number of folds, the time required to perform cross-validation increases accordingly, because a model must be generated and tested for each fold. You may experience performance problems if the number of folds is too high.

Setting the Accuracy Threshold

The state threshold lets you set the accuracy bar for predictions. For each case, the model calculates the *predict probability*, meaning the probability that the predicted state is correct. If the predict probability exceeds the accuracy bar, the prediction is counted as correct; if not, the prediction is counted as incorrect. You control this value by setting **State Threshold** to a number between 0.0 and 1.0, where numbers closer to 1 indicate a strong level of confidence in the predictions, and numbers closer to 0 indicate that the prediction is less likely to be true. The default value for state threshold is NULL, which means that the predicted state with the highest probability is considered the target value.

You should be aware that the setting for state threshold affects measures of model accuracy. For example, assume that you have three models that you want to test. All are based on the same mining structure and all predict the column [Bike Buyer]. Moreover, you want to predict a single value of 1, meaning "yes, will buy." The three models return predictions with predict probabilities of 0.05, 0.15, and 0.8. If you set the state threshold to 0.10, two of the predictions are counted as correct. If you set the state threshold to 0.5, only one model is counted as having returned a correct prediction. If you use the default value, null, the most probable prediction is counted as correct. In this case, all three predictions would be counted as correct.

NOTE

You can set a value of 0.0 for the threshold, but the value is meaningless, because every prediction will be counted as correct, even those with zero probability. Be careful not to accidentally set **State Threshold** to 0.0.

Choosing Models and Columns to Validate

When you use the **Cross Validation** tab in Data Mining Designer, you must first select the predictable column from a list. Typically, a mining structure can support many mining models, not all of which use the same predictable column. When you run cross-validation, only those models that use the same predictable column can be included in the report.

To choose a predictable attribute, click **Target Attribute** and select the column from the list. If the target attribute is a nested column, or a column in a nested table, you must type the name of the nested column using the format <Nested Table Name>(key).<Nested Column>. If the only column used from the nested table is the key column, you can use <Nested Table Name>(key).

After you select the predictable attribute, Analysis Services automatically tests all models that use the same predictable attribute. If the target attribute contains discrete values, after you have selected the predictable column, you can optionally type a target state, if there is a specific value that you want to predict.

The selection of the target state affects the measures that are returned. If you specify a target attribute—that is, a column name—and do not pick a specific value that you want the model to predict, by default the model will be evaluated on its prediction of the most probable state.

When you use cross-validation with clustering models, there is no predictable column; instead, you select **#Cluster** from the list in the **Target Attribute** list box. After you have selected this option, other options that are not relevant to clustering models, such as **Target State**, are disabled. Analysis Services will then test all clustering models that are associated with the mining structure.

Tools for Cross-Validation

You can use cross-validation from the Data Mining Designer, or you can perform cross-validation by running stored procedures.

If you use the Data Mining Designer tools to perform cross-validation, you can configure the training and accuracy results parameters in a single dialog box. This makes it easier to set up and view results. You can measure the accuracy of all mining models that are related to a single mining structure and then immediately view the results in an HTML report. However, the stored procedures offer some advantages, such as added customizations and the ability to script the process.

Cross-Validation in Data Mining Designer

You can perform cross-validation by using the **Cross-Validation** tab of the Mining Accuracy Chart view in either SQL Server Management Studio or SQL Server Development Studio.

To see an example of how to create a cross-validation report using the user interface, see [Create a Cross-Validation Report](#).

Cross-Validation Stored Procedures

For advanced users, cross-validation is also available in the form of fully parameterized system stored procedures. You can run the stored procedures by connecting to an instance from SQL Server Management Studio, or from any managed code application.

The stored procedures are grouped by mining model type. One set of stored procedures works with clustering models only. The other set of stored procedures works with other mining models.

For each type of mining model, clustered or non-clustered, the stored procedures perform cross-validation in two separate phases.

Partition data and generate metrics for partitions

For the first phase, you call a system stored procedure that creates as many partitions as you specify within the data set, and returns accuracy results for each partition. For each metric, Analysis Services then calculates the mean and standard deviation for the partitions.

- [SystemGetCrossValidationResults \(Analysis Services - Data Mining\)](#)
- [SystemGetClusterCrossValidationResults \(Analysis Services - Data Mining\)](#)

Generate metrics for entire data set

In the second phase, you call a different set of stored procedures. These stored procedures do not partition the data set, but generate accuracy results for the specified data set as a whole. If you have already partitioned and processed a mining structure, you can call this second set of stored procedures to get just the results.

- [SystemGetAccuracyResults \(Analysis Services - Data Mining\)](#)
- [SystemGetClusterAccuracyResults \(Analysis Services - Data Mining\)](#)

Defining the Testing Data

When you run the cross-validation stored procedures that calculate accuracy (SystemGetAccuracyResults or SystemGetClusterAccuracyResults), you can specify the source of the data that is used for testing during cross-validation. This option is not available in the user interface.

You can specify as a testing data source any of the following options:

- Use only the training data.
- Include an existing testing data set.
- Use only the testing data set.
- Apply existing filters to each model.
- Any combination of the training set, testing set, and model filters.

To specify a testing data source, you provide an integer value for the **DataSet** parameter of the stored procedure. For a list of the argument values, see the Remarks section of the relevant stored procedure reference topic.

If you perform cross-validation by using the **Cross-Validation** report in the Data Mining Designer, you cannot change the data set that is used. By default, the training cases for each model are used. If a filter is associated with a model, the filter is applied.

Results of Cross-Validation

If you use the Data Mining Designer, these results are displayed in a grid-like Web viewer. If you use the cross-validation stored procedures, these same results are returned as a table.

The report contains two types of measures: aggregates that indicate the variability of the data set when divided into folds, and model-specific measures of accuracy for each fold. The following topics provide more information about these metrics:

[Cross-Validation Formulas](#)

Lists all the measures by test type. Describes in general how the measures can be interpreted.

[Measures in the Cross-Validation Report](#)

Describes the formulas for calculating each measure, and lists the type of attribute that each measure can be applied to.

Restrictions on Cross-Validation

If you perform cross-validation by using the cross-validation report in SQL Server Development Studio, there are some limitations on the models that you can test and the parameters you can set.

- By default, all models associated with the selected mining structure are cross-validated. You cannot specify the model or a list of models.
- Cross-validation is not supported for models that are based on the Microsoft Time Series algorithm or the Microsoft Sequence Clustering algorithm.
- The report cannot be created if your mining structure does not contain any models that can be tested by cross-validation.
- If the mining structure contains both clustering and non-clustering models and you do not choose the **#Cluster** option, results for both types of models are displayed in the same report, even though the attribute, state, and threshold settings might not be appropriate for the clustering models.
- Some parameter values are restricted. For example, a warning is displayed if the number of folds is more than 10, because generating so many models might cause the report to display slowly.

If you are testing multiple mining models, and the models have filters, each model is filtered separately. You cannot add a filter to a model or change the filter for a model during cross-validation.

Because cross-validation by defaults tests all mining models that are associated with a structure, you may receive inconsistent results if some models have a filter and others do not. To ensure that you compare only those models that have the same filter, you should use the stored procedures and specify a list of mining models. Or, use only the mining structure test set with no filters to ensure that a consistent set of data is used for all models.

If you perform cross-validation by using the stored procedures, you have the additional option of choosing the source of testing data. If you perform cross-validation by using the Data Mining Designer, you must use the testing data set that is associated with the model or structure, if any. Generally, if you want to specify advanced settings, you should use the cross-validation stored procedures.

Cross-validation cannot be used with time series or sequence clustering models. Specifically, no model that contains a KEY TIME column or a KEY SEQUENCE column can be included in cross-validation.

Measures in the Cross-Validation Report

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

During cross-validation, Analysis Services divides the data in a mining structure into multiple cross-sections and then iteratively tests the structure and any associated mining models. Based on this analysis, it outputs a set of standard accuracy measures for the structure and each model.

The report contains some basic information about the number of folds in the data and the amount of data in each fold, and a set of general metrics that describe data distribution. By comparing the general metrics for each cross-section, you can assess the reliability of the structure or model.

Analysis Services also displays a set of detailed measures for mining models. These measures depend on the model type and on the type of attribute that is being analyzed: for example, whether it is discrete or continuous.

This section provides a list of the measures that are contained in the **Cross-Validation** report, and what they mean. For details on how each measure is calculated, see [Cross-Validation Formulas](#).

List of Measures in the Cross-Validation Report

The following table lists the measures that appear in the cross-validation report. The measures are grouped by *test type*, which is provided in the left-hand column of the following table. The right-hand column lists the name of the measure as it appears in the report, and provides a brief explanation of what it means.

TEST TYPE	MEASURES AND DESCRIPTIONS
Clustering	Measures that apply to clustering models
	Case likelihood: This measure usually indicates how likely it is that a case belongs to a particular cluster. For cross-validation, the scores are summed and then divided by the number of cases, so here the score is an average case likelihood.
Classification	Measures that apply to classification models
	True Positive/True Negative/False Positive/False Negative: Count of rows or values in the partition where the predicted state matches the target state, and the predict probability is greater than the specified threshold. Cases that have missing values for the target attribute are excluded, meaning the counts of all values might not add up.
	Pass/Fail: Count of rows or values in the partition where the predicted state matches the target state, and where the predict probability value is greater than 0.
Likelihood	Likelihood measures apply to multiple model types.

TEST TYPE	MEASURES AND DESCRIPTIONS
	<p>Lift: The ratio of the actual prediction probability to the marginal probability in the test cases. Rows that have missing values for the target attribute are excluded.</p> <p>This measure generally shows how much the probability of the target outcome improves when the model is used.</p>
	<p>Root Mean Square Error: Square root of the mean error for all partition cases, divided by the number of cases in the partition, excluding rows that have missing values for the target attribute.</p> <p>RMSE is a popular estimator for predictive models. The score averages the residuals for each case to yield a single indicator of model error.</p>
	<p>Log score: The logarithm of the actual probability for each case, summed, and then divided by the number of rows in the input dataset, excluding rows that have missing values for the target attribute.</p> <p>Because probability is represented as a decimal fraction, log scores are always negative numbers. A number closer to 0 is a better score. Whereas raw scores can have very irregular or skewed distributions, a log score is similar to a percentage.</p>
Estimation	Measures that apply only to estimation models, which predict a continuous numeric attribute.
	<p>Root Mean Square Error: Average error when the predicted value is compared to the actual value.</p> <p>RMSE is a popular estimator for predictive models. The score averages the residuals for each case to yield a single indicator of model error.</p>
	<p>Mean Absolute Error: Average error when predicted values are compared to actual values, calculated as the mean of the absolute sum of errors.</p> <p>Mean absolute error is useful for understanding how close overall the predictions were to actual values. A smaller score means predictions were more accurate.</p>
	<p>Log Score: The logarithm of the actual probability for each case, summed, and then divided by the number of rows in the input dataset, excluding rows that have missing values for the target attribute.</p> <p>Because probability is represented as a decimal fraction, log scores are always negative numbers. A number closer to 0 is a better score. Whereas raw scores can have very irregular or skewed distributions, a log score is similar to a percentage.</p>

TEST TYPE	MEASURES AND DESCRIPTIONS
Aggregates	<p>Aggregate measures provide an indication of the variance in the results for each partition.</p>
	<p>Mean: Average of the partition values for a particular measure.</p>
	<p>Standard Deviation: Average of the deviation from the mean for a specific measure, across all the partitions in a model.</p> <p>For cross-validation, a higher value for this score implies substantial variation between the folds.</p>

[Testing and Validation \(Data Mining\)](#)

Cross-Validation Formulas

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you generate a cross-validation report, it contains accuracy measures for each model, depending on the type of mining model (that is, the algorithm that was used to create the model), the data type of the predictable attribute, and the predictable attribute value, if any.

This section lists the measures used in the cross-validation report and describes the method of calculation.

For a breakdown of the accuracy measures by model type, see [Measures in the Cross-Validation Report](#).

Formulas used for Cross-Validation Measures

NOTE

Important: These measures of accuracy are computed for each target attribute. For each attribute you can specify or omit a target value. If a case in the data set does not have any value for the target attribute, the case is treated as having a special value called the *missing value*. Rows that have missing values are not counted when computing the accuracy measure for a particular target attribute. Note that because the scores are computed for each attribute individually, if values are present for the target attribute but missing for other attributes, it does not affect the score for the target attribute.

MEASURE	APPLIES TO	IMPLEMENTATION
True positive	Discrete attribute, value is specified	Count of cases that meet these conditions: Case contains the target value. Model predicted that case contains the target value.
True Negative	Discrete attribute, value is specified	Count of cases that meet these conditions: Case does not contain the target value. Model predicted that case does not contain the target value.
False positive	Discrete attribute, value is specified	Count of cases that meet these conditions: Actual value is equal to target value. Model predicted that case contains the target value.

MEASURE	APPLIES TO	IMPLEMENTATION
False Negative	Discrete attribute, value is specified	Count of cases that meet these conditions: Actual value not equal to target value. Model predicted that case does not contain the target value.
Pass/fail	Discrete attribute, no specified target	Count of cases that meet these conditions: Pass if the predicted state with the highest probability is the same as the input state and probability is greater than the value of State Threshold . Otherwise, fail.
Lift	Discrete attribute. Target value can be specified but is not required.	The mean log likelihood for all rows with values for the target attribute, where log likelihood for each case is calculated as $\text{Log}(\text{ActualProbability}/\text{MarginalProbability})$. To compute the mean, the sum of the log likelihood values is divided by the number of rows in the input dataset, excluding rows with missing values for the target attribute. Lift can be either a negative or positive value. A positive value means an effective model that outperforms the random guess.
Log score	Discrete attribute. Target value can be specified but is not required.	Log of the actual probability for each case, summed, and then divided by the number of rows in the input dataset, excluding rows with missing values for the target attribute. Because probability is represented as a decimal fraction, log scores are always negative numbers. A score that is closer to 0 is a better score.
Case likelihood	Cluster	Sum of the cluster likelihood scores for all cases, divided by the number of cases in the partition, excluding rows with missing values for the target attribute.
Mean absolute error	Continuous attribute	Sum of the absolute error for all cases in the partition, divided by the number of cases in the partition.
Root mean square error	Continuous attribute	Square root of the mean squared error for the partition.

MEASURE	APPLIES TO	IMPLEMENTATION
Root mean squared error	Discrete attribute. Target value can be specified but is not required.	Square root of the mean of the squares of complement of the probability score, divided by the number of cases in the partition, excluding rows with missing values for the target attribute.
Root mean squared error	Discrete attribute, no specified target.	Square root of the mean of the squares of complement of the probability score, divided by the number of cases in the partition, excluding cases with missing values for the target attribute.

Testing and Validation Tasks and How-tos (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

You can use the **Mining Accuracy Chart** tab of Data Mining Designer in Visual Studio with Analysis Services projects to compare the predictive accuracy of the mining models in your mining structure.

You can create four kinds of charts:

- Lift chart
- Profit chart
- Classification matrix
- Cross-validation report

The first three charts use the **Input Selection** tab to define the data that is used for generating the chart.

The Cross-validation chart is created by using additional inputs, available on the **Cross-Validation** tab. For more information, see [Cross-Validation \(Analysis Services - Data Mining\)](#).

For more information about how to use the mining accuracy chart, see [Testing and Validation \(Data Mining\)](#).

In This Section

- [Create a Lift Chart, Profit Chart, or Classification Matrix](#)
- [Create a Cross-Validation Report](#)
- [Choose and Map Model Testing Data](#)
- [Apply Filters to Model Testing Data](#)
- [Choose the Column to Use for Testing a Mining Model](#)
- [Using Nested Table Data as an Input for an Accuracy Chart](#)

Create a Lift Chart, Profit Chart, or Classification Matrix

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can create an accuracy chart for an Analysis Services data mining model in five basic steps:

- Select the mining structure that contains the mining models that you want to compare.
- Select the mining models to add to the chart.
- Specify a source of testing data to use in generating the chart.
- Choose the chart type.
- Configure the chart options.

These basic steps are the same for the lift chart, profit chart, and classification matrix. The following procedures outline the steps to configure the basic chart options for these chart types. For information about how to create a cross-validation report, see [Measures in the Cross-Validation Report](#).

Open the mining structure in the Accuracy Chart Designer

1. Open the Data Mining Designer in Visual Studio with Analysis Services projects.
2. In Solution Explorer, double-click the structure that contains the mining model or models.
3. Click the **Mining Accuracy Chart** tab.

Select mining models for inclusion in the chart

1. On the **Mining Accuracy Chart** tab of Data Mining Designer in Visual Studio with Analysis Services projects, click the **Input Selection** tab.

The list displays all models in the current structure that have the same predictable attribute.
2. Select the **Show box** for each model that you want to include in the chart.
3. Click the **Predictable Column Name** text box, and select the name of a predictable column from the list.

All models that you put in one chart must have the same predictable column.
4. If you compare two models and the predictable columns have different values or different data types, clear the **Synchronize prediction columns and values** box to force a comparison.

NOTE

If the **Synchronize prediction columns and values** box is selected, Analysis Services analyzes the data in the predictable columns of the model and the test data, and attempts to find the best match. Therefore, do not clear the box unless absolutely necessary to force a comparison of the columns.

5. Click the **Predict Value** text box, and select a value from the list. If the predictable column is a continuous data type, you must type a value in the text box.

For more information, see [Choose the Column to Use for Testing a Mining Model](#).

Select testing data

1. On the **Input Selection** tab of the **Mining Accuracy Chart** tab, specify the source of the data that you will use to generate the chart by selecting one of the options in the group, **Select data set to be used for accuracy chart**.

- Select the option, **Use Mining Model test cases**, if you want to use the subset of cases that is defined by the intersection of the mining structure test cases and any filters that may have been applied during model creation.
- Select the option, **Use mining structure test cases**, to use the full set of testing cases that were defined as part of the mining structures holdout data set.
- Select the option, **Specify a different data set**, if you want to use external data. The data set must be available as a data source view. Click the browse (...) button to choose the data tables to use for the accuracy chart. For more information, see [Choose and Map Model Testing Data](#).

If you are using an external data set, you can optionally filter the input data set. For more information, see [Apply Filters to Model Testing Data](#).

NOTE

You cannot create a filter on the model test cases or the mining structure test cases on the **Input Selection** tab. To create a filter on the mining model, modify the Filter property of the model. For more information, see [Apply a Filter to a Mining Model](#).

Configure chart settings and generate the chart

1. In the **Mining Accuracy Chart** tab, click the tab for the chart you want to create.
2. For a **lift chart**, click the **Lift Chart** tab. The chart is automatically generated based on the model, predictable attributes, and input data that you just selected.
3. For a **classification matrix**, click the **Classification Matrix** tab. No further settings are needed; the chart is automatically generated based on the input data and model that you selected.
4. For a **profit chart**, first click the **Lift Chart** tab. Then, from the **Chart type** drop-down list, select **Profit chart**.

Enter the following settings in the **Profit Chart Settings** dialog box.

Population

The number of cases from the data set that you want to use when creating the lift chart.

The model always chooses the cases in order of decreasing probability; that is, if you are assessing potential customers and you choose a number that represents only half the records in your customer database, the model will measure accuracy on the subset of cases that best fit your model.

This is because when you use the model to generate a mailing or create a campaign, you will use the prediction probability associated with each case to target only the customers who have the highest probability of making a positive response.

Fixed Cost

The fixed cost that is associated with the business problem.

If this were for a targeted mailing solution, the fixed cost might represent a printer setup fee that covers the initial cost of preparing the promotional mailing.

This cost applies one time to the entire target population.

Individual Cost

Costs that are in addition to the fixed cost, that can be associated with each customer contact. For example, you might enter the postage cost for a promotional mailing or the cost of making telephone calls.

This cost must be the same for the entire target population. Each value is multiplied by the number of cases that are targeted.

Revenue Per Individual

The amount of revenue that is associated with each successful sale.

[Lift Chart \(Analysis Services - Data Mining\)](#)

[Classification Matrix \(Analysis Services - Data Mining\)](#)

Create a Cross-Validation Report

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic walks you through creation of a cross-validation report using the Accuracy Chart tab in Data Mining Designer. For general information about what a cross-validation report looks like, and the statistical measures it includes, see [Cross-Validation \(Analysis Services - Data Mining\)](#).

A cross-validation report is fundamentally different from an accuracy chart, such as a lift chart or classification matrix.

- Cross-validation assesses the overall distribution of data that is used in a model or structure; therefore, you do not specify a testing data set. Cross-validation always uses only the original data that was used to train the model or the mining structure.
- Cross-validation can only be performed with respect to a single predictable outcome. If the structure supports models that have different predictable attributes, you must create separate reports for each predictable output.
- Only models that are related to the currently selected structure are available for cross-validation.
- If the structure that is currently selected supports a combination of clustering and non-clustering models, when you click **Get Results**, the cross-validation stored procedure will automatically load models that have the same predicted column, and ignore clustering models that do not share the same predictable attribute.
- You can create a cross-validation report on a clustering model that does not have a predictable attribute only if the mining structure does not support any other predictable attributes.

Select a mining structure

1. Open the Data Mining Designer in Visual Studio with Analysis Services projects.
2. In Solution Explorer, open the database that contains the structure or model for which you want to create a report.
3. Double-click the mining structure to open the structure and its related models in Data Mining Designer.
4. Click the **Mining Accuracy Chart** tab.
5. Click the **Cross Validation** tab.

Set cross-validation options

1. On the **Cross Validation** tab, for **Fold Count**, click the down arrow to select a number between 1 and 10. The default value is 10.

The **Fold Count** represents the number of partitions that will be created within the original data set. If you set Fold Count to 1, the training set will be used without partitioning.

2. For **Target Attribute**, click the down arrow, and select a column from the list. If the model is a clustering model, select **#Cluster** to indicate that the model does not have a predictable attribute. Note that the value, **#Cluster**, is available only when the mining structure does not support other types of predictable attributes.

You can select only one predictable attribute per report. By default, all related models that have the same predictable attribute are included in the report.

3. For **Max Cases**, type a number that is large enough to provide a representative sample of data when the data is split among the specified number of folds. If the number is greater than the count of cases in the model training set, all cases will be used.

If the training data set is very large, setting the value for **Max Cases** limits the total number of cases processed, and lets the report finish faster. However, you should not set **Max Cases** too low or there may be insufficient data for cross-validation.

4. Optionally, for **Target State**, type the value of the predictable attribute that you want to model. For example, if the column [Bike Buyer] has two possible values, 1 (Yes) and 2 (No), you can enter the value 1 to assess the accuracy of the model for just the desired outcome.

NOTE

If you do not enter a value, the **Target Threshold** option is not available, and the model is assessed for all possible values of the predictable attribute.

5. Optionally, for **Target Threshold**, type a decimal number between 0 and 1 to specify the minimum probability that a prediction must have to be counted as accurate.

For additional tips about how to set probability thresholds, see [Measures in the Cross-Validation Report](#).

6. Click **Get Results**.

Print the cross-validation report

1. Right-click the completed report on the **Cross Validation** tab.
2. In the shortcut menu, select **Print** or **Print Preview** to review the report first.

Create a copy of the report in Microsoft Excel

1. Right-click the completed report on the **Cross Validation** tab.
2. In the shortcut menu, select **Select All**.
3. Right-click the selected text, and select **Copy**.
4. Paste the selection into an open Excel workbook. If you use the **Paste** option, the report is pasted into Excel as HTML, which preserves row and column formatting. If you paste the report by using the **Paste Special** options for text or Unicode text, the report is pasted in row-delimited format.

Choose and Map Model Testing Data

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

To create an accuracy chart in Analysis Services, you must choose the data that will be used to test the model, and map the data to the model.

By default, Analysis Services will use the mining model testing data, provided that you created a holdout data set when you built the mining structure. Creating a holdout test set is the easiest way to test models that are based on the same mining structure, because the column names and data types will always match the model, and you can be reasonably assured that the distribution of the data is similar. Also, the designer will automatically create the relationships between the input and model columns.

Alternatively, you can specify an external source of data. For external data, there are some additional requirements:

- The external data set must be defined as a data source view in an instance of Analysis Services.
- The external data set must at least contain one column that can be mapped to the predictable column in the mining model. You can choose to ignore some columns.
- You cannot add new columns or map columns in a different data source view. The data source view that you select must contain all the columns that you need for the prediction query.
- If the external column names exactly match those in the model, the designer will map them for you. If the mappings are wrong, you can change them, or delete and create new mappings for existing columns.
- If you use an external data source, you can apply filters to restrict the testing data to a relevant subset of cases.
- Even when you use the holdout test set, you should be aware that filters can cause differences between the testing data associated with a mining structure and the mining model test cases.

This topic describes how to choose and map the testing data:

[Select input tables to test the accuracy of a mining model](#)

[Map model columns to the columns in the testing data](#)

[Change the way that columns in the testing data are mapped to the model](#)

To select input tables to test the accuracy of a mining model

1. In Data Mining Designer in Visual Studio with Analysis Services projects, double-click the mining structure that contains the models you want to chart.
2. Select the **Mining Accuracy Chart** tab.
3. On the **Input Selection Tab** of the **Mining Accuracy Chart** view, select one of the following options:

Use mining model test cases

Use mining structure test cases

Specify a different data set

4. If you selected **Specify a different data set**, optionally click **Open Filter Editor** to create filter conditions

on the input data set. Click **OK**.

5. Click the **Lift Chart** tab or the **Classification Matrix** tab to automatically build the chart by using the testing data you specified.

To map model columns to the columns in the testing data

1. Double-click the mining structure that contains the models you want to chart, to open the structure and models in Data Mining Designer.
2. Select the **Mining Accuracy Chart** tab, and then select the **Input Selection** tab.
3. In the **Input Selection** tab, under **Select data set to be used for Accuracy Chart**, select **Specify a different data set**.
4. Click the browse button (...) to open a dialog box and build the definition of the external data set.
5. In the **Select Mining Structure** dialog box, select the mining structure that contains the models you want to work with, and then click **OK**.
6. On the **Select Input Table(s)** table of the **Mining Accuracy Chart** tab, click **Select Case Table** to open the **Select Table** dialog box.
7. In the **Select Table** dialog box, select a data source from the **Data Source** list. Choose a table that contains the data that you want to use in the prediction queries to determine the accuracy of the models.
8. In the **Table/View Name** box, select the table that contains the data that you want to use to test the models.
9. Edit the mappings, if necessary. Columns in the mining structure are automatically mapped to the columns with the same name in the input table. To manually create mappings, click a column in the **Select Input Table(s)** table and drag it onto the corresponding column in the **Mining Structure** table. To delete a mapping, click the line that links the column in the **Mining Structure** table to the mapped column in the **Select Input Table(s)** table, and then press DELETE.
10. Click **OK**.

To modify the way input data is mapped to the model

1. In Data Mining Designer, double-click the structure that contains the models you want to chart.
2. Select the **Mining Accuracy Chart** tab.
3. Click the **Input Selection** tab.
4. In **Select data set to be used for Accuracy Chart**, select the option **Specify a different data set**.
5. Click the browse button (...) to open a dialog box and build the definition of the external data source.
6. In the **Specify Column Mapping** dialog box, click **Select Case Table**.
7. In the Select Table dialog box, Select a data source view from the list, and select the table that contains the case data. Click **OK**.
8. If the tables you need are not available, close the dialog box and create a new data source view that contains the table. For information about how to create a data source view, see [Defining a Data Source View \(Analysis Services\)](#).
9. If the mining model contains a nested table, click **Select Nested Table**, and select the nested table from the list of tables in the data source view. Click **OK**.

10. Select the join line of the mapping you want to modify, and select **Modify Connections**.

The **Modify Mapping** dialog box opens. In the table in this dialog box, **Mining Structure Column** lists each column that the selected mining structure contains, and **Table Column** lists the columns from input tables that are mapped to columns in the mining structure.

11. Under **Table Column**, select the row that corresponds to the row under **Mining Structure Column** for which you want to modify a relationship. Select a new column from the list, or select the blank entry from the list to delete the column.

12. Click **OK**.

The new column mappings are displayed in the **Specify Column Mapping** dialog box. You can remove a mapping by selecting the line between the columns and pressing the DELETE key. You can create a new connection by selecting a column in the **Mining Structure** table and dragging it to the corresponding column in the **SelectInput Table(s)** table.

Apply Filters to Model Testing Data

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you specify an external data source to use in testing a model, you can optionally apply a filter to restrict the input data. For example, you might want to test the model specifically for predictions on customers in a certain income range.

For example, in the Adventure Works targeted mailing scenario, you can create a filter expression like the following one on ProspectiveBuyer, which is the table that contains the testing data, and restrict testing cases by income range:

```
[YearlyIncome] = '50000'
```

The behavior of filters is slightly different, depending on whether you are filtering model training data or a testing data set:

- When you define a filter on a testing data set, you create a WHERE clause on the incoming data. If you are filtering an input data set used for evaluating a model, the filter expression is translated to a Transact-SQL statement and applied to the input table when the chart is created. As a result, the number of test cases can be greatly reduced.
- When you apply a filter to a mining model, the filter expression that you create is translated to a Data Mining Extensions (DMX) statement, and applied to the individual model. Therefore, when you apply a filter to a model, only a subset of the original data is used to train the model. This can cause problems if you filter the training model with one set of criteria, so that the model is tuned to a certain set of data, and then test the model with another set of criteria.
- If you defined a testing data set when you created the structure, the model cases used for training include only those cases that are in the mining structure training set **and** which meet the conditions of the filter. Thus, when you are testing a model and select the option **Use mining model test cases**, the testing cases will include only the cases that are in the mining structure test set and which meet the conditions of the filter. However, if you did not define a holdout data set, the model cases used for testing include all the cases in the data set that meet the filter conditions
- Filter conditions that you apply on a model also affect drillthrough queries on the model cases.

In summary, when you test multiple models, even if all the models are based on the same mining structure, you must be aware that the models potentially use different subsets of data for training and testing. This can have the following effects on accuracy charts:

- The total number of cases in the testing sets can vary among the models being tested.
- The percentages for each model may not align in the chart, if the models use different subsets of training data or testing data.

To determine whether a model contains a predefined filter that might affect results, you can look for the **Filter** property in the **Property** pane, or you can query the model by using the data mining schema rowsets. For example, the following query returns the filter text for the specified model:

```
SELECT [FILTER] FROM $system.DMSCHEMA_MINING_MODELS WHERE MODEL_NAME = 'name of model'
```

WARNING

If you want to remove the filter from an existing mining model, or change the filter conditions, you must reprocess the mining model.

For more information about the kinds of filters you can apply, and how filter expressions are evaluated, see [Model Filter Syntax and Examples \(Analysis Services - Data Mining\)](#).

Create a filter on external testing data

1. Double-click the mining structure that contains the model you want to test, to open Data Mining Designer.
2. Select the **Mining Accuracy Chart** tab, and then select the **Input Selection** tab.
3. On the **Input Selection** tab, under **Select data set to be used for Accuracy Chart**, select the option **Specify a different data set**.
4. Click the browse button (...) to open a dialog box and choose the external data set.
5. Choose the case table, and add a nested table if necessary. Map columns in the model to columns in the external data set as necessary. Close the **Specify Column Mapping** dialog box to save the source table definition.
6. Click **Open Filter Editor** to define a filter for the data set.

The **Data Set Filter** dialog box opens. If the structure contains a nested table, you can create a filter in two parts. First, set conditions on the case table by using the **Data Set Filter** dialog box, and then set conditions on the nested rows by using the **Filter** dialog box.

7. In the **Data Set Filter** dialog box, click the top row in the grid, under **Mining Structure Column**, and select a table or column from the list.

If the data source view contains multiple tables, or a nested table, you must first select the table name. Otherwise, you can select columns from the case table directly.

Add a new row for each column that you want to filter.

8. Use **Operator**, and **Value** columns to define how the column is filtered.

Note Type values without using quotation marks.

9. Click the **And/Or** text box and select a logical operator to define how multiple conditions are combined.
10. Optionally, click the browse button (...) at the right of the **Value** text box to open the **Filter** dialog box and set conditions on the nested table or on the individual case table columns.
11. Verify that the completed filter conditions are correct by viewing the text in the **Expression** pane.
12. Click **OK**.

The filter condition is applied to the data source when you create the accuracy chart.

Choose the Column to Use for Testing a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Before you can measure the accuracy of a mining model, you must decide which outcome it is that you want to assess. Most data mining models require that you choose at least one column to use as the predictable attribute when you create the model. Therefore, when you test the accuracy of the model, you generally must select that attribute to test.

The following list describes some additional considerations for choosing the predictable attribute to use in testing:

- Some types of data mining models can predict multiple attributes—such as neural networks, which can explore the relationships between many attributes.
- Other types of mining models—such as clustering models—do not necessarily have a predictable attribute. Clustering models cannot be tested unless they have a predictable attribute.
- To create a scatter plot or measure the accuracy of a regression model requires that you choose a continuous predictable attribute as the outcome. In that case, you cannot specify a target value. If you are creating anything other than a scatter plot, the underlying mining structure column must also have a content type of **Discrete** or **Discretized**.
- If you choose a discrete attribute as the predictable outcome, you can also specify a target value, or you can leave the **Predict Value** field blank. If you include a **Predict Value**, the chart will measure only the model's effectiveness at predicting the target value. If you do not specify a target outcome, the model is measured for its accuracy in predicting all outcomes.
- If you want to include multiple models and compare them in a single accuracy chart, all models must use the same predictable column.
- When you create a cross-validation report, Analysis Services will automatically analyze all models that have the same predictable attribute.
- When the option, **Synchronize Prediction columns and Values**, is selected, Analysis Services automatically chooses predictable columns that have the same names and matching data types. If your columns do not meet these criteria, you can turn off this option and manually choose a predictable column. You might need to do this if you are testing the model with an external data set that has different columns than the model. However, if you choose a column with the wrong type of data you will either get an error or bad results.

Specify the outcome to predict

1. Double-click the mining structure to open it in Data Mining Designer.
2. Select the **Mining Accuracy Chart** tab.
3. Select the **Input Selection** tab.
4. On the **Input Selection** tab, under **Predictable Column Name**, select a predictable column for each model that you include in the chart.

The mining model columns that are available in the **Predictable Column Name** box are only those with the usage type set to **Predict** or **Predict Only**.

5. If you want to determine the lift for a model, you must select a specific outcome value to measure, for by choosing from the **Predict Value** list.

[Choose and Map Model Testing Data](#)

[Choose an Accuracy Chart Type and Set Chart Options](#)

Choose an Accuracy Chart Type and Set Chart Options

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

SQL Server Analysis Services provides multiple methods for determining the validity of your mining models. The type of accuracy chart that you can create for each model or structure depends on these factors:

- The type of algorithm that was used to create the model
- The data type of the predictable attribute
- The number of predictable attributes to measure

This topic provides an overview of the different accuracy charts.

Note Charts and their definitions are not saved. If you close the window that contains a chart, you must create the chart again.

Accuracy Chart Types

Depending on the chart type that you choose, you have the ability to further configure options, to browse the chart, or copy the chart to the Clipboard and work with the data in Excel.

Lift chart

After you have configured the options for the models and the testing data, click the **Lift Chart** tab to view the results. You can also copy the chart to the Clipboard, or view details of individual trend lines or data points in the Mining Legend.

Profit Chart

After you have configured the options for the models and the testing data, click the **Lift Chart** tab, select **Profit Chart** from the **Chart Type** list to set profit chart options, and then click **OK** to view the results.

You can use the **Profit Chart Settings** dialog box as many times as you want to try different cost options and redisplay the chart. The Mining Legend contains detailed information about the estimated profit for each model. You can also copy the chart and the contents of the Mining Legend to the Clipboard to work with it in Excel.

Scatter Plot

If you have selected the appropriate type of model, when you click the **Lift Chart** tab, the chart type is automatically set to **Scatter Plot** and a scatter plot is displayed. No further configuration is possible. You can also copy the chart to the Clipboard and paste the chart as a graphic into Excel or another application.

Classification Matrix

For a classification matrix, use the **Input Selection** tab to choose the models and the testing data, and then click the **Classification Matrix** tab to view the results.

The contents of a classification matrix are the same for all model types, and cannot be configured. You can copy the data in the chart to the Clipboard and then work with it in Excel.

Cross-Validation Report

For a cross-validation report, after you have selected a mining structure or mining model in Solution Explorer, click the **Cross Validation** tab, configure all relevant options, and then click **Get Results** to generate the report. No further configuration is possible.

The format of the cross-validation report is the same for all model types, and cannot be configured. However, the content of the report differs depending on the type of model that you are analyzing, and the data type of the predictable attribute. You can also copy the results of the report to the Clipboard and work with the data in Excel.

Using Nested Table Data as an Input for an Accuracy Chart

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you test the accuracy of a mining model by using external data, if the mining model contains nested tables, the external data must also contain a case table and an associated nested table.

This topic describes how to work with nested tables used for model testing, how to map nested and case tables in the mode and in the external data, and how to apply a filter to a nested table.

When working with nested tables, keep in mind these tips:

- If you select the option **Use mining model test cases** or **Use mining structure test cases**, you do not need to specify a case table or nested table. With those options, the definition of the test data is stored in the mining structure and the test data is automatically selected when you create the accuracy chart.
- If a relationship already exists between the case and nested table in the data source, the columns in the mining structure are automatically mapped to the columns that have the same name in the input table.
- You cannot select a nested table until you have specified the case table. Also, you cannot specify a nested table as an input unless the mining model also uses a case table and nested table structure.

Use a nested table as input to an accuracy chart

1. Double-click the mining structure to open it in Data Mining Designer.
2. Select the **Mining Accuracy Chart** tab, and then select the **Input Selection** tab.
3. In **Select data set to be used for accuracy chart**, select the option **Specify a different data set**.
4. Click the browse button (...) to choose the external data set from a list of data source views on the current server.
5. Click **Select Case Table**. In the **Select Table** dialog box, choose the table from the data source view that contains the case data, and then click **OK**.
6. Click **Select Nested Table**. In the **Select Table** dialog box, select the table that contains the nested data, and then click **OK**.
7. Click **OK**.

If you need to modify the relationship between the nested table and the case table, click **Modify Join** to open the **Create Relationship** dialog box.

[Apply Filters to Model Testing Data](#)

Data Mining Queries

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Data mining queries are useful for many purposes. You can:

- Apply the model to new data, to make single or multiple predictions. You can provide input values as parameters, or in a batch.
- Get a statistical summary of the data used for training.
- Extract patterns and rules, or generate a profile of the typical case representing a pattern in the model.
- Extract regression formulas and other calculations that explain patterns.
- Get the cases that fit a particular pattern.
- Retrieve details about individual cases used in the model, including data not used in analysis.
- Retrain a model by adding new data, or perform cross-prediction.

This section provides an overview of the information you need to get started with data mining queries. It describes the types of queries you can create against data mining objects, introduces the query tools and query languages, and provides links to examples of queries that you can create against models that were built using the algorithms provided in SQL Server Data Mining.

[Understanding Data Mining Queries](#)

[Query Tools and Interfaces](#)

[Queries for Different Model Types](#)

[Requirements](#)

Understanding Data Mining Queries

Analysis Services Data Mining supports the following types of queries:

- [Prediction Queries \(Data Mining\)](#)

Queries that make inferences based on patterns in the model, and from input data.

- [Content Queries \(Data Mining\)](#)

Queries that return metadata, statistics, and other information about the model itself.

- [Drillthrough Queries \(Data Mining\)](#)

Queries that can retrieve the underlying case data for the model, or even data from the structure that was not used in the model.

- [Data Definition Queries \(Data Mining\)](#)

Queries that do not return information from the model, but rather are used to build models and structures or to update the data in a model or structure.

Before you create queries, we recommend that you familiarize yourself with the differences between models created with each of the data mining algorithms provided by SQL Server.

- Browse and explore each model type by using the custom data mining viewers that are provided for each algorithm type. For more information, see [Mining Model Viewer Tasks and How-tos](#).
- Review the model content for each model type, by using the **Microsoft Generic Content Tree Viewer**. To interpret this information, refer to [Mining Model Content \(Analysis Services - Data Mining\)](#).

Query Tools and Interfaces

You can build data mining queries interactively by using one of the query tools provided by SQL Server. The graphical Prediction Query Builder is provided in both Visual Studio with Analysis Services projects and SQL Server Management Studio. If you have not used the Prediction Query Builder before, we recommend that you follow the steps in the [Basic Data Mining Tutorial](#) to familiarize yourself with the interface. For a quick overview of the steps, see Create a Query using the [Create a Prediction Query Using the Prediction Query Builder](#).

The Prediction Query Builder is helpful for starting queries that you will customize later. You can easily add data sources and map them to columns, and then switch to DMX view and customize the query by adding a WHERE clause or other functions.

Once you are familiar with data mining models and how to build queries, you can also write queries directly by using Data Mining Extensions (DMX). DMX is a query language that is similar to Transact-SQL, and that you can use from many different clients. DMX is the tool of choice for creating both custom predictions and complex queries. For an introduction to DMX, see [Creating and Querying Data Mining Models with DMX: Tutorials \(Analysis Services - Data Mining\)](#).

DMX editors are provided in both Visual Studio with Analysis Services projects and SQL Server Management Studio. You can also use the Prediction Query Builder to start your queries, then change the view to the text editor and copy the DMX statement to another client. For more information, see [Data Mining Query Tools](#).

You can compose DMX statements programmatically and send them from your client to the Analysis Services server by using AMO or XMLA. However, DMX is the language that you must use to create queries against a mining model.

You can also query the metadata, statistics, and some content of the model by using Dynamic Management Views (DMVs) that are based on the data mining schema rowsets. These DMVs make it easy to retrieve information about the model by typing SELECT statements; however, you cannot create predictions. For more information about DMVs supported by Analysis Services, see [Use Dynamic Management Views \(DMVs\) to Monitor Analysis Services](#).

Finally, you can create data mining queries for use in Integration Services packages, by using the [Data Mining Query Task](#), or the [Data Mining Query Transformation](#). The control flow task supports multiple types of DMX queries, whereas the data flow transformation supports only queries that work with data in the data flow, meaning queries that use the PREDICTION JOIN syntax.

Queries for Different Model Types

The algorithm that was used when the model was created greatly influences the type of information that you can get from a data mining query. The reason for the differences is that each algorithm processes the data in a different way, and stores different kinds of patterns. For example, some algorithms create clusters; others create trees. Therefore, you might need to use specialized prediction and query functions, depending on the type of model that you are working with.

The following list provides a summary of the functions that you can use in queries:

- **General prediction functions:** The **Predict** function is polymorphic, meaning it works with all model types. This function will automatically detect the type of model you are working with and prompt you for additional parameters. For more information, see [Predict \(DMX\)](#).

WARNING

Not all models are used to make predictions. For example, you can create a clustering model that does not have a predictable attribute. However, even if a model does not have a predictable attribute, you can create prediction queries that return other types of useful information from the model.

- **Custom prediction functions:** Each model type provides a set of prediction functions designed for working with the patterns created by that algorithm.

For example, the **Lag** function is provided for time series models, to let you view the historical data used for the model. For clustering models, functions such as **ClusterDistance** are more meaningful.

For more information about the functions that are supported for each model type, see the following links:

Association Model Query Examples	Microsoft Naive Bayes Algorithm
Clustering Model Query Examples	Neural Network Model Query Examples
Decision Trees Model Query Examples	Sequence Clustering Model Query Examples
Linear Regression Model Query Examples	Time Series Model Query Examples
Logistic Regression Model Query Examples	

You can also call VBA functions, or create your own functions. For more information, see [Functions \(DMX\)](#).

- **General statistics:** There are a number of functions that can be used with almost any model type, which return a standard set of descriptive statistics, such as standard deviation.

For example, the **PredictHistogram** function returns a table that lists all the states of the specified column.

For more information, see [General Prediction Functions \(DMX\)](#).

- **Custom statistics:** Additional supporting functions are provided for each model type, to generate statistics that are relevant to the specific analytical task.

For example, when you are working with a clustering model, you can use the function, **PredictCaseLikelihood**, to return the likelihood score associated with a certain case and cluster. However, if you created a linear regression model, you would be more interested in retrieving the coefficient and intercept, which you can do using a content query.

- **Model content functions:** The *content* of all models is represented in a standardized format that lets you retrieve information with a simple query. You create queries on the model content by using DMX. You can also get some type of model content by using the data mining schema rowsets.

In the model content, the meaning of each row or node of the table that is returned differs depending on the type of algorithm that was used to build the model, as well as the data type of the column. For more information, see [Content Queries \(Data Mining\)](#).

Requirements

Before you can create a query against a model, the data mining model must have been processed. Processing of Analysis Services objects requires special permissions. For more information on processing mining models, see [Processing Requirements and Considerations \(Data Mining\)](#).

To execute queries against a data mining model requires different levels of permissions, depending on the type of query that you run. For example, drillthrough to case or structure data typically requires additional permissions which can be set on the mining structure object or mining model object.

However, if your query uses external data, and includes statements such as OPENROWSET or OPENQUERY, the database that you are querying must enable these statements, and you must have permission on the underlying database objects.

For more information on the security contexts required to run data mining queries, see [Security Overview \(Data Mining\)](#)

In This Section

The topics in this section introduce each type of data mining query in more detail, and provide links to detailed examples of how to create queries against data mining models.

Prediction Queries (Data Mining)

7/16/2019 • 10 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The goal of a typical data mining project is to use the mining model to make predictions. For example, you might want to predict the amount of expected downtime for a certain cluster of servers, or generate a score that indicates whether segments of customers are likely to respond to an advertising campaign. To do all these things, you would create a prediction query.

Functionally, there are different types of prediction queries supported in SQL Server, depending on the type of inputs to the query:

QUERY TYPE	QUERY OPTIONS
Singleton prediction queries	Use a singleton query when you want to predict outcomes for a single new case, or multiple new cases. You provide the input values directly in the query, and the query is executed as a single session.
Batch predictions	Use batch predictions when you have external data that you want to feed into the model, to use as the basis for predictions. To make predictions for an entire set of data, you map the data in the external source to the columns in the model, and then specify the type of predictive data you want to output. The query for the entire dataset is executed in a single session, making this option much more efficient than sending multiple repeated queries.
Time Series predictions	Use a time series query when you want to predict a value over some number of future steps. SQL Server Data Mining also provides the following functionality in time series queries: You can extend an existing model by adding new data as part of the query, and make predictions based on the composite series. You can apply an existing model to a new data series by using the REPLACE_MODEL_CASES option. You can perform cross-prediction.

The following sections describe the general syntax of prediction queries, the different types of prediction queries, and how to work with the results of prediction queries.

[Basic Prediction Query Design](#)

- [Adding Prediction Functions](#)
- [Singleton Queries](#)
- [Batch Prediction Queries](#)
- [Time Series Queries](#)

Basic Prediction Query Design

When you create a prediction, you typically provide some piece of new data and ask the model to generate a prediction based on the new data.

- In a batch prediction query, you map the model to an external source of data by using a *prediction join*.
- In a singleton prediction query, you type one or more values to use as inputs. You can create multiple predictions using a singleton prediction query. However, if you need to create many predictions, performance is better when you use a batch query.

Both singleton and batch prediction queries use the PREDICTION JOIN syntax to define the new data. The difference is in how the input side of the prediction join is specified.

- In a batch prediction query, the data comes from an external data source that is specified by using the OPENQUERY syntax.
- In a singleton prediction query, the data is supplied inline as part of the query.

For time series models, input data is not always required; it is possible to make predictions using just the data already in the model. However, if you do specify new input data, you must decide whether you will use the new data to update and extend the model, or to replace the original series of data that was used in the model. For more information about these options, see [Time Series Model Query Examples](#).

Adding Prediction Functions

In addition to predicting a value, you can customize a prediction query to return various kinds of information that are related to the prediction. For example, if the prediction creates a list of products to recommend to a customer, you might also want to return the probability for each prediction, so that you can rank them and present only the top recommendations to the user.

To do this, you add *prediction functions* to the query. Each model or query type supports specific functions. For example, clustering models support special prediction functions that provide extra detail about the clusters created by the model, whereas time series models have functions that calculate differences over time. There are also general prediction functions that work with almost all model types. For a list of the prediction functions supported in different types of queries, see this topic the DMX reference: [General Prediction Functions \(DMX\)](#).

Creating Singleton Prediction Queries

A singleton prediction query is useful when you want to create quick predictions in real time. A common scenario might be that you have obtained information from a customer, perhaps by using a form on a Web site, and you want to submit that data as the input to a singleton prediction query. For example, when a customer chooses a product from a list, you could use that selection as the input to a query that predicts the best products to recommend.

Singleton prediction queries do not require a separate table that contains input. Instead, you provide one or multiple rows of values as input to the model, and the prediction or predictions are returned in real time.

WARNING

Despite the name, singleton prediction queries do not just make single predictions—you can generate multiple predictions for each set of inputs. You provide multiple input cases by creating a SELECT statement for each input case and combining them with the UNION operator.

When you create a singleton prediction query, you must provide the new data to the model in the form of a PREDICTION JOIN. This means that even though you are not mapping to an actual table, you must make sure

that the new data matches the existing columns in the mining model. If the new data columns and the new data match exactly, Analysis Services will map the columns for you. This is called a *NATURAL PREDICTION JOIN*. However, if the columns do not match, or if the new data does not contain the same kind and amount of data that is in the model, you must specify which columns in the model map to the new data, or specify the missing values.

Batch Prediction Queries

A batch prediction query is useful when you have external data that you want to use in making predictions. For example, you might have built a model that categorizes customers by their online activity and purchasing history. You could apply that model to a list of newly acquired leads, to create projections for sales, or to identify targets for proposed campaigns.

When you perform a prediction join, you must map the columns the model to the columns in the new data source. Therefore, the data source that you choose for an input must data that is somewhat similar to the data in the model. The new information does not have to match exactly, and can be incomplete. For example, suppose the model was trained using information about income and age, but the customer list you are using for predictions has age but nothing about income. In this scenario, you could still map the new data to the model and create a prediction for each customer. However, if income was an important predictor for the model, the lack of complete information would affect the quality of predictions.

To get the best results, you should join as many of the matching columns as possible between the new data and the model. However, the query will succeed even if there are no matches. If no columns are joined, the query will return the marginal prediction, which is equivalent to the statement `SELECT <predictable-column> FROM <model>` without a PREDICTION JOIN clause.

After you have successfully mapped all relevant columns, you run the query, and Analysis Services makes predictions for each row in the new data based on patterns in the model. You can save the results back to a new table in the data source view that contains the external data, or you can copy and paste the data is you are using Visual Studio with Analysis Services projects or SQL Server Management Studio.

WARNING

If you use the designer in Visual Studio with Analysis Services projects, the external data source must first be defined as a data source view.

If you use DMX to create a prediction join, you can specify the external data source by using the OPENQUERY, OPENROWSET, or SHAPE commands. The default data access method in the DMX templates is OPENQUERY. For information about these methods, see [<source data query>](#).

Predictions in Time Series Mining Models

Time series models are different from other models types; you can either use the model as it is to create predictions, or you can provide new data to the model to update the model and create predictions based on recent trends. If you add new data, you can specify the way the new data should be used.

- *Extending the model cases* means that you add the new data onto the existing series of data in the time series model. Henceforth, predictions are based on the new, combined series. This option is good when you want to simply add a few data points to an existing model.

For example, suppose that you have an existing time series model that has been trained on the sales data from the previous year. After you have collected several months of new sales data, you decide to update your sales forecasts for the current year. You can create a prediction join that updates the model by adding new data and extends the model to make new predictions.

- *Replacing the model cases* means that you keep the trained model, but replace the underlying cases with a new set of case data. This option is useful when you want to keep the trend in the model, but apply it to a different set of data.

For example, your original model might have been trained on a set of data with very high sales volumes; when you replace the underlying data with a new series (perhaps from a store with lower sales volume), you preserve the trend, but the predictions begin from the values in the replacement series.

Regardless of which approach you use, the starting point for predictions is always the end of the original series.

For more information about how to create prediction joins on time series models, see [Time Series Model Query Examples](#) or [PredictTimeSeries \(DMX\)](#).

Working with the Results of a Prediction Query

Your options for saving the results of a data mining prediction query are different depending on how you create the query.

- When you build a query using Prediction Query Builder in either SQL Server Management Studio or Visual Studio with Analysis Services projects, you can save the results of a prediction query to an existing Analysis Services data source. For more information, see [View and Save the Results of a Prediction Query](#).
- When you create prediction queries using DMX in the Query pane of SQL Server Management Studio, you can use the query output options to save the results to a file, or to the Query Results pane as text or in a grid. For more information, see [Query and Text Editors \(SQL Server Management Studio\)](#).
- When you run a prediction query using the Integration Services components, the tasks provides the ability to write the results to a database by using an available ADO.NET connection manager or OLEDB connection manager. For more information, see [Data Mining Query Task](#).

It is important to understand that the results of a prediction query are not like the results of a query on a relational database, which always returns a single row of related values. Each DMX prediction function that you add to a query returns its own rowset. Therefore, when you make a prediction on a single case, the result might be a predicted value together with several columns of nested tables containing additional detail.

If you combine multiple functions in one query, the return results are combined as a hierarchical rowset. For example, say you use a time series model to predict future values for sales amount and sales quantity, using a query such as this DMX statement:

```
SELECT
    PredictTimeSeries([Forecasting].[Amount]) as [PredictedAmount]
    , PredictTimeSeries([Forecasting].[Quantity]) as [PredictedQty]
FROM
    [Forecasting]
```

The results of this query are two columns, one for each predicted series, where each row contains a nested table with the predicted values:

PredictedAmount

\$TIME	AMOUNT
201101	172067.11

\$TIME	AMOUNT
201102	363390.68

PredictedQty

\$TIME	QUANTITY
201101	77
\$TIME	QUANTITY
201102	260

If your provider cannot handle hierarchical rowsets, you can flatten the results by using the FLATTEN keyword in the prediction query. For more information, including examples of flattened rowsets, see [SELECT \(DMX\)](#).

Content Queries (Data Mining)

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A content query is a way of extracting information about the internal statistics and structure of the mining model. Sometimes a content query can provide details that are not readily available in the viewer. You can also use the results of a content query to extract information programmatically for other uses.

This section provides general information about the types of information that you can retrieve by using a content query, and the general DMX syntax for content queries.

Basic Content Queries

- [Queries on Structure and Case Data](#)
- [Queries on Model Patterns](#)

Examples

- [Content Query on an Association Model](#)
- [Content Query on a Decision Trees Model](#)

Working with the Query Results

Basic Content Queries

You can create content queries by using the Prediction Query Builder, use the DMX content query templates that are provided in SQL Server Management Studio, or write queries directly in DMX. Unlike prediction queries you do not need to join external data, so content queries are easy to write.

This section provides an overview of the types of content queries you can create.

- Queries on the mining structure or case data let you view the detailed data that was used for training.
- Queries on the model can return patterns, lists of attributes, formulas, and so forth.

Queries on Structure and Case Data

DMX supports queries on the cached data that is used to build mining structures and models. By default, this cache is created when you define the mining structure, and is populated when you process the structure or model.

WARNING

This cache cannot be cleared or deleted if you need to separate data into training and testing sets. If the cache is cleared, you cannot query the case data.

The following examples show the common patterns for creating queries on the case data, or queries on the data in the mining structure:

Get all the cases for a model

```
SELECT FROM <model>.CASES
```

Use this statement to retrieve specified columns from the case data used to build a model. You must have drillthrough permissions on the model to run this query.

View all the data that is included in the structure

```
SELECT FROM <structure>.CASES
```

Use this statement to view all the data that is included in the structure, including columns that are not included in a particular mining model. You must have drillthrough permissions on the model, as well as on the structure, to retrieve data from the mining structure.

Get range of values

```
SELECT DISTINCT RangeMin(<column>), RangeMax(<column>) FROM <model>
```

Use this statement to find the minimum value, maximum value, and mean of a continuous column, or of the buckets of a DISCRETIZED column.

Get distinct values

```
SELECT DISTINCT <column> FROM <model>
```

Use this statement to retrieve all the values of a DISCRETE column. Do not use this statement for DISCRETIZED columns; use the **RangeMin** and **RangeMax** functions instead.

Find the cases that were used to train a model or structure

```
SELECT FROM <mining structure>.CASES WHERE IsTrainingCase()
```

Use this statement to get the complete set of data that was used in training a model.

Find the cases that are used for testing a model or structure

```
SELECT FROM <mining structure>.CASES WHERE IsTestingCase()
```

Use this statement to get the data that has been set aside for testing mining models related to a specific structure.

Drillthrough from a specific model pattern to underlying case data

```
SELECT FROM <model>.CASES WHERE IsTrainingCase() AND IsInNode(<node>)
```

Use this statement to retrieve detailed case data from a trained model. You must specify a specific node: for example, you must know the node ID of the cluster, the specific branch of the decision tree, etc. Moreover, you must have drillthrough permissions on the model to run this query.

Queries on Model Patterns, Statistics, and Attributes

The content of a data mining model is useful for many purposes. With a model content query, you can:

- Extract formulas or probabilities for making your own calculations.
- For an association model, retrieve the rules that are used to generate a prediction.
- Retrieve the descriptions of specific rules so that you can use the rules in a custom application.
- View the moving averages detected by a time series model.
- Obtain the regression formula for some segment of the trend line.
- Retrieve actionable information about customers identified as being part of a specific cluster.

The following examples show some of the common patterns for creating queries on the model content:

Get patterns from the model

```
SELECT FROM <model>.CONTENT
```

Use this statement to retrieve detailed information about specific nodes in the model. Depending on the algorithm type, the node can contain rules and formulas, support and variance statistics, and so forth.

Retrieve attributes used in a trained model

```
CALL System.GetModelAttributes(<model>)
```

Use this stored procedure to retrieve the list of attributes that were used by a model. This information is useful for determining attributes that were eliminated as a result of feature selection, for example.

Retrieve content stored in a data mining dimension

```
SELECT FROM <model>.DIMENSIONCONTENT
```

Use this statement to retrieve the data from a data mining dimension.

This query type is principally for internal use. However, not all algorithms support this functionality. Support is indicated by a flag in the MINING_SERVICES schema rowset.

If you develop your own plug-in algorithm, you might use this statement to verify the content of your model for testing.

Get the PMML representation of a model

```
SELECT * FROM <model>.PMML
```

Gets an XML document that represents the model in PMML format. Not all model types are supported.

Examples

Although some model content is standard across algorithms, some parts of the content vary greatly depending on the algorithm that you used to build the model. Therefore, when you create a content query, you must understand what information in the model is most useful to your specific model.

A few examples are provided in this section to illustrate how the choice of algorithm affects the kind of information that is stored in the model. For more information about mining model content, and the content that is specific to each model type, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Example 1: Content Query on an Association Model

The statement, `SELECT FROM <model>.CONTENT`, returns different kinds of information, depending on the type of model you are querying. For an association model, a key piece of information is the *node type*. Nodes are like containers for information in the model content. In an association model, nodes that represent rules have a NODE_TYPE value of 8, whereas nodes that represent itemsets have a NODE_TYPE value of 7.

Thus, the following query returns the top 10 itemsets, ranked by support (the default ordering).

```
SELECT TOP 10 NODE_DESCRIPTION, NODE_PROBABILITY, SUPPORT  
FROM <model>.CONTENT WHERE NODE_TYPE = 7
```

The following query builds on this information. The query returns three columns: the ID of the node, the complete rule, and the product on the right-hand side of the itemset—that is, the product that is predicted to be associated with some other products as part of an itemset.

```
SELECT FLATTENED NODE_UNIQUE_NAME, NODE_DESCRIPTION,  
      (SELECT RIGHT(ATTRIBUTE_NAME, (LEN(ATTRIBUTE_NAME)-LEN('Association model name'))))  
  FROM NODE DISTRIBUTION  
 WHERE LEN(ATTRIBUTE_NAME)>2  
 )  
 AS RightSideProduct  
  FROM [<Association model name>].CONTENT  
 WHERE NODE_TYPE = 8  
 ORDER BY NODE_SUPPORT DESC
```

The FLATTENED keyword indicates that the nested rowset should be converted into a flattened table. The attribute that represents the product on the right-hand side of the rule is contained in the NODE_DISTRIBUTION table; therefore, we retrieve only the row that contains an attribute name, by adding a requirement that the length

be greater than 2.

A simple string function is used to remove the name of the model from the third column. (Usually the model name is prefixed to the values of nested columns.)

The WHERE clause specifies that the value of NODE_TYPE should be 8, to retrieve only rules.

For more examples, see [Association Model Query Examples](#).

Example 2: Content Query on a Decision Trees Model

A decision tree model can be used for prediction as well as for classification. This example assumes that you are using the model to predict an outcome, but you also want to find out which factors or rules can be used to classify the outcome.

In a decision tree model, nodes are used to represent both trees and leaf nodes. The caption for each node contains the description of the path to the outcome. Therefore, to trace the path for any particular outcome, you need to identify the node that contains it, and get the details for that node.

In your prediction query, you add the prediction function [PredictNodeID \(DMX\)](#), to get the ID of the related node, as shown in the following example:

```
SELECT Predict([Bike Buyer]), PredictNodeID([Bike Buyer])
FROM [<decision tree model name>]
PREDICTION JOIN
<input rowset>
```

Once you have the ID of the node that contains the outcome, you can retrieve the rule or path that explains the prediction by creating a content query that includes the NODE_CAPTION, as follows:

```
SELECT NODE_CAPTION
FROM [<decision tree model name>]
WHERE NODE_UNIQUE_NAME= '<node id>'
```

For more examples, see [Decision Trees Model Query Examples](#).

Working with the Query Results

As the examples demonstrate, content queries mostly return tabular rowsets, but can also include information from nested columns. You can flatten the rowset that is returned, but this can make working with results more complex. The content of the NODE_DISTRIBUTION node in particular is nested, but contains much interesting information about the model.

For more information about how to work with hierarchical rowsets, see the OLEDB specification on MSDN.

[Understanding the DMX Select Statement](#)

[Data Mining Queries](#)

Drillthrough Queries (Data Mining)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A *drillthrough query* lets you retrieve details from the underlying cases or structure data, by sending a query to the mining model. Drillthrough is useful if you want to view the cases that were used to train the model, versus the cases that are used to test the model, or if you want to see additional details from the case data.

Analysis Services Data Mining provides two different options for drillthrough:

- Drilling through to the **model cases**

Drillthrough to model cases is used when you want to go from a specific pattern in the model—such as a cluster or branch of a decision tree—and view details about the individual cases.

- Drilling through to the **structure cases**

Drillthrough to structure cases is used when the structure contains information that might not be available in the model. For example, you would not use customer contact information in a clustering model, even if the data was included in the structure. However, after you create the model, you might want to retrieve contact information for customers who are grouped into a particular cluster.

This section provides examples of how you can create these queries.

[Using Drillthrough in Data Mining Designer](#)

[Creating Drillthrough Queries using DMX](#)

[Considerations When Using Drillthrough](#)

- [Security Issues](#)
- [Limitations](#)

Using Drillthrough in Data Mining Designer

If a mining model has been configured to allow drillthrough, and if you have the appropriate permissions, when you browse the model, you can click on a node in the appropriate viewer and retrieve detailed information about the cases in that particular node.

[Drill Through to Case Data from a Mining Model.](#)

If the training cases were cached when you processed the mining structure, and you have the necessary permissions, you can return information from the model cases and from the mining structure, including columns that were not included in the mining model.

Creating Drillthrough Queries using DMX

You can drill through to case data by creating a DMX query, if you have permissions on the model or on the structure. For examples of the syntax for creating drillthrough queries in DMX, see the following topic:

[Create Drillthrough Queries using DMX](#)

Considerations When Using Drillthrough

- If you use the Data Mining Wizard, the option to enable drillthrough to the model cases is on the final page of the wizard. Drillthrough is disabled by default. For more information, see [Completing the Wizard \(Data Mining Wizard\)](#).
- You can add the ability to drill through on an existing mining model, but if you do, the model must be reprocessed before you can drill through to the data.
- Drillthrough works by retrieving information about the training cases that was cached when you processed the mining structure. Therefore, if you cleared the cached data after processing the structure by changing the [MiningStructureCacheMode](#) property to **ClearAfterProcessing**, drillthrough will not work. To enable drillthrough to structure columns, you must change the [MiningStructureCacheMode](#) property to **KeepTrainingCases** and then reprocess the structure.
- If the mining structure does not allow drillthrough but the mining model does, you can view information only from the model cases, and not from the mining structure.

Security Issues for Drillthrough

If you want to drill through to structure cases from the model, you must verify that both the mining structure and the mining model have the [AllowDrillThrough](#) property set to **True**. Moreover, you must be a member of a role that has drillthrough permissions on both the structure and the model. For information about how to create roles, see [Role Designer \(Analysis Services - Multidimensional Data\)](#).

Drillthrough permissions are set separately on the structure and model. The model permission lets you drill through from the model, even if you do not have permissions on the structure. Drillthrough permissions on the structure provide the additional ability to include structure columns in drillthrough queries from the model, by using the [StructureColumn \(DMX\)](#) function.

NOTE

If you enable drillthrough on both the mining structure and the mining model, any user who is a member of a role that has drillthrough permissions on the mining model can also view columns in the mining structure, even if those columns are not included in the mining model. Therefore, to protect sensitive data, you should set up the data source view to mask personal information, and allow drillthrough access on the mining structure only when necessary.

Limitations on Drillthrough

- The following limitations apply to drillthrough operations on a model, depending on the algorithm that was used to create the model:

ALGORITHM NAME	ISSUE
Microsoft Naïve Bayes algorithm	Not supported. These algorithms do not assign cases to specific nodes in the content.
Microsoft Neural Network algorithm	Not supported. These algorithms do not assign cases to specific nodes in the content.
Microsoft Logistic Regression algorithm	Not supported. These algorithms do not assign cases to specific nodes in the content.
Microsoft Linear Regression algorithm	Supported. However, because the model creates a single node, All , drilling through returns all the training cases for the model. If the training set is large, loading the results may take a very long time.

ALGORITHM NAME	ISSUE
Microsoft Time Series algorithm	<p>Supported. However, you cannot drill through to structure or case data by using the Mining Model Viewer in Data Mining Designer. You must create a DMX query instead.</p> <p>Also, you cannot drill through to specific nodes, or write a DMX query to retrieve cases in specific nodes of a time series model. You can retrieve case data from either the model or the structure by using other criteria, such as date or attribute values.</p> <p>You can also return the dates from the cases in the model, by using the Lag (DMX) function.</p> <p>If you wish to view details of the ARTXP and ARIMA nodes created by the Microsoft Time Series algorithm, you can use the Microsoft Generic Content Tree Viewer (Data Mining).</p>

Related Tasks

[Data Mining Model Viewers](#)

[Data Mining Queries](#)

Drill Through to Case Data from a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If a mining model has been configured to let you drill through to model cases, when you browse the model, you can retrieve detailed information about the cases that were used to create the model. Moreover, if the underlying mining structure has been configured to allow drillthrough to structure cases, and you have the appropriate permissions, you can return information from the mining structure. This can include columns that were not included in the mining model.

If the mining structure does not allow you to drill through to the underlying data, but the mining model does, you can view information from the model cases, but not from the mining structure.

NOTE

You can add the ability to drillthrough on an existing mining model by setting the property **AllowDrillthrough** to **True**. However, after you enable drillthrough, the model must be reprocessed before you can see the case data. For more information, see [Enable Drillthrough for a Mining Model](#).

Depending on the type of viewer you are using, you can select the node for drillthrough in the following ways:

VIEWER NAME	PANE OR TAB NAME	SELECT NODE
Microsoft Tree Viewer	Decision Tree tab	Click a tree node. Note Avoid using drillthrough on the All node, because it may take a very long time to return results.
Microsoft Cluster Viewer	Cluster Diagram	Click a cluster node.
Microsoft Cluster Viewer	Cluster Profiles	Click anywhere in cluster column.
Microsoft Association Viewer	Rules tab	Click a row that contains a set of rules.
Microsoft Association Viewer	Itemsets tab	Click a row that contains an itemset.
Microsoft Sequence Clustering Viewer	Rules tab	Click a row that contains a set of rules.
Microsoft Sequence Clustering Viewer	Itemsets tab	Click a row that contains an itemset.

NOTE

Some models cannot use drillthrough. The ability to use drillthrough depends on the algorithm that was used to create the model. For a list of the mining model types that support drillthrough, see [Drillthrough Queries \(Data Mining\)](#).

To view drillthrough data from a mining model

1. In Visual Studio with Analysis Services projects, open the mining structure that contains the mining model you want.
2. In Data Mining Designer, click the **Mining Model Viewer** tab.
3. Select the model from the **Mining Model** drop-down list.
4. Select a viewer from the **Viewer** drop-down list, and right-click the specific node.
5. Select **Drill Through**, and then select either **Models Columns Only**, or **Model and Structure Columns** to open the **Drill Through** window.
6. To copy the data to the Clipboard, right-click any row in the table, and select **Copy All**.

[Drillthrough Queries \(Data Mining\)](#)

Create Drillthrough Queries using DMX

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

For all models that support drillthrough, you can retrieve case data and structure data by creating a DMX query in SQL Server Management Studio or any other client that supports DMX.

WARNING

To view the data, drillthrough must have been enabled, and you must have the necessary permissions.

Specifying Drillthrough Options

The general syntax is for retrieving model cases and structure cases is as follows:

```
SELECT <model column list>, StructureColumn('<structure column name>') FROM <modelname>.CASES
```

For additional information about using DMX queries to return case data, see [SELECT FROM <model>.CASES \(DMX\)](#) and [SELECT FROM <structure>.CASES](#).

Examples

The following DMX query returns the case data for a specific product series, from a time series model. The query also returns the column **Amount**, which was not used in the model but is available in the mining structure.

```
SELECT [DateSeries], [Model Region], Quantity, StructureColumn('Amount') AS [M200 Pacific Amount]
FROM Forecasting.CASES
WHERE [Model Region] = 'M200 Pacific'
```

Note that in this example, an alias has been used to rename the structure column. If you do not assign an alias to the structure column, the column is returned with the name 'Expression'. This is the default behavior for all unnamed columns.

[Drillthrough on Mining Structures](#)

Data Definition Queries (Data Mining)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

For data mining, the category *data definition query* means DMX statements or XMLA commands that do the following:

- Create, alter, or manipulate data mining objects, such as a model.
- Define the source of data to be used in training or for prediction.
- Export or import mining models and mining structures.

[Creating Data Definition Queries](#)

- [Data Definition Queries in SQL Server Data Tools](#)
- [Data Definition Queries in SQL Server Management Studio](#)

[Scripting Data Definition Statements](#)

[Scripting Data Definition Statements](#)

Creating Data Definition Queries

You can create data definition queries (statements) by using the Prediction Query Builder in Visual Studio with Analysis Services projects and SQL Server Management Studio, or by using the DMX Query window in SQL Server Management Studio. Data definition statements in DMX are part of the Analysis Services data definition language (DDL).

For information about the syntax of specific data definition statements, see [Data Mining Extensions \(DMX\) Reference](#).

Data Definition Queries in SQL Server Data Tools

The Data Mining Wizard is the preferred tool in Visual Studio with Analysis Services projects for creating and modifying mining models and mining structures, and for defining the data sources that are used in prediction queries and for training.

However, if you want to know what statements are being sent to the server by the wizard to create data structures or mining models, you can use SQL Server Profiler to capture the data definition statements. For more information, see [Use SQL Server Profiler to Monitor Analysis Services](#).

To view the statements used for defining data sources used for training or prediction, you can use the **SQL View** in the Prediction Query Builder. Sometimes it can be helpful to build basic queries for training and testing models by using Prediction Query Builder, to establish the correct syntax. You can then switch to **SQL View** and manually edit the query. For more information, see [Manually Edit a Prediction Query](#).

Data Definition Queries in SQL Server Management Studio

For data mining objects, you can use data definition queries to perform the following actions:

- Create specific types of models, such as a clustering model or decision tree model, by using [CREATE MINING MODEL \(DMX\)](#).
- Alter an existing mining structure by adding a model or by changing the columns, by using [ALTER](#)

MINING STRUCTURE (DMX). Note that you cannot alter a mining model by using DMX; you only add new models to an existing structure.

- Make a copy of a mining model and then alter it, by using [SELECT INTO \(DMX\)](#).
- Define the data set used for training a model, by using [INSERT INTO \(DMX\)](#) together with a data source query such as OPENROWSET.

SQL Server Management Studio provides query templates that can help you create data definition queries. For more information, see [Use Analysis Services Templates in SQL Server Management Studio](#).

In general, the templates that are provided for Analysis Services in SQL Server Management Studio contain only the general syntax definition, which you must customize, either by typing in the **Query** window, or by using the dialog box provided for entering parameters.

For an example of how to enter parameters using the interface, see [Create a Singleton Prediction Query from a Template](#).

Scripting Data Definition Statements

Analysis Services provides multiple scripting and programming languages that you can use to create or alter data mining objects, or to define data sources. Although DMX is designed for expediting data mining tasks, you can also use both XMLA and AMO to manipulate objects in scripts or in custom code.

The Data Mining Add-in for Excel also includes many query templates, and provides the **Advanced Query Editor**, which helps you compose complex DMX statements. You can build a query interactively and then switch to SQL View to capture the DMX statement.

Exporting and Importing Models

You can use data definition statements in DMX to export the definition of a model and its required structure and data sources, and then import that definition into a different server. Using export and import is the fastest and easiest way to move data mining models and mining structures between instances of Analysis Services. For more information, see [Management of Data Mining Solutions and Objects](#).

WARNING

If your model is based on data from a cube data source, you cannot use DMX to export the model, and should use backup and restore instead.

Data Mining Schema Rowsets (SSAs)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In SQL Server 2017, many of the existing OLE DB data mining schema rowsets are exposed as a set of system tables that you can query by using Data Mining Extensions (DMX) statements. By creating queries against the data mining schema rowset, you can identify the services that are available, get updates on the status of your models and structures, and find out details about the model content or parameters. For a description of the data mining schema rowsets, see [Data Mining Schema Rowsets](#).

NOTE

You can also query the data mining schema rowsets by using XMLA. For more information about how to do this in SQL Server Management Studio, see [Create a Data Mining Query by Using XMLA](#).

List of Data Mining Schema Rowsets

The following table lists the data mining schema rowsets that may be useful for querying and monitoring.

ROWSET NAME	DESCRIPTION
DMSHEMA_MINING_MODELS	<p>Lists all mining models in the current context.</p> <p>Includes such information as the date created, parameters used to create the model, and the size of the training set.</p>
DMSHEMA_MINING_COLUMNS	<p>Lists all columns used in mining models in the current context.</p> <p>Information includes mapping to mining structure source column, data type, precision, and prediction functions that can be used with the column.</p>
DMSHEMA_MINING_STRUCTURES	<p>Lists all mining structure in the current context.</p> <p>Information includes whether the structure is populated, the date the structure was last processed, and the definition of the holdout data set for the structure, if any.</p>
DMSHEMA_MINING_STRUCTURE_COLUMNS	<p>Lists all columns used in mining structures in the current context.</p> <p>Information includes content type and data type, nullability, and whether the column contains nested table data.</p>
DMSHEMA_MINING_SERVICES	<p>Lists all mining services, or algorithms, that are available on the specified server.</p> <p>Information includes supported modeling flags, input types, and supported data source types.</p>

ROWSET NAME	DESCRIPTION
DMSHEMA_MINING_SERVICE_PARAMETERS	<p>Lists all parameters for the mining services that are available on the current instance.</p> <p>Information includes the data type for each parameter, the default values, and the upper and lower limits.</p>
DMSHEMA_MODEL_CONTENT	<p>Returns the content of the model if the model has been processed.</p> <p>For more information, see Mining Model Content (Analysis Services - Data Mining).</p>
DBSCHEMA_CATALOGS	Lists all databases (catalogs) in the current instance of Analysis Services.
MDSHEMA_INPUT_DATASOURCES	Lists all data sources in the current instance of Analysis Services.

NOTE

The list in the table is not comprehensive; it shows only those rowsets that may be of most interest for troubleshooting.

Examples

The following section provides some examples of queries against the data mining schema rowsets.

Example 1: List Data Mining Services

The following query returns a list of the mining services that are available on the current server, meaning the algorithms that are enabled. The columns provided for each mining service include the modeling flags and content types that can be used by each algorithm, the GUID for each service, and any prediction limits that may have been added for each service.

```
SELECT *
FROM $system.DMSHEMA_MINING_SERVICES
```

Example 2: List Mining Model Parameters

The following example returns the parameters that were used to create a specific mining model:

```
SELECT MINING_PARAMETERS
FROM $system.DMSHEMA_MINING_MODELS
WHERE MODEL_NAME = 'TM Clustering'
```

Example 3: List All Rowsets

The following example returns a comprehensive list of the rowsets that are available on the current server:

```
SELECT *
FROM $system.DBSCHEMA_TABLES
```

Data Mining Query Tools

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

All data mining queries use the Data Mining Extensions (DMX) language. DMX can be used to create models for all kinds of machine learning tasks, including classification, risk analysis, generation of recommendations, and linear regression. You can also write DMX queries to get information about the patterns and statistics that were generated when you processed the model.

You can write your own DMX, or you can build basic DMX using a tool such as the **Prediction Query Builder** and then modify it. Both SQL Server Management Studio and Visual Studio with Analysis Services projects provide tools that help you build DMX prediction queries. This topic describes how to create and execute data mining queries using these tools.

- [Prediction Query Builder](#)
- [Query Editor](#)
- [DMX Templates](#)
- [Integration Services](#)
- [Application Programming Interfaces](#)

Prediction Query Builder

Prediction Query Builder is included in the **Mining Model Prediction** tab of Data Mining Designer, which is available in both SQL Server Management Studio and Visual Studio with Analysis Services projects.

When you use the query builder, you select a mining model, add new case data, and add prediction functions. You can then switch to the text editor to modify the query manually, or switch to the **Results** pane to view the results of the query.

Query Editor

The Query Editor in SQL Server Management Studio also lets you build and run DMX queries. You can connect to an instance of Analysis Services, and then select a database, mining structure columns, and a mining model. The **Metadata Explorer** contains a list of prediction functions that you can browse.

DMX Templates

SQL Server Management Studio provides interactive DMX query templates that you can use to build DMX queries. If you do not see the list of templates, click **View** on the toolbar, and select **Template Explorer**. To see all Analysis Services templates, including templates for DMX, MDX, and XMLA, click the cube icon.

To build a query using a template, you can drag the template into an open query window, or you can double-click the template to open a new connection and a new query pane.

For an example of how to create a prediction query from a template, see [Create a Singleton Prediction Query from a Template](#).

WARNING

The Data Mining Add-in for Microsoft Office Excel also contains a number of templates, along with an interactive query builder which can help you compose complex DMX statements. To use the templates, click **Query**, and click **Advanced** in the Data Mining Client.

Integration Services Data Mining Components

You can also include prediction queries as part of a SQL Server Integration Services package. The following tasks and transformations in Integration Services support the creation and execution of DMX prediction queries and DMX statements.

COMPONENT	DESCRIPTION
Data Mining Query task	<p>Executes DMX queries and other DMX statements as part of a control flow.</p> <p>The task editor provides the Prediction Query Builder, and a text box for modifying the DMX query manually. However, the task editor cannot validate the query against objects in an Analysis Services solution. Therefore, it is best to create a query within Visual Studio with Analysis Services projects or Management Studio and then paste the text of the statement or query into the task editor.</p>
Data Mining Query transformation	<p>Executes a prediction query within a data flow, using data supplied by a data flow source.</p> <p>The task editor provides the Prediction Query Builder, and a text box for modifying the DMX query manually.</p> <p>The transformation can only be used for creating queries that use data in the data flow; that is, queries that use the PREDICTION JOIN syntax. This component cannot be used for executing content queries or other kinds of DMX statements.</p>

Application Programming Interfaces

You can create custom applications that execute queries against data mining models by using a variety of programming languages, in combination with server protocols such as OLE DB or Analysis Services ADOMD client. For more information, see [Data Mining Programming](#).

However, XMLA constitutes the underlying message format for all interactions with an Analysis Service server. Within an XMLA message, queries are represented differently depending on whether you are sending a prediction query based on DMX, a content query, or a query that retrieves model metadata using the data mining schema rowsets.

- The text of **prediction queries** (and all other DMX statements) is sent in XMLA by using the [Execute Method \(XMLA\)](#) method, with the DMX query placed as text within the [Statement Element \(XMLA\)](#) element of the XMLA [Command Element \(XMLA\)](#) element.
- To retrieve **model content** and **model metadata**, such as the number of clusters, the attributes used in decision trees, the date the model was last processed, and the algorithm parameters used when creating the model, you can use the [Discover Method \(XMLA\)](#) method and specify one of the data mining schema rowsets in the [RequestType Element \(XMLA\)](#) header. To narrow the scope of the query, enter criteria as

restrictions within the [RestrictionList Element \(XMLA\)](#) element.

Data Mining Query Tasks and How-tos

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The ability to create queries is critical if you are to make use of your data mining models. This section provides links to examples of how to create queries against a data mining model by using the tools provided in SQL Server Management Studio and Visual Studio with Analysis Services projects. If you need more information about what a data mining query is, or the different types of queries you can create, see [Data Mining Queries](#).

Creating Queries with Prediction Query Builder

The Prediction Query Builder is provided in both Visual Studio with Analysis Services projects and SQL Server Management Studio as a way of graphically building queries against data mining models. The following topics explain how you can select a model, specify a data source, customize the predictions, and save output.

- [Create a Prediction Query Using the Prediction Query Builder](#)
- [Create a Singleton Query in the Data Mining Designer](#)
- [Create a Prediction Query Using the Prediction Query Builder](#)
- [View and Save the Results of a Prediction Query](#)
- [Manually Edit a Prediction Query](#)
- [Apply Prediction Functions to a Model](#)
- [Choose and Map Input Data for a Prediction Query](#)

Using Other Data Mining Query Tools

In addition to using the Prediction Query Builder, you can type a query directly into SQL Server Management Studio by using DMX or by using XMLA. You can also build prediction queries programmatically and send them to an Analysis Services server. The following topics provide more information about how to create and work with prediction queries outside of the Prediction Query Builder.

[Create a Singleton Prediction Query from a Template](#)

Describes how to use the tools in SQL Server Management Studio to build and run a prediction query.

[Create a Singleton Prediction Query from a Template](#)

Describes how to use the templates that are provided in SQL Server Management Studio to add parameters to a prediction query.

[Change the Time-out Value for Data Mining Queries](#)

Describes how to set properties on the server that control behavior related to data mining queries.

[Create a Content Query on a Mining Model](#)

Describes how to create queries that return detailed information that is stored in the mining model by using the data mining schema rowsets.

[Create a Data Mining Query by Using XMLA](#)

Describes how to create a query against mining model content by using the XMLA templates in SQL Server Management Studio.

Create a Prediction Query Using the Prediction Query Builder

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can create prediction queries either while you are building a data mining solution in BI Development Studio, or by right-clicking an existing mining model in SQL Server Management Studio, and then choosing the option, **Build Prediction Query**.

The **Prediction Query Builder** has the following three design modes, which you can switch among by clicking the icons in the upper-left corner.

- **Design**
- **Query**
- **Result**

Design mode lets you build a prediction query by choosing input data, mapping the data to the model, and then adding prediction functions into statements you build by using the grid. The design grid contains these building blocks:

Source

Choose the source of the new column. You can use columns from the mining model, input tables included in the data source view, a prediction function, or a customized expression.

Field

Determines the specific column or function that is associated with the selection in the **Source** column.

Alias

Determines how the column is to be named in the result set.

Show

Determines whether the selection in the **Source** column is displayed in the results.

Group

Works with the **And/Or** column to group expressions together by using parentheses. For example, (expr1 or expr2) and expr3.

And/Or

Creates logic in the query. For example, (expr1 or expr2) and expr3.

Criteria/Argument

Specifies a condition or user expression that applies to the column. You can drag columns from the tables to the cell.

Query mode provides a text editor that gives you direct access to the Data Mining Extensions (DMX) language, along with a view of the input data and model columns. When you select **Query** mode, the grid that you used to define the query is replaced by a basic text editor. You can use this editor to copy and save queries you have composed, or to paste in existing DMX queries and from the Clipboard and run them.

Result view runs the current query and displays the results in a grid. If the underlying data has changed and you want to rerun the query, click the Play button in the status bar

You can design a data mining query by using a combination of the visual tools and the text editor. If you type changes to the query in the text editor and switch back to the **Design** view, all the changes are lost, and the query reverts to the original query created by Prediction Query Builder. This topic walks you through use of the graphical query builder.

To create a prediction query

1. Click the **Mining Model Prediction** tab in Data Mining Designer.

2. Click **Select Model** on the **Mining Model** table.

The **Select Mining Model** dialog box opens to show all the mining structures that exist in the current project.

3. Select the model on which you want to create a prediction, and then click **OK**.

4. On the **Select Input Table(s)** table, click **Select Case Table**.

The **Select Table** dialog box opens.

5. In the **Data Source** list, select the data source that contains the data on which to create a prediction.

6. In the **Table/View Name** box, select the table that contains the data on which to create a prediction, and then click **OK**.

After you select the input table, Prediction Query Builder creates a default mapping between the mining model and the input table, based on the names of the columns. To delete a mapping, click to select the line that links the column in the **Mining Model** table to the mapped column in the **Select Input Table(s)** table, and then press **DELETE**. You can also manually create mappings by clicking a column in the **Select Input Table(s)** table and dragging it onto the corresponding column in the **Mining Model** table.

7. Add any combination of the following three types of information to the Prediction Query Builder grid:

- Predictable columns from the **Mining Model** box.
- Any combination of input columns from the **Select Input Table(s)** box.
- Prediction functions

8. Run the query by clicking the first button on the toolbar of the **Mining Model Prediction** tab, and then selecting **Result**.

[Create a Singleton Query in the Data Mining Designer](#)

[Data Mining Queries](#)

Create a DMX Query in SQL Server Management Studio

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

SQL Server provides a set of features to help you create prediction queries, content queries, and data definition queries against mining models and mining structures.

- The graphical Prediction Query Builder is available in both Visual Studio with Analysis Services projects and SQL Server Management Studio, to simplify the process of writing prediction queries and mapping data sets to a model.
- The query templates provided in the Template Explorer jump-start the creation of many kinds of DMX queries, including many types of prediction queries. Templates are provided for content queries, queries used nested data sets, queries that return cases from the mining structure, and even data definition queries.
- The Metadata Explorer in the MDX and DMX query panes provides a list of available models and structures that you can drag and drop into the query builder, as well as a list of DMX functions. This feature makes it easy to get object names right, without typing.

This topic describes how to build a DMX query by using the Metadata Explorer and the DMX query editor.

DMX Query Templates

Templates for creating basic DMX queries are available in Template Explorer. The **DMX** folder contains data mining templates, which are divided into these categories:

- **Model Content**
- **Model Management**
- **Prediction Queries**
- **Structure Content**

You can also create custom templates, for queries or commands that you run frequently.

XMLA Query Templates

Analysis Services also provides templates for XMLA queries.

There is some overlap between the types of queries that you can perform by using XMLA and DMX. For example, you can create some model content queries by using either DMX or the data mining schema rowsets, but the schema rowsets sometimes contain information that is not exposed in DMX content queries.

There are also some key differences in the way that operations are handled in DMX and in XMLA. For example, you can use XMLA to perform administrative operations such as backup of an entire Analysis Services database, but if you want to back up a single mining model, DMX provides a simple command, [EXPORT \(DMX\)](#), that is better suited to that purpose.

Build and Run a DMX Query

[Open a new DMX Query window](#)

1. Click **New Query** in Management Studio, and then select **New Analysis Server DMX Query**.
2. When the **Connect to Server** dialog box appears, select the instance of Analysis Services that contains the mining models you want to work with.

Open Template Explorer

1. In SQL Server Management Studio, on the **View** menu, select **Template Explorer**.
2. Click **Analysis Server** to see a tree view of the templates that apply to Analysis Services.

Apply a template to build a query

- Right-click the appropriate query type and select **Open**.
- Or, drag the template into the query editor.
- You can also fill in the parameters for the query by using the option, **Specify Values for Parameters**, from the **Query** menu.

For examples of how to create specific types of queries from templates, see the following topics:

[Create a Singleton Prediction Query from a Template](#)

[Create a Content Query on a Mining Model](#)

See Also

[Data Mining Query Tools](#)

[Data Mining Extensions \(DMX\) Reference](#)

Create a Singleton Query in the Data Mining Designer

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A singleton query is useful if you want to create a prediction for a single case. For more information about singleton queries, see [Data Mining Queries](#).

In the **Mining Model Prediction** tab of Data Mining Designer, you can create many different types of queries. You can create a query by using the designer, or by typing Data Mining Extensions (DMX) statements. You can also start with the designer and modify the query that it creates by changing the DMX statements, or by adding a WHERE or ORDER BY clause.

To switch between the query design view and the query text view, click the first button on the toolbar. When you are in the query text view, you can view the DMX code that Prediction Query Builder creates. You can also run the query, modify the query, and run the modified query. However, the modified query is not persisted if you switch back to the query design view.

The following code shows an example of a singleton query against the targeted mailing model, TM_Decision_Tree.

```
SELECT [Bike Buyer], PredictProbability([Bike Buyer]) as ProbableBuyer
FROM [TM_Decision_Tree]
NATURAL PREDICTION JOIN
(SELECT '2' AS [Number Children At Home], '45' as [Age])
AS [t]
```

The following steps explain how to create this prediction query.

To create a singleton query by using the Data Mining Designer

1. Click the **Mining Model Prediction** tab in Data Mining Designer.
2. Click **Select Model** on the **Mining Model** table.

The **Select Mining Model** dialog box opens to show all the mining structures that exist in the current project.

Select the model that you want to use for creating a prediction.

For example, to create the sample code shown at the start of this topic, select TM_Decision_Tree, and then click **OK**.

3. Click **Singleton query** on the toolbar of the **Mining Model Prediction** tab.

The **Singleton Query Input** table appears on the tab, with the columns automatically mapped to the columns in the **Mining Model** table.

4. On the **Singleton Query Input** table, select values in the **Value** column to describe the case for which you want to create a prediction.

For example, select **2** for **Number Children At Home**, and then type **45** for **Age**.

5. Drag a predictable column from the **Mining Model** table to the **Source** column at the bottom of the tab. Optionally, you can type an alias for the column.

For example, drag **Bike Buyer** to the **Source** column.

6. Add any additional functions to the query by selecting **Prediction Function** or **Custom Expression** from the drop-down list in the **Source** column.

For example, click **Prediction Function**, and select **PredictProbability**.

7. Click **Criteria/Argument** in the **PredictProbability** row, and type the name of the column to predict, and optionally a specific value to predict.

For example, type **[Bike Buyer], 1**.

8. Click the **Alias** box in the **PredictProbability** row, and type a name to refer to the new column.

For example, type **ProbableBuyer**.

9. Click **Switch to query result view** on the toolbar of the **Mining Model Prediction** tab.

A new screen opens to show the result of the query. To view the DMX statement that you just created, click **SQL**.

See Also

[Prediction Queries \(Data Mining\)](#)

Apply Prediction Functions to a Model

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

To create a prediction query in SQL Server Data Mining, you must first select the mining model on which the query will be based. You can select any mining model that exists in the current project.

After you have selected a model, add a *prediction function* to the query. A prediction function can be used to get a prediction, but you can also add prediction functions that return related statistics, such as the probability of the predicted value, or information that was used in generating the prediction.

Prediction functions can return the following types of values:

- The name of the predictable attribute, and the value that is predicted.
- Statistics about the distribution and variance of the predicted values.
- The probability of a specified outcome, or of all possible outcomes.
- The top or bottom scores or values.
- Values associated with a specified node, object, or attribute.

The type of prediction functions that are available depend on the type of model you are working with. For example, prediction functions applied to decision tree models can return rules and node descriptions; prediction functions for time series models can return the lag and other information specific to time series.

For a list of the prediction functions that are supported for almost all model types, see [General Prediction Functions \(DMX\)](#).

For examples of how to query a specific type of mining model, see the algorithm reference topic, in [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

Choose a mining model to use for prediction

1. From SQL Server Management Studio, right-click the model, and select **Build Prediction Query**.

--OR--

In Visual Studio with Analysis Services projects, click the tab, **Mining Model Prediction**, and then click **Select Model** in the **Mining Model** table.

2. In the **Select Mining Model** dialog box, select a mining model, and then click **OK**.

You can choose any model within the current Analysis Services database. To create a query using a model in a different database, you must either open a new query window in the context of that database, or open the solution file that contains that model.

Add prediction functions to a query

1. In the **Prediction Query Builder**, configure the input data used for prediction, either by providing values in the **Singleton Query Input** dialog box, or by mapping the model to an external data source.

For more information, see [Choose and Map Input Data for a Prediction Query](#).

WARNING

It is not required that you provide inputs to generate predictions. When there is no input, the algorithm will typically return the mostly likely predicted value across all possible inputs.

2. Click the **Source** column, and choose a value from the list:

<model name>	Select this option to include values from the mining model in the output. You can only add predictable columns. When you add a column from the model, the result returned is the non-distinct list of values in that column. The columns that you add with this option are included in the SELECT portion of the resulting DMX statement.
Prediction Function	Select this option to browse a list of prediction functions. The values or functions you select are added to the SELECT portion of the resulting DMX statement. The list of prediction functions is not filtered or constrained by the type of model you have selected. Therefore, if you have any doubt about whether the function is supported for the current model type, you can just add the function to the list and see if there is an error. List items that are preceded by \$ (such as \$AdjustedProbability) represent columns from the nested table that is output when you use the function, PredictHistogram . These are shortcuts that you can use to return a single column and not a nested table.
Custom Expression	Select this option to type a custom expression and then assign an alias to the output. The custom expression is added to the SELECT portion of the resulting DMX prediction query. This option is useful if you want to add text for output with each row, to call VB functions, or to call custom stored procedures. For information about using VBA and Excel functions from DMX, see VBA functions in MDX and DAX .

3. After adding each function or expression, switch to DMX view to see how the function is added within the DMX statement.

WARNING

The Prediction Query Builder does not validate the DMX until you click **Results**. Often, you will find that the expression that is produced by the query builder is not valid DMX. Typical causes are referencing a column that is not related to the predictable column, or trying to predict a column in a nested table, which requires a sub-SELECT statement. At this point, you can switch to DMX view and continue editing the statement.

Example: Create a query on a clustering model

- If you do not have a clustering model available for building this sample query, create the model, [TM_Clustering], using the [Basic Data Mining Tutorial](#).
- From SQL Server Management Studio, right-click the model, [TM_Clustering], and select **Build Prediction Query**.
- From the **Mining Model** menu, select **Singleton Query**.
- In the **Singleton Query Input** dialog box, set the following values as inputs:
 - Gender = M
 - Commute Distance = 5-10 miles
- In the query grid, for **Source**, select TM_Clustering mining model, and add the column, [Bike Buyer].
- For **Source**, select **Prediction Function**, and add the function, **Cluster**.
- For **Source**, select **Prediction Function**, add the function, **PredictSupport**, and drag the model column [Bike Buyer] into the **Criteria/Argument** box. Type **Support** in the **Alias** column.
Copy the expression representing the prediction function and column reference from the **Criteria/Argument** box.
- For **Source**, select **Custom Expression**, type an alias, and then reference the Excel CEILING function by using the following syntax:

```
Excel![CEILING](<arguments>) as <return type>
```

Paste the column reference in as the argument to the function.

For example, the following expression returns the CEILING of the support value:

```
EXCEL!CEILING(PredictSupport([TM_Clustering].[Bike Buyer]),2)
```

Type CEILING in the **Alias** column.

- Click **Switch to query text view** to review the DMX statement that was generated, and then click **Switch to query result view** to see the columns output by the prediction query.

The following table shows the expected results:

BIKE BUYER	\$CLUSTER	SUPPORT	CEILING
0	Cluster 8	954	953.948638926372

If you want to add other clauses elsewhere in the statement—for example, if you want to add a WHERE clause—you cannot add it by using the grid; you must switch to DMX view first.

See Also

[Data Mining Queries](#)

Choose and Map Input Data for a Prediction Query

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When you create predictions from a mining model, you generally do this by feeding new data into the model. (The exception is time series models, which can make predictions based on historical data only.) To provide the model with new data, you must make sure that the data is available as part of a data source view. If you know in advance which data you will use for prediction, you can include it in the data source view that you used to create the model. Otherwise, you might have to create a new data source view. For more information, see [Data Source Views in Multidimensional Models](#).

Sometimes the data that you need might be contained within more than one table in a one-to-many join. This is the case with data used for association models or sequence clustering models, which use a case table linked to a nested table that contains product or transaction details. If your model uses a case-nested table structure, the data that you use for prediction must also have a case-nested table structure.

WARNING

You cannot add new columns or map columns that are in a different data source view. The data source view that you select must contain all the columns that you need for the prediction query.

After you have identified the tables that contain the data you will use for predictions, you must map the columns in the external data to the columns in the mining model. For example, if your model predicts customer purchasing behavior based on demographics and survey responses, your input data should contain information that generally corresponds to what is in the model. You do not need to have matching data for every single column, but the more columns you can match, the better. If you try to map columns that have different data types, you might get an error. In that case, you could define a named calculation in the data source view to cast or convert the new column data to the data type required by the model. For more information, see [Define Named Calculations in a Data Source View \(Analysis Services\)](#).

When you choose the data to use for prediction, some columns in the selected data source might be automatically mapped to the mining model columns, based on name similarity and matching data type. You can use the **Modify Mapping** dialog box in the **Mining Model Prediction** to change the columns that are mapped, delete inappropriate mappings, or create new mappings for existing columns. The **Mining Model Prediction** design surface also supports drag-and-drop editing of connections.

- To create a new connection, just select a column in the **Mining Model** table and drag it to the corresponding column in the **SelectInput Table(s)** table.
- To remove a connection, select the connection line and press the DELETE key.

The following procedure describes how you can modify the joins that have been created between the case table and a nested table used as inputs to a prediction query, using the **Specify Nested Join** dialog box.

Select an input table

1. On the **Select Input Table(s)** table of the **Mining Accuracy Chart** tab in Data Mining Designer in Visual Studio with Analysis Services projects, click **Select Case Table**.

The **Select Table** dialog box opens, in which you can select the table that contains the data on which to base your queries.

2. In the **Select Table** dialog box, select a data source from the **Data Source** list.
3. Under **Table/View Name**, select the table that contains the data you want to use to test the models.
4. Click **OK**.

The columns in the mining structure are automatically mapped to the columns that have the same name in the input table.

Change the way that input data is mapped to the model

1. In Data Mining Designer in Visual Studio with Analysis Services projects, select the **Mining Model Prediction** tab.
2. On the **Mining Model** menu, select **Modify Connections**.

The **Modify Mapping** dialog box opens. In this dialog box, the column **Mining Model Column** lists the columns in the selected mining structure. The column **Table Column** lists the columns in the external data source that you chose in the **Select Input Table(s)** dialog box. The columns in the external data source are mapped to columns in the mining model.

3. Under **Table Column**, select the row that corresponds to the mining model column that you want to map to.
4. Select a new column from the list of available columns in the external data source. Select the blank item in the list to delete the column mapping.

5. Click **OK**.

The new column mappings are displayed in the designer.

Remove a relationship between input tables

1. On the **Select Input Table(s)** table of the **Mining Model Prediction** tab in Data Mining Designer in Visual Studio with Analysis Services projects, click **Modify Join**.

The **Specify Nested Join** dialog box opens.

2. Select a relationship.
3. Click **Remove Relationship**.
4. Click **OK**.

The relationship between the case table and the nested table has been removed.

Create a new relationship between input tables

1. On the **Select Input Table(s)** table of the **Mining Model Prediction** tab in Data Mining Designer, click **Modify Join**.

The **Specify Nested Join** dialog box opens.

2. Click **Add Relationship**.
3. The **Create Relationship** dialog box opens.
4. Select the key of the nested table in **Source Columns**.
5. Select the key of the case table in **Destination Columns**.
6. Click **OK** in the **Create Relationship** dialog box.
7. Click **OK** in the **Specify Nested Join** dialog box.

A new relationship has been created between the case table and the nested table.

Add a nested table to the input tables of a prediction query

1. On the **Mining Model Prediction** tab in Data Mining Designer, click **Select Case Table** to open the **Select Table** dialog box.

NOTE

You cannot add a nested table to the inputs unless you have specified a case table. Use of a nested table requires that the mining model you are using for prediction also uses a nested table.

2. In the **Select Table** dialog box, select a data source from the **Data Source** list, and select the table in the data source view that contains the case data. Click **OK**.
3. Click **Select Nested Table** to open the **Select Table** dialog box.
4. In the **Select Table** dialog box, select a data source from the **Data Source** list, and select the table in the data source view that contains the nested data. Click **OK**.

If a relationship already exists, the columns in the mining model are automatically mapped to the columns that have the same name in the input table. You can modify the relationship between the nested table and the case table by clicking **Modify Join**, which opens the **Create Relationship** dialog box.

[Prediction Queries \(Data Mining\)](#)

Manually Edit a Prediction Query

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

After you have designed a query by using the Prediction Query Builder, you can modify the query by switching to Query Text view on the **Mining Model Prediction** tab of Data Mining Designer. A text editor appears at the bottom of the screen to display the query that the query builder created.

Switching to Query Text view is useful for making additions to the query. For example, you can add a WHERE clause or ORDER BY clause.

Use the grid in the Prediction Query Builder to insert the names of objects and columns and set up the syntax for individual prediction functions, and then switch to manual editing mode to change parameter values.

NOTE

If you switch back to **Design** view from **Query Text** view, any changes that you made in **Query Text** view will be lost.

Modify a query

1. On the **Mining Model Prediction** tab in Data Mining Designer in Visual Studio with Analysis Services projects, click **SQL**.

The grid at the bottom of the screen is replaced by a text editor that contains the query. You can type changes to the query in this editor.

2. To run the query, on the **Mining Model** menu, select **Result**, or click the button to switch to query results.

NOTE

If the query that you have created is invalid, the Results window does not display an error and does not display any results. Click the **Design** button, or select **Design** or **Query** from the **Mining Model** menu to correct the problem and run the query again.

[Data Mining Queries](#)

[Prediction Query Builder \(Data Mining\)](#)

[Lesson 6: Creating and Working with Predictions \(Basic Data Mining Tutorial\)](#)

View and Save the Results of a Prediction Query

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

After you have defined a query in Microsoft SQL Server Analysis Services by using Prediction Query Builder, you can run the query and view the results by switching to the query result view.

You can save the results of a prediction query to a table in any data source that is defined in a Microsoft SQL Server Analysis Services project. You can either create a new table or save the query results to an existing table. If you save the results to an existing table, you can choose to overwrite the data that is currently stored in the table; otherwise, the query results are appended to the existing data in the table.

Run a query and view the results

1. On the toolbar of the **Mining Model Prediction** tab of Data Mining Designer in Visual Studio with Analysis Services projects, click **Result**.

The query results view opens and runs the query. The results are displayed in a grid in the viewer.

Save the results of a prediction query to a table

1. On the toolbar of the **Mining Model Prediction** tab in Data Mining Designer, click **Save query result**.

The **Save Data Mining Query Result** dialog box opens.

2. Select a data source from the **Data Source** list, or click **New** to create a new data source.
3. In the **Table Name** box, enter the name of the table. If the table already exists, select **Overwrite if exists** to replace the contents of the table with the query results. If you do not want to overwrite the contents of the table, do not select this check box. The new query results will be appended to the existing data in the table.
4. Select a data source view from **Add to DSV** if you want to add the table to a data source view.
5. Click **Save**.

WARNING

If the destination does not support hierarchical rowsets, you can add the **FALTTENED** keyword to the results to save as a flat table.

Create a Content Query on a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can query the mining model content programmatically by using AMO or XML/A, but it is easier to create queries by using DMX. You can also create queries against the data mining schema rowsets by establishing a connection to the Analysis Services instance and creating a query using the DMVs provided by Analysis Services.

The following procedures demonstrate how to create queries against a mining model by using DMX, and how to query the data mining schema rowsets.

For an example of how to create a similar query by using XML/A, see [Create a Data Mining Query by Using XMLA](#).

Querying Data Mining Model Content by Using DMX

To create a DMX model content query

1. In SQL Server Management Studio, on the **View** menu, click **Template Explorer**.
2. In the **Template Explorer** pane, click the cube icon to change the list and display Analysis Services templates.
3. In the list of template categories, expand **DMX**, expand **Model Content**, and double-click **Content Query**.
4. In the **Connect to Analysis Services** dialog box, select the instance that contains the mining model you want to query, and click **Connect**.

The **Content Query** template opens in the appropriate code editor. The metadata pane lists the models that are available in the current database. To change the database, select a different database from the **Available Databases** list.

5. Enter the name of a mining model in the line, `FROM [<mining model, name, MyModel>] .CONTENT`. If the mining model name contains spaces, you must enclose the name in brackets.

If you don't want to type the name, you can select a mining model in **Object Explorer** and drag it into the template.

6. In the line, `SELECT <select list, expr list, *>`, type the names of columns in the mining model content schema rowset.

To view a list of columns that you can return in mining model content queries, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

7. Optionally, type a condition in the WHERE clause of the template to restrict the rows returned to specific nodes or values.
8. Click **Execute**.

Querying the Data Mining Schema Rowsets

To create a query against the data mining schema rowset

1. In SQL Server Management Studio, on the **New Query** toolbar, click **Analysis Services DMX Query**, or **Analysis Services MDX query**.

2. In the **Connect to Analysis Services** dialog box, select the instance that contains the objects you want to query, and click **Connect**.

The **Content Query** template opens in the appropriate code editor. The metadata pane lists the objects that are available in the current database. To change the database, select a different database from the **Available Databases** list.

3. In the query editor, type the following:

```
SELECT *  
  
FROM $system.DMSCHEMA_MINING_MODEL_CONTENT  
  
WHERE MODEL_NAME = '<model name>'
```

4. Click **Execute**.

The Results pane displays the contents of the model.

NOTE

To view a list of all the schema rowsets that you can query on the current instance, use this query:

```
SELECT * FROM $system.DISCOVER_SCHEMA_ROWSETS. Or, for a list of schema rowsets specific to data mining,  
see Data Mining Schema Rowsets.
```

[Data Mining Schema Rowsets](#)

Query the Parameters Used to Create a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The composition of a mining model is affected not only by the training cases, but by the parameters that were set when the model was created. Therefore, you might find it useful to retrieve the parameter settings of an existing model to better understand the behavior of the model. Retrieving parameters is also useful when documenting a particular version of that model.

To find the parameters that were used when the model was created, you create a query against one of the mining model schema rowsets. These schema rowsets are exposed as a set of system views that you can query easily by using Transact-SQL syntax. This procedure describes how to create a query that returns the parameters that were used to create the specified mining model.

To open a Query window for a schema rowset query

1. In SQL Server Management Studio, open the instance of Analysis Services that contains the model you want to query.
2. Right-click the instance name, select **New Query**, and then select **DMX**.

NOTE

You can also create a query against a data mining model by using the **MDX** template.

3. If the instance contains multiple databases, select the database that contains the model you want to query from the **Available Databases** list in the toolbar.

To return model parameters for an existing mining model

1. In the DMX query pane, type or paste the following text:

```
SELECT MINING_PARAMETERS  
FROM $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = ''
```

2. In Object Explorer, select the mining model you want, and then drag it into the DMX Query pane, between the single quotation marks.
3. Press F5, or click **Execute**.

Example

The following code returns a list of the parameters that were used to create the mining model that you build in the [Basic Data Mining Tutorial](#). These parameters include the explicit values for any defaults used by the mining services available from providers on the server.

```
SELECT MINING_PARAMETERS  
FROM $system.DMSCHEMA_MINING_MODELS  
WHERE MODEL_NAME = 'TM Clustering'
```

The code example returns the following parameters for the clustering model:

eExample Results:

MINING_PARAMETERS

CLUSTER_COUNT=10,CLUSTER_SEED=0,CLUSTERING_METHOD=1,MAXIMUM_INPUT_ATTRIBUTES=255,
MAXIMUM_STATES=100,MINIMUM_SUPPORT=1,MODELLING_CARDINALITY=10,SAMPLE_SIZE=50000,S
TOPPING_TOLERANCE=10

[Data Mining Queries](#)

Create a Singleton Prediction Query from a Template

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A singleton query is useful when you have a model that you want to use for prediction, but don't want to map it to an external input data set or make bulk predictions. With a singleton query, you can provide a value or values to the model and instantly see the predicted value.

For example, the following DMX query represents a singleton query against the targeted mailing model, TM_Decision_Tree.

```
SELECT * FROM [TM_Decision_tree] ;
NATURAL PREDICTION JOIN
(SELECT '2' AS [Number Children At Home], '45' as [Age])
AS [t]
```

The procedure that follows describes how to use the Template Explorer in SQL Server Management Studio to quickly create this query.

To open the Analysis Services templates in SQL Server Management Studio

1. In SQL Server Management Studio, on the **View** menu, click **Template Explorer**.
2. Click the cube icon to open the **Analysis Server** templates.

To open a prediction query template

1. In **Template Explorer**, in the list of Analysis Server templates, expand **DMX**, and then expand **Prediction Queries**.
2. Double-click **Singleton Prediction**.
3. In the **Connect to Analysis Services** dialog box, type the name of the server that has the instance of Analysis Services that contains the mining model to be queried.
4. Click **Connect**.
5. The template opens in the specified database, together with a mining model Object Browser that contains data mining functions and a list of data mining structures and related models.

To customize the singleton query template

1. In the template, click the **Available Databases** drop-down list, and then select an instance of Analysis Service from the list.
2. In the **Mining Model** list, select the mining model that you want to query.

The list of columns in the mining model appears in the **Metadata** pane of the object browser.

3. On the **Query** menu, select **Specify Values for Template Parameters**.
4. In the **select list** row, type * to return all columns, or type a comma-delimited list of columns and expressions to return specific columns.

If you type *, the predictable column is returned, together with any columns for which you provide new

values for in step 6.

For the sample code shown at the start of this topic, the **select list** row was set to *.

5. In the **mining model** row, type the name of the mining model from among the list of mining models that appear in **Object Explorer**.

For the sample code shown at the start of this topic, the **mining model** row was set to the name, **TM_Decision_Tree**.

6. In the **value** row, type the new data value for which you want to make a prediction.

For the sample code shown at the start of this topic, the **value** row was set to **2** to predict bike buying behavior based on the number of children at home.

7. In the **column** row, type the name of the column in the mining model to which the new data should be mapped.

For the sample code shown at the start of this topic, the **column** row was set to **Number Children at Home**.

NOTE

When you use the **Specify Values for Template Parameters** dialog box, you do not have to add square brackets around the column name. The brackets will automatically be added for you.

8. Leave the **input alias** as **t**.

9. Click **OK**.

10. In the query text pane, find the red squiggle under the comma and ellipsis that indicates a syntax error.

Delete the ellipsis, and add any additional query condition that you want. If you do not add any other conditions, delete the comma.

For the sample code shown at the start of this topic, the additional query condition was set to **'45' as [Age]**.

11. Click **Execute**.

[Creating Predictions \(Basic Data Mining Tutorial\)](#)

Create a Data Mining Query by Using XMLA

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can create a variety of queries against data mining objects by using AMO, DMX, or XML/A.

XML is used for communication between the Analysis Services server and all clients. Therefore, although it is generally much easier to create content queries by using DMX, you can write queries by using the DISCOVER and COMMAND statements in XML/A, either by using a client that supports the SOAP protocol, or by creating an XML/A query in SQL Server Management Studio.

This topic explains how to use the XML/A templates that are available in SQL Server Management Studio to create a model content query against a mining model stored on the current server.

Querying Data Mining Schema Rowsets by Using XML/A

To open an XML/A template

1. In SQL Server Management Studio, on the **View** menu, click **Template Explorer**.
2. Click the cube icon to open the list of Analysis Services templates.
3. In the list of template categories, expand **XMLA**, expand **Schema Rowsets**, and double-click **Discover Schema Rowsets** to open the template in the appropriate code editor.
4. In the **Connect to Analysis Services** dialog box, complete the connection information and then click **Connect**. A new query editor window opens, populated with the **Discover Schema Rowsets** template.

To discover column names from the MINING MODEL CONTENT schema rowset

1. With the **Discover Schema Rowsets** template open, click **Execute**.

A list of schema rowsets is returned in the **Results** pane that contains the rowset names and rowset columns for all rowsets available on the current instance.

2. In the **Query** pane, place the cursor after <**Restriction List**> and press ENTER to add a new line.
3. Place the cursor on the blank line and type
<SchemaName>DMSchema_Minining_Model_Content</SchemaName>

The complete section for restrictions should appear as follows:

```
<Restrictions>
  <RestrictionList>
    <SchemaName>DMSchema_Minining_Model_Content</SchemaName>
  </RestrictionList>
</Restrictions>
```

4. Click **Execute**.

The **Results** pane shows a list of column names for the specified schema rowset.

To create a content query using the MINING MODEL CONTENT schema rowset

1. In the **Discover Schema Rowsets** template, change the request type by replacing the text inside the

request type tags.

Replace this line:

```
<RequestType>DISCOVER_SCHEMA_ROWSETS</RequestType>
```

with the following line:

```
<RequestType>DMSCHEMA_MINING_MODEL_CONTENT</RequestType>
```

2. Change the restriction list to specify a mining model by name, by adding a new condition to the restriction lists.
3. In the template, place the cursor after `<Restriction List>` and press ENTER to add a new line.
4. Place the cursor on the blank line and type `<MODEL_NAME>My model name</MODEL_NAME>`

The complete section for restrictions should appear as follows:

```
<Restrictions>
  <RestrictionList>
    <MODEL_NAME>My model name</MODEL_NAME>
  </RestrictionList>
</Restrictions>
```

5. Click **Execute**.

The Results pane displays the schema definition, together with the values for the specified model.

[Data Mining Schema Rowsets](#)

Change the Time-out Value for Data Mining Queries

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

When you build a lift chart or execute a prediction query, sometimes it can take a long time to generate all the data required for the prediction. To prevent the query from timing out, you can change the value that controls how long the Analysis Services server waits to complete a query.

The default value is 15; however, if your models are complex or the data source is large, this might not be enough. If necessary, you can increase the value significantly, to enable enough time for processing. For example, if you set **Query Timeout** to 600, the query could continue to run for up to 10 minutes.

For more information about prediction queries, see [Data Mining Query Tasks and How-tos](#).

Configure the time-out value for data mining queries

1. In Visual Studio with Analysis Services projects, from the **Tools** menu, selection **Options**.
2. In the **Options** pane, expand **Business Intelligence Designers**.
3. Click the **Query Timeout** text box, and type a value for the number of seconds.

Data Mining Solutions

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

A data mining solution is an Analysis Services solution that contains one or more data mining projects.

The topics in this section provide information about how to design and implement an integrated data mining solution by using SQL Server Analysis Services. For an overview of the data mining design process and related tools, see [Data Mining Concepts](#).

For more information about additional projects types that are useful for data mining, see [Related Projects for Data Mining Solutions](#).

[Relational vs. Multidimensional Solutions](#)

[Deploying Data Mining Solutions](#)

[Solution Walkthroughs](#)

Relational vs. Multidimensional Solutions

A data mining solution can be based either on multidimensional data—that is, an existing cube—or on purely relational data, such as the tables and views in a data warehouse, or on text files, Excel workbooks, or other external data sources.

- You can create data mining objects within an existing multidimensional database solution.

Typically you would create a solution like this if you have already created a cube and want to perform data mining by using the cube as a data source. When you move and backup models based on a cube, the cube must also be moved or copied.

- You can create a data mining solution that contains only data mining objects, including the supporting data sources and data source views, and that uses relational data source only.

This is the preferred method for creating data mining models, as processing and querying is generally fastest against relational data sources. You can also easily move and backup models between servers by using the EXPORT and IMPORT commands.

Deploying Data Mining Solutions

The instance of Analysis Services to which you deploy the solution must be running in a mode that supports multidimensional objects and data mining objects; that is, you cannot deploy data mining objects to an instance that hosts tabular models or Power Pivot data.

Therefore, when you create a data mining solution in Visual Studio, be sure to use the template, **Analysis Services Multidimensional and Data Mining Project**.

When you deploy the solution, the objects used for data mining are created in the specified Analysis Services instance, in a database with the same name as the solution file.

For more information about how to deploy both relational and multidimensional solutions, see [Deployment of Data Mining Solutions](#).

Solution Walkthrough

Provides an overview of how to create data mining solutions by using the Data Mining Wizard.

[Create a Relational Mining Structure](#)

Create a mining structure from relational data, text files, and other sources that can be combined in a data source view.

[Create an OLAP Mining Structure](#)

Create a mining structure based on data in an OLAP cube. Models that you create from OLAP data can be saved as a data mining dimension, or you can save the set of data and your models as a new cube.

[Data Mining Tutorials \(Analysis Services\)](#)

Data Mining Projects

7/16/2019 • 14 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A data mining project is part of an Analysis Services solution. During the design process, the objects that you create in this project are available for testing and querying as part of a workspace database. When you want users to be able to query or browse the objects in the project, you must deploy the project to an instance of Analysis Services running in multidimensional mode.

This topic provides you with the basic information needed to understand and create data mining projects.

[Creating Data Mining Projects](#)

[Objects in Data Mining Projects](#)

- [Data sources](#)
- [Data source views](#)
- [Mining structures](#)
- [Mining models](#)

[Using the Completed Data Mining Project](#)

- [View and explore models](#)
- [Test and validate models](#)
- [Create predictions](#)

[Programmatic Access to Data Mining Projects](#)

Creating Data Mining Projects

In Visual Studio with Analysis Services projects, you build data mining projects using the template, **OLAP and Data Mining Project**. You can also create data mining projects programmatically, by using AMO. Individual data mining objects can be scripted using the Analysis Services Scripting language (ASSL). For more information, see [Multidimensional Model Data Access \(Analysis Services - Multidimensional Data\)](#).

If you create a data mining project within an existing solution, by default the data mining objects will be deployed to an Analysis Services database with the same name as the solution file. You can change this name and the target server by using the **Project Properties** dialog box. For more information, see [Configure Analysis Services Project Properties \(SSDT\)](#).

WARNING

To successfully build and deploy your project, you must have access to an instance of Analysis Services that is running in OLAP/Data Mining mode. You cannot develop or deploy data mining solutions on an instance of Analysis Services that supports tabular models, nor can you use data directly from a Power Pivot workbook or from a tabular model that uses the in-memory data store. To determine whether the instance of Analysis Services that you have can support data mining, see [Determine the Server Mode of an Analysis Services Instance](#).

Within each data mining project that you create, you will follow these steps:

1. Choose a *data source*, such as a cube, database, or even Excel or text files, which contains the raw data you will use for building models.
2. Define a subset of the data in the data source to use for analysis, and save it as a *data source view*.
3. Define a *mining structure* to support modeling.
4. Add *mining models* to the mining structure, by choosing an *algorithm* and specifying how the algorithm will handle the data.
5. Train models by populating them with the selected data, or a filtered subset of the data.
6. Explore, test, and rebuild models.

When the project is complete, you can deploy it for users to browse or query, or provide programmatic access to the mining models in an application, to support predictions and analysis.

Objects in Data Mining Projects

All data mining projects contain the following four types of objects. You can have multiple objects of all types.

- Data sources
- Data source views
- Mining structures
- Mining models

For example, a single data mining project can contain a reference to multiple data sources, with each data source supporting multiple data source views. In turn, each data source view can support multiple mining structures, each with many related mining models.

Additionally, your project might include plug-in algorithms, custom assemblies, or custom stored procedures; however, these objects are not described here. For more information, see [Analysis Services Developer Documentation](#).

Data Sources

The data source defines the connection string and authentication information that the Analysis Services server will use to connect to the data source. The data source can contain multiple tables or views; it can be as simple as a single Excel workbook or text file, or as complex as an Online Analytical Processing (OLAP) database or large relational database.

A single data mining project can reference multiple data sources. Even though a mining model can use only one data source at a time, the project could have multiple models drawing on different data sources.

Analysis Services supports data from many external providers, and SQL Server Data Mining can use both relational and cube data as a data source. However, if you develop both types of projects-models based on relational sources and models based on OLAP cubes-you might wish to develop and manage these in separate projects.

- Typically models that are based on an OLAP cube should be developed within the OLAP design solution. One reason is that models based on a cube must process the cube to update data. Generally, you should use cube data only when that is the principal means of data storage and access, or when you require the aggregations, dimensions, and attributes created by the multidimensional project.
- If your project uses relational data only, you should create the relational models within a separate project, so that you do not unnecessarily reprocess other objects. In many cases, the staging database or the data warehouse used to support cube creation already contains the views that are needed to perform data

mining, and you can use those views for data mining rather than use the aggregations and dimensions in the cube.

- You cannot use in-memory or Power Pivot data directly to build data mining models.

The data source only identifies the server or provider and the general type of data. If you need to change data formatting and aggregations, use the data source view object.

To control the way that data from the data source is handled, you can add derived columns or calculation, modify aggregates, or rename columns in the data in the data source view. (You can also work with data downstream, by modifying mining structure columns, or by using modeling flags and filters at the level of the mining model column.)

If data cleansing is required, or the data in the data warehouse must be modified to create additional variables, change data types, or create alternate aggregation, you might need to create additional project types in support of data mining. For more information about these related projects, see [Related Projects for Data Mining Solutions](#).

Data Source Views

After you have defined this connection to a data source, you create a view that identifies the specific data that is relevant to your model.

The data source view also enables you to customize the way that the data in the data source is supplied to the mining model. You can modify the structure of the data to make it more relevant to your project, or choose only certain kinds of data.

For example, by using the Data Source View editor, you can:

- Create derived columns, such as dateparts, substrings, etc.
- Aggregate values using Transact-SQL statements such as GROUP BY
- Restrict data temporarily, or sample data

For more information about how you can modify data within a data source view, see [Data Source Views in Multidimensional Models](#).

WARNING

If you want to filter the data, you can do so in the data source view, but you can also create filters on the data at the level of the mining model. Because the filter definition is stored with the mining model, using model filters makes it easier to determine the data that was used for training the model. Moreover, you can create multiple related models, with different filter criteria. For more information, see [Filters for Mining Models \(Analysis Services - Data Mining\)](#).

Note that the data source view that you create can contain additional data that is not directly used for analysis. For example, you might add to your data source view data that is used for testing, predictions, or for drillthrough. For more information about these uses, see [Testing and Validation \(Data Mining\)](#) and [Drillthrough](#).

Mining Structures

Once you have created your data source and data source view, you must select the columns of data that are most relevant to your business problem, by defining *mining structures* within the project. A mining structure tells the project which columns of data from the data source view should actually be used in modeling, training, and testing.

To add a new mining structure, you start the Data Mining Wizard. The wizard automatically defines a mining structure, walks you through the process of choosing the data, and optionally lets you add an initial mining model to the structure. Within the mining structure, you choose tables and columns from the data source view or from an OLAP cube, and define relationships among tables, if your data includes nested tables.

Your choice of data will look very different in the Data Mining Wizard, depending on whether you use relational or

online analytical processing (OLAP) data sources.

- When you choose data from a relational data source, setting up a mining structure is easy: you choose columns from the data in the data source view, and set additional customizations such as aliases, or define how values in the column should be grouped or binned. For more information, see [Create a Relational Mining Structure](#).
- When you use data from an OLAP cube, the mining structure must be in the same database as the OLAP solution. To create a mining structure, you select attributes from the dimensions and related measures in your OLAP solution. Numeric values are typically found in measures, and categorical variables in dimensions. For more information, see [Create an OLAP Mining Structure](#).
- You can also define mining structures by using DMX. For more information, see [Data Mining Extensions \(DMX\) Data Definition Statements](#).

After you have created the initial mining structure, you can copy, modify, and alias the structure columns.

Each mining structure can contain multiple mining models. Therefore, after you are done, you can open the mining structure again, and use [Data Mining Designer](#) to add more mining models to the structure.

You also have the option to separate your data into a training data set, used for building models, and a holdout data set to use in testing or validating your mining models.

WARNING

Some model types, such as time series models, do not support the creation of holdout data sets because they require a continuous series of data for training. For more information, see [Training and Testing Data Sets](#).

Mining Models

The mining model defines the algorithm, or the method of analysis that you will use on the data. To each mining structure, you add one or more mining models.

Depending on your needs, you can combine many models in a single project, or create separate projects for each type of model or analytical task.

After you have created a structure and model, you *process* each model by running the data from the data source view through the algorithm, which generates a mathematical model of the data. This process is also known as *training the model*. For more information, see [Processing Requirements and Considerations \(Data Mining\)](#).

After the model has been processed, you can then visually explore the mining model and create prediction queries against it. If the data from the training process has been cached, you can use *drillthrough* queries to return detailed information about the cases used in the model.

When you want to use a model for production (for example, for use in making predictions, or for exploration by general users) you can deploy the model to a different server. If you need to reprocess the model in future, you must also export the definition of the underlying mining structure (and, necessarily, the definition of the data source and data source view) at the same time.

When you deploy a model, you must also ensure that the correct processing options are set on the structure and model, and that potential users have the permissions they need to perform queries, view models, or drillthrough to structure or model data. For more information, see [Security Overview \(Data Mining\)](#).

Using the Completed Data Mining Project

This section summarizes the ways that you can use the completed data mining project. You can create accuracy charts, explore and validate the data, and make the data mining patterns available to users.

WARNING

The charts, queries, and visualizations that you use with data mining models are not saved as part of the data mining project, and cannot be deployed. If you need to persist these objects, you must either save the content that is presented or script it as described for each object.

View and Explore Models

After you have created a model, you can use visual tools and queries to explore the patterns in the model and learn more about the underlying patterns and statistics. On the **Mining Model Viewer** tab in Data Mining Designer, Analysis Services provides viewers for each mining model type, which you can use to explore the mining models.

These visualizations are temporary, and are closed without saving when you exit the session with Analysis Services. Therefore, if you need to export these visualizations to another application for presentation or further analysis, use the **Copy** commands provided in each tab or pane of the viewer interface.

The Data Mining Add-ins for Excel also provides a Visio template that you can use to represent your models in a Visio diagram and annotate and modify the diagram using Visio tools. For more information, see [Microsoft SQL Server 2008 SP2 Data Mining Add-ins for Microsoft Office 2007](#).

Test and Validate Models

After you have created a model, you can investigate the results and make decisions about which models perform the best.

Analysis Services provides several charts that you can use to provide tools that you can use to directly compare mining models and choose the most accurate or useful mining model. These tools include a lift chart, profit chart, and a classification matrix. You can generate these charts by using the **Mining Accuracy Chart** tab of Data Mining Designer.

You can also use the cross-validation report to perform iterative subsampling of your data to determine whether the model is biased to a particular set of data. The statistics that the report provides can be used to objectively compare models and assess the quality of your training data.

Note that these reports and charts are not stored with the project or in the ssASnoversion database, so if you need to preserve or duplicate the results, you should either save the results, or script the objects by using DMX or AMO. You can also use stored procedures for cross-validation.

For more information, see [Testing and Validation \(Data Mining\)](#).

Create Predictions

Analysis Services provides a query language called Data Mining Extensions (DMX) that is the basis for creating predictions and is easily scriptable. To help you build DMX prediction queries, SQL Server provides a query builder, available in SQL Server Management Studio. There are also many DMX templates for the query editor in SQL Server Management Studio. If you are new to prediction queries, we recommend that you use the query builder that is provided in both Data Mining Designer and SQL Server Management Studio. For more information, see [Data Mining Tools](#).

The predictions that you create in either Visual Studio with Analysis Services projects or SQL Server Management Studio are not persisted, so if your queries are complex, or you need to reproduce the results, we recommend that you save your prediction queries to DMX query files, script them, or embed the queries as part of an Integration Services package.

Programmatic Access to Data Mining Objects

Analysis Services provides several tools that you can use to programmatically work with data mining projects and the objects in them. The DMX language provides statements that you can use to create data sources and data

source views, and to create, train, and use data mining structure and models. For more information, see [Data Mining Extensions \(DMX\) Reference](#).

You can also perform these tasks by using the Analysis Services Scripting Language (ASSL), or by using Analysis Management Objects (AMO). For more information, see [Developing with XMLA in Analysis Services](#).

[Data Mining Designer](#)

[Creating Multidimensional Models Using SQL Server Data Tools \(SSDT\)](#)

[Workspace Database](#)

Import a Data Mining Project using the Analysis Services Import Wizard

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

This topic describes how to create a new data mining project by importing the metadata from an existing data mining project on another server, using the template, **Import from Server (Multidimensional and Data Mining) Project**, in Visual Studio with Analysis Services projects.

Import data sources, mining structures, and mining models from an existing data mining project

When you use the template, **Import from Server (Multidimensional and Data Mining) Project**, Visual Studio with Analysis Services projects creates a new data mining project, and then copies the metadata from the specified data mining project. The new project contains the same data sources, data source views, mining structures, and mining models as the ssASnover version database that you imported from. However, the project cannot be used until you have updated certain properties and processed the objects as described:

- The data itself is not copied from the source server to the new data mining project-only the definitions of the data sources and data source views are imported. Therefore, after the import process has completed, and the objects have been created, you must populate the objects with data by training the mining structures and dependent models. You can use the command **Process All** in Data Mining Designer to train the models and structures.
- If you are importing a project that was created in a previous version of Analysis Services, the data source might use providers that are not installed on the server to which you are importing the project. If you encounter errors when processing the imported mining structures, right-click each data source and select **Open Designer** to edit the connection string and review the provider properties.

At this time, you might also need to verify that the account you are using to process the data mining objects or query data mining models has the necessary permissions on the data source.

- By default, when you import a project, the workspace database is set to localhost, or whatever default instance is configured as the **Default Target Server** in Visual Studio with Analysis Services projects. To set this property, from the **Options** menu, select **Business Intelligence Designers**, select **Analysis Services**, and then select **General**.

Note that, in SQL Server 2017, there is another, separate option that you can set to configure the default deployment server for Analysis Services tabular model projects. The setting, **Default Deployment Server**, determines the default workspace database for tabular model projects. You cannot use instances that support tabular models for data mining projects.

If you cannot change the default deployment database to use an instance of Analysis Services running in multidimensional or data mining mode, you can always specify the deployment database by using the **Project Properties** dialog box.

To create a new data mining project by importing an existing data mining project

1. In Visual Studio with Analysis Services projects, on the **File** menu, click **New**, and then click **Project**.
2. In the **New Project** dialog box, under **Installed Templates**, click **Business Intelligence**, click **Analysis**

Services, and then click **Import from Server (Multidimensional/Data Mining)**.

3. For **Name**, type a name for the project, then specify a location and solution name, and then click **OK**.

The **Import Analysis Services Database wizard** starts. Click **OK** on the Welcome page to proceed.

4. On the page, **Select Source Database**, for **Server**, specify the Analysis Services instance that contains the solution you want to import.

For **Database**, choose the Analysis Services database that contains the data mining objects you want to import.

WARNING

You cannot specify the objects you want to import; when you choose an existing Analysis Services database, all multidimensional and data mining objects are imported.

Click **Next**.

5. The page, **Completing the Wizard**, displays the progress of the import operation. You cannot cancel the operation or change the objects that are being imported. Click **Finish** when done.

The new project is automatically opened using Visual Studio with Analysis Services projects.

[Project Properties](#)

Processing Data Mining Objects

7/16/2019 • 2 minutes to read • [Edit Online](#)

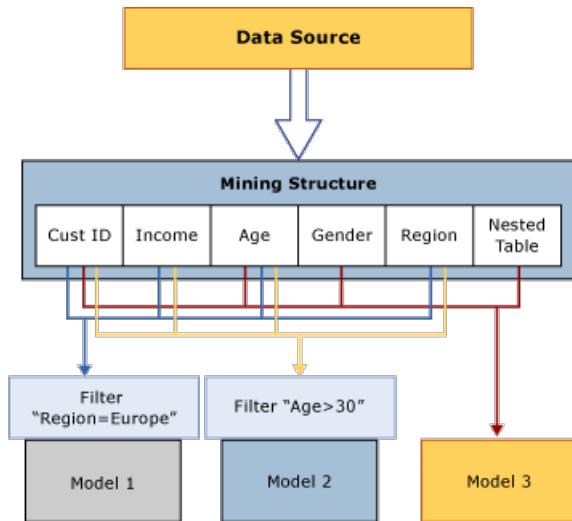

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A data mining object is only an empty container until it has been processed. *Processing* a data mining model is also called *training*.

Processing mining structures: A mining structure gets data from an external data source, as defined by the column bindings and usage metadata, and reads the data. This data is read in full and then analyzed to extract various statistics. Analysis Services stores a compact representation of the data, which is suitable for analysis by data mining algorithms, in a local cache. You can either keep this cache or delete it after your models have been processed. By default, the cache is stored. For more information, see [Process a Mining Structure](#).

Processing mining models: A mining model is empty, containing definitions only, until it is processed. To process a mining model, the mining structure that it is based on must have been processed. The mining model gets the data from the mining structure cache, applies any filters that may have been created on the model, and then passes the data set through the algorithm to detect patterns. After the model is processed, the model stores only the results of processing, not the data itself. For more information, see [Process a Mining Model](#).

The following diagram illustrates the flow of data when a mining structure is processed, and when a mining model is processed.

Viewing the Results of Processing

After a mining structure has been processed, it contains a compact representation of the data for use in statistical analysis. If the cache has not been cleared, you can access the data in this cache in the following ways:

- Creating a Data Mining Extensions (DMX) query on the model and drilling through to the structure. For more information, see [SELECT FROM <model>.CASES \(DMX\)](#).
- Browsing a model based on the structure, and using one of the options in the user interface to drill through to structure cases. For more information, see [Data Mining Model Viewers](#), or [Drill Through to Case Data from a Mining Model](#).
- Creating a DMX query on the structure cases. For more information, see [SELECT FROM <structure>.CASES](#).

After a mining model has been processed, it contains only the patterns that were derived from analysis, and mappings from the model results to the cached training data. You can browse or query the model results, called *model content*, or you can query the model and structure cases, if they have been cached.

The model content for each mining model depends on the algorithm that was used to create it. For example, if one model is a clustering model and another is a decision trees model, the model content is very different even though the models use exactly the same data. For more information, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

Processing Requirements

Processing requirements may differ depending on whether your mining models are based solely on relational data, or on multidimensional data source.

For relational data source, processing requires only that you create training data and run mining algorithms on that data. However, mining models that are based on OLAP objects, such as dimensions and measures, require that the underlying data be in a processed state. This may require that the multidimensional objects be processed to populate the mining model.

For more information, see [Processing Requirements and Considerations \(Data Mining\)](#).

Related Projects for Data Mining Solutions

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The minimum that is required for a data mining solution is the data mining project, which defines data sources, data source views, mining structures and mining models. However, when data mining models are used in daily decision making, it is important that data mining be integrated with other part of a predictive analytics solution, which can include these processes and components:

- Preparation and selection of data and of variables. Includes data cleansing, metadata management and integration of multiple data sources, and the conversion, merging, and uploading of data into a data warehouse.
- Reporting of analysis, presentation of predictions, and auditing/tracking of data mining activities.
- Using multidimensional models or tabular models to explore findings.
- Refinement of the data mining solution to support new data, or changes in the support infrastructure driven by current analysis.

This topic describes the other features of SQL Server 2017 that are often part of a predictive analytics solution, either to support the processes of data preparation and data mining, or to support users by providing tools for analysis and action.

[Integration Services](#)

[Reporting Services](#)

[Data Quality Service](#)

[Full-Text Search](#)

[Semantic Indexing](#)

SQL Server Integration Services

Integration Services provides components and features that are required for the data preparation and training phases of a data mining project. Although you can perform many data cleansing or preparation tasks by using other tools, such as scripts, Integration Services has numerous advantages for data mining:

- Represents tasks as part of a workflow, which can be repeated, automated, branched, and extended.
- Provides extensive support for auditing and multiple ways of capturing errors and logging events.

In addition to capturing data lineage, you can monitor changes to the data throughout the data transformation pipeline.

You can also integrate your SSIS workflows with the features that support Change Data Capture functionality in SQL Server.

- Data mining can be incorporated in the Integration Services workflow, to intelligently separate incoming data into multiple tables. For example, you could use a prediction query to split new customers into different groups for targeting in a mailing campaign.

The following lists provide links to the Integration Services components that are most widely used in support of

data mining.

Control Flow Components

- [Analysis Services Execute DDL Task](#)
- [Analysis Services Processing Task](#)
- [CDC Control Task](#)
- [Data Cleansing](#)
- [Data Mining Query Task](#)
- [Data Profiling Task](#)

Data Flow Components

- [CDC Flow Components](#)
- [Conditional Split Transformation](#)
- [Data Conversion Transformation](#)
- [Data Mining Model Training Destination](#)
- [Data Mining Query Transformation](#)
- [Derived Column Transformation](#)
- [Percentage Sampling Transformation](#)
- [Term Extraction Transformation](#)
- [Term Lookup Transformation](#)

SQL Server Reporting Services

Although Reporting Services is typically not seen as a critical component of data mining solutions, it provides the following features that are useful for presentation of data mining solutions.

- Integration of data from multiple sources in complex reports. Create queries against the model content for analysts, and reports that show predictions and trends for end users.
- The ability to create a report that lets users directly query against an existing mining model.
- Integration with Analysis Services, to support drillthrough and exploration of data mining dimensions and data mining cubes created from OLAP models.
- parameterization and formatting features that are available in Reporting Services.

For more information about how to use Reporting Services with DMX queries as a data source, see these links:

[Retrieve Data from a Data Mining Model \(DMX\) \(SSRS\)](#)

[Analysis Services DMX Query Designer User Interface](#)

[Analysis Services Connection Type for DMX \(SSRS\)](#)

However, it is not necessary to use DMX as the data source. The Integration Services components for data mining also support saving the results of a prediction query to a relational database. If you have an established workflow for updating models using Integration Services, persisting predictions and other data mining query results to SQL Server enable you to use Power View for reporting, as well as other tools that do not interface with DMX.

For more information about using Reporting Services as the presentation layer for data sources, see [Integrating Reporting Services into Applications](#).

Data Quality Services

Data Quality Services (DQS) is new in SQL Server 2017. Because data problems can make data mining impossible, data miners who perform repeated analysis or who work in large organizations with complex data sources are expected to find that a well-planned data project using DQS is a more reliable solution for support of data mining than ad hoc cleansing of data using Transact-SQL or other scripts.

The following features of DQS should be considered for data preparation and data integrity in a data mining solution.

A computer-assisted data cleansing process that analyzes source data and proposes changes.

DQS can compare source data with cloud-based reference data maintained and guaranteed by data quality providers.

DQS can also analyze raw source data and create a knowledge base from user data. The processed data is categorized and then displayed to the user for further processing. The cleansing process is interactive, meaning the data steward can approve, reject, or modify the data proposed by the computer-assisted data cleansing process.

The outcome of the process is a knowledge base that you can continuously improve, or reuse in multiple data-enhancement phases.

For more information, see [Data Cleansing](#).

A computer-assisted matching process that analyzes source data and proposes changes.

To prevent data duplication, you can perform addition cleansing of the data source, to identify exact and approximate matches. These components let you specify the matching rules, and the thresholds at which to apply them.

By finding data matches, you can remove duplicates, which can be a problem for data mining. Data de-duplication is not automatic; the data steward or IT professional must verify both the knowledge in the knowledge base and the changes to be made to the data.

After you have created the initial DQS project, you can automate many of the tasks by using Integration Services components.

For more information, see [Data Matching](#).

While performing cleansing and matching activities in a data quality project, you can get real-time statistics and information about the data that is being processed by DQS. Data profiling helps you assess the extent to which data cleansing or matching helped improve the data quality, and understand the changes that were made. For information about data profiling and notifications, see [Data Profiling and Notifications in DQS](#).

A knowledge base that represents three types of knowledge: out-of-the-box knowledge, knowledge generated by the DQS server, and knowledge generated by the user.

Once you have created a knowledge base, you can use it iteratively to cleanse and verify other data.

You can import new data into the knowledge base data from multiple sources, either known clean data from reference providers, or raw data that is matched to existing data in the knowledge base.

For detailed information about the cleansing activity in a data quality project, see [Data Cleansing \(DQS\)](#).

You can also apply the knowledge in the knowledge base to other sources, to perform data cleansing within other processes. Such data cleansing can help identify user entry errors, corruption in transmission or storage, or mismatched data dictionary definitions.

For more information, see [DQS Knowledge Bases and Domains](#).

Full-Text Search

Full-Text Search in SQL Server lets applications and users run full-text queries against character-based data in SQL Server tables. When full-text search is enabled, you can perform searches against text data that are enhanced by language-specific rules about the multiple forms of a word or phrase. You can also configure search conditions, such as the distance between multiple terms, and use functions to constrain the results that are returned in order of likelihood.

Because full-text queries are a feature provided by the SQL Server engine, you can create parameterized queries, generate custom data sets or term vectors by using full-text search features on a text data source, and use these sources in data mining.

For more information about how full-text queries interact with the full-text index, see [Query with Full-Text Search](#).

An advantage of using the full-text search features of SQL Server is that you can leverage the linguistic intelligence that is contained in the word breakers and stemmers shipped for all SQL Server languages. By using the supplied word breakers and stemmers, you can ensure that words are separated using the characters appropriate for each language, and that synonyms based on diacritics or orthographic variations (such as the multiple number formats in Japanese) are not overlooked.

In addition to linguistic intelligence that governs word boundaries, the stemmers for each language can reduce variants of a word to a single term, based on knowledge of the rules for conjugation and orthographic variation in that language. The rules for linguistic analysis differ for each language and are developed based on extensive research on real-life corpora.

For more information, see [Configure and Manage Word Breakers and Stemmers for Search](#).

The version of a word that is stored after full-text indexing is a token in compressed form. Subsequent queries to the full-text index generate multiple inflectional forms of a particular word based on the rules of that language, to ensure that all probable matches are made. For example, although the token that is stored might be "run", the query engine also looks for the terms "running", "ran", and "runner," because these are regularly derived morphological variations of the root word "run".

You can also create and build a user thesaurus to store synonyms and enable better search results, or categorization of terms. By developing a thesaurus tailored to your full-text data, you can effectively broaden the scope of full-text queries on that data. For more information, see [Configure and Manage Thesaurus Files for Full-Text Search](#).

Requirements for using full-text search include the following:

- The database administrator must create a full-text index on the table.
- Only one full-text index is allowed per table.
- Each column that you index must have a unique key.
- Full-text indexing is supported only for columns with these data types: char, varchar, nchar, nvarchar, text, ntext, image, xml, varbinary, and varbinary(max). If the column is varbinary, varbinary(max), image, or xml, you must specify the file extension of the indexable document (.doc, .pdf, .xls, and so forth), in a separate type column.

Semantic Indexing

Semantic search builds upon the existing full-text search features in SQL Server, but uses additional capabilities and statistics to enable scenarios such as automatic keyword extraction and discovery of related documents. For example, you might use semantic search to build a base taxonomy for an organization, or classify a corpus of

documents. Or, you could use the combination of extracted terms and document similarity scores in clustering or decision tree models.

After you have enabled semantic search successfully, and indexed your data columns, you can use the functions that are provided natively with semantic indexing to do the following:

- Return single-word key phrases with their score.
- Return documents that contain a specified key phrase.
- Return similarity scores, and the terms that contribute to the score.

For more information, see [Find Key Phrases in Documents with Semantic Search](#) and [Find Similar and Related Documents with Semantic Search](#).

For more information about the database objects that support semantic indexing, see [Enable Semantic Search on Tables and Columns](#).

Requirements for using semantic search include the following:

- Full-text search also be enabled.
- Installation of the semantic search components also creates a special system database, which cannot be renamed, altered, or replaced.
- Documents that you index using the service must be stored in SQL Server, in any of the database objects that are supported for full-text indexing, including tables and indexed views.
- Not all of the full-text languages support semantic indexing. For a list of supported languages, see [sys.fulltext_semantic_languages \(Transact-SQL\)](#).

Deployment of Data Mining Solutions

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The last step in the data mining process is to deploy the models to a production environment. Deployment is important because it makes the models available to users so that you can perform any of the following tasks:

- Use the models to create predictions and make business decisions. For information about the tools you can use to create queries, see [Data Mining Query Tools](#).
- Embed data mining functionality directly into an application. You can include Analysis Management Objects (AMO) or an assembly that contains a set of objects that your application can use to create, alter, process, and delete mining structures and mining models.
- Create reports that let users request predictions, view trends, or compare models.

This section provides detailed information about deployment options.

Requirements for Deployment of Data Mining Solutions

Deploying a Relational Solution

Deploying a Multidimensional Solution

Related Resources

In This Section

[Deploy a Data Mining Solution to Previous Versions of SQL Server](#)

[Export and Import Data Mining Objects](#)

Requirements for Deployment of Data Mining Solutions

The instance of Analysis Services to which you deploy the solution must be running in a mode that supports multidimensional objects and data mining objects; that is, you cannot deploy data mining objects to an instance that hosts tabular models or Power Pivot data.

Therefore, when you create a data mining solution in Visual Studio, be sure to use the template, **Analysis Services Multidimensional and Data Mining Project**.

When you deploy the solution, the objects used for data mining are created in the specified Analysis Services instance, in a database with the same name as the solution file.

Deploying a Relational Solution

When you deploy a relational data mining solution, the required data mining objects are created within a new Analysis Services database, and the objects are processed by default. You can change processing options by using the configuration property, **Processing Option**. For more information, see [Configure Analysis Services Project Properties \(SSDT\)](#).

By default, only incremental changes are deployed each time. In other words, you can modify a mining model, and when you re-deploy the project, only that mining model would be updated. However, if you have multiple clients editing the Analysis Services database, this can lead to errors. To change the default deployment mode so that the entire database is refreshed when you deploy the solution, change the **Deployment Mode** property

In a relational data mining solution, the only objects that must be deployed are the data source definition, any data source views that were used, the mining structures, and all dependent mining models.

Deploying a Multidimensional Solution

When you deploy a multidimensional data mining solution, this solution creates your data mining objects within the same database as the source cube.

When you process the mining structure or mining model, you must process the source cube as well. For this reason, deploying a solution that uses OLAP mining models can take longer than relational data mining solutions.

Typically data mining objects also use the same data sources and data source views that are used for the cube. However, you can add data sources and data source views that are targeted specifically to data mining. For example, typically a cube would not contain data about prospective clients, or external data not used in the multidimensional objects.

Related Resources

[Moving Data Mining Objects](#)

If your model is based on relational data only, exporting and importing objects using DMX is the easiest way to move models.

[Move an Analysis Services Database](#)

When models use a cube as a data source, refer to this topic for more information about how to move models and their supporting cube data.

[Deploying Models with Filters](#)

[Restoring from Database Backups](#)

[Using Database Synchronization](#)

Deploying Times Series Models

The Microsoft Time Series algorithm was enhanced in SQL Server 2008 by the addition of a second, complementary algorithm, ARIMA. For more information about the changes in the time series algorithm, see [Microsoft Time Series Algorithm](#).

Therefore, time series mining models that use the new ARIMA algorithm may behave differently when deployed to an instance of SQL Server 2005 Analysis Services.

If you have explicitly set the parameter PREDICTION_SMOOTHING to control the mixture of ARTXP and ARIMA models in prediction, when you deploy this model to an instance of SQL Server 2005, Analysis Services will raise an error stating that the parameter is not valid. To prevent this error, you must delete the PREDICTION_SMOOTHING parameter and convert the models to a pure ARTXP model.

Conversely, if you deploy a time series model that was created using SQL Server 2005 Analysis Services to an instance of SQL Server 2017, when you open the mining model in Visual Studio with Analysis Services projects, the definition files are first converted to the new format, and two new parameters are added by default to all time series models. The parameter FORECAST_METHOD is added with the default value of MIXED, and the parameter PREDICTION_SMOOTHING is added with the default value of 0.5. However, the model will continue to use only ARTXP for forecasting until you reprocess the model. As soon as you reprocess the model, prediction changes to use both ARIMA and ARTXP.

Therefore, if you wish to avoid changing the model, you should only browse the model and never process it. Alternatively, you could explicitly set the FORECAST_METHOD or PREDICTION_SMOOTHING parameters.

For detailed information about configuring mixed models, see [Microsoft Time Series Algorithm Technical Reference](#).

If the provider that is used for the model's data source is SQL Client Data Provider 10, you must also modify the data source definition to specify the previous version of the SQL Server Native Client. Otherwise, Visual Studio with Analysis Services projects generates an error stating that the provider is not registered.

Deploying Models with Holdout

If you create a mining structure that contains a holdout partition used for testing data mining models, the mining structure can be deployed to an instance of SQL Server 2005, but the partition information will be lost.

When you open the mining structure in SQL Server 2005 Analysis Services, Visual Studio with Analysis Services projects raises an error, and then regenerates the structure to remove the holdout partition.

After the structure has been rebuilt, the size of the holdout partition is no longer available in the Properties window; however, the value <ddl100_100:HoldoutMaxPercent>30</ddl100_100:HoldoutMaxPercent>) may still be present in the ASSL script file.

Deploying Models with Filters

If you apply a filter to a mining model, the model can be deployed to an instance of SQL Server 2005, but the filter will not be applied.

When you open the mining model, Visual Studio with Analysis Services projects raises an error, and then regenerates the model to remove the filter.

Restoring from Database Backups

You cannot restore a database backup that was created in SQL Server 2017 to an instance of SQL Server 2005. If you do so, SQL Server Management Studio generates an error.

If you create a backup of a SQL Server 2005 Analysis Services database and restore this backup on an instance of SQL Server 2017, all time series models are modified as described in the previous section.

Using Database Synchronization

Database synchronization is not supported from SQL Server 2017 to SQL Server 2005.

If you attempt to synchronize a SQL Server 2017 database, the server returns an error and database synchronization fails.

[Analysis Services Backward Compatibility](#)

Export and Import Data Mining Objects

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In addition to the functionality provided in Analysis Services for backing up, restoring, and migrating solutions, SQL Server Data Mining provides the ability to quickly transfer data mining structures and models between different servers by using Data Mining Extensions (DMX).

If your data mining solution uses relational data instead of a multidimensional database, transferring models by using **EXPORT** and **IMPORT** is much faster and easier than either using database restore or deploying an entire solution.

This section provides an overview of how to transfer data mining structures and models by using DMX statements. For details of the syntax, together with examples, see [EXPORT \(DMX\)](#) and [IMPORT \(DMX\)](#).

NOTE

You must be a database or server administrator to export or import objects from a Microsoft SQL Server Analysis Services database.

Exporting Data Mining Structures

When you export a mining structure, the EXPORT statement automatically exports all associated models. If you want to control the objects that are exported, you must specify each object by name.

If the mining structure has been processed and the results have been cached, which is the default behavior, when you export the mining structure, the definition contains a summary of the data on which the structure is based. To remove this summary, you must clear the cache associated with the mining structure by performing a **Process Clear Structure** operation. For more information, see [Process a Mining Structure](#).

Exporting Data Mining Models

You can use the **WITHDEPENDENCIES** keyword to export the data source and data source view definition together with the mining model and its structure.

When you export a mining model without exporting its dependencies, the EXPORT statement will export the definition of the mining model and its mining structure, but does not export the definition of the data sources. As a consequence, after you import the model you will be able to browse the model immediately, but if you want to reprocess the mining model on the target server, or run queries against the underlying data, you must create a corresponding data source on the destination server.

Importing Data Mining Structures and Models

When you import a data mining object, the object is imported to the server and database to which you are connected when you execute the IMPORT statement. If the import file includes a database that does not exist on the server, the database will be created.

You can also import a mining structure or mining model by using the **Restore** command. Your models or structures will be restored into the database that has the same name as the database from which they were exported. For more information, see [Restore Options](#).

Remarks

You cannot import a model or structure to a server if a model or structure of the same name already exists on that server. Also, you cannot export a data mining object and then modify the name of that object in the export file. Therefore, if you anticipate naming conflicts, you should either delete the data mining object on the target server, or rename the data mining object before you export the definition.

Data Mining Architecture

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

This section describes the architecture of data mining solutions that are hosted in an instance of Analysis Services. The topics in this section describe the logical and physical architecture of an Analysis Services instance that supports data mining, and also provide information about the clients, providers, and protocols that can be used to communicate with data mining servers, and to work with data mining objects either locally or remotely.

In general, SQL Server Data Mining operates as a service that is provided as part of an Analysis Services instance running in multidimensional mode; therefore, we recommend that you also review the following sections of Books Online that describe the operation, maintenance, and configuration of Analysis Services multidimensional solutions.

[Processing a multidimensional model \(Analysis Services\)](#)

[Connect to Analysis Services](#)

[Database Storage Location](#)

[Switch an Analysis Services database between ReadOnly and ReadWrite modes](#)

For more information about how you can implement data mining in your business intelligence solution, see the Solution Guides section of the MSDN Library.

Logical Architecture (Analysis Services - Data Mining)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Data mining is a process that involves the interaction of multiple components.

- You access sources of data in a SQL Server database or any other data source to use for training, testing, or prediction.
- You define data mining structures and models by using Visual Studio with Analysis Services projects or Visual Studio.
- You manage data mining objects and create predictions and queries by using SQL Server Management Studio.
- When the solution is complete, you deploy it to an instance of Analysis Services.

The process of creating these solution objects has already been described elsewhere. For more information, see [Data Mining Solutions](#).

The following sections describe the logical architecture of the objects in a data mining solution.

[Data Mining Source Data](#)

[Mining Structures](#)

[Mining Models](#)

[Custom Data Mining Objects](#)

Data Mining Source Data

The data that you use in data mining is not stored in the data mining solution; only the bindings are stored. The data might reside in a database created in a previous version of SQL Server, a CRM system, or even a flat file. When you train the structure or model by processing, a statistical summary of the data is created and stored in a cache that can be persisted for use in later operations, or deleted after processing. For more information, see [Mining Structures \(Analysis Services - Data Mining\)](#).

You combine disparate data within the Analysis Services data source view (DSV) object, which provides an abstraction layer on top of your data source. You can specify joins between tables, or add tables that have a many-to-one relationship to create nested table columns. The definition of these objects, the data source and the data source view, are stored within the solution with the file name extensions, *.ds and *.dsv. For more information about creating and using Analysis Services data sources and data source views, see [Supported Data Sources \(SSAS - Multidimensional\)](#).

You can also define and alter data sources and data source views by using AMO or XMLA. For more information about working with these objects programmatically, see [Logical Architecture Overview \(Analysis Services - Multidimensional Data\)](#).

Mining Structures

A data mining structure is a logical data container that defines the data domain from which mining models are built. A single mining structure can support multiple mining models.

When you need to use the data in the data mining solution, Analysis Services reads the data from the source and generates a cache of aggregates and other information. By default this cache is persisted so that training data can be reused to support additional models. If you need to delete the cache, change the **CacheMode** property on the mining structure object to the value, **ClearAfterProcessing**. For more information, see [AMO Data Mining Classes](#).

Analysis Services also provides the ability to separate your data into training and testing data sets, so that you can test your mining models on a representative, randomly selected set of data. The data is not actually stored separately; rather, case data in the structure cache is marked with a property that indicates whether that particular case is used for training or for testing. If the cache is deleted, that information cannot be retrieved.

For more information, see [Mining Structures \(Analysis Services - Data Mining\)](#).

A data mining structure can contain nested tables. A nested table provides additional detail about the case that is modeled in the primary data table. For more information, see [Nested Tables \(Analysis Services - Data Mining\)](#)

Mining Models

Before processing, a data mining model is only a combination of metadata properties. These properties specify a mining structure, specify a data mining algorithm, and define collection of parameter and filter settings that affect how the data is processed. For more information, see [Mining Models \(Analysis Services - Data Mining\)](#).

When you process the model, the training data that was stored in the mining structure cache is used to generate patterns, based both on statistical properties of the data and on heuristics defined by the algorithm and its parameters. This is known as *training* the model.

The result of training is a set of summary data, contained within the *model content*, which describes the patterns that were found and provides rules by which to generate predictions. For more information, see [Mining Model Content \(Analysis Services - Data Mining\)](#).

In limited cases, the logical structure of the model can also be exported into a file that represents model formulas and data bindings according to a standard format, the Predictive Modeling Markup Language (PMML). This logical structure can be imported into other systems that utilize PMML and the model so described can then be used for prediction. For more information, see [Understanding the DMX Select Statement](#).

Custom Data Mining Objects

Other objects that you use in the context of a data mining project, such as accuracy charts or prediction queries, are not persisted within the solution, but can be scripted using ASSL or built using AMO.

Additionally, you can extend the services and features available on an instance of Analysis Services by adding these custom objects:

Custom assemblies

.NET assemblies can be defined by using any CLR-or COM-compliant language, and then registered with an instance of SQL Server. Assembly files are loaded from the location defined by the application, and a copy is saved in the server along with the data. The copy of the assembly file is used to load the assembly every time the service is started.

For more information, see [Multidimensional Model Assemblies Management](#).

Custom stored procedures

Analysis Services data mining supports the use of stored procedures to work with data mining objects. You can create your own stored procedures to extend functionality and more easily work with data returned by prediction queries and content queries.

[Defining Stored Procedures](#)

The following stored procedures are supported for use in performing cross-validation.

[Data Mining Stored Procedures \(Analysis Services - Data Mining\)](#)

Additionally, Analysis Services contains many system stored procedures that are used internally for data mining. Although the system stored procedures are for internal use, you might find them useful shortcuts. Microsoft reserves the right to change these stored procedures as needed; therefore, for production use, we recommend that you create queries by using DMX, AMO, or XMLA.

Custom plug-in algorithms

Analysis Services provides a mechanism for creating your own algorithms, and then adding the algorithms as a new data mining service to the server instance.

Analysis Services uses COM interfaces to communicate with plugin algorithms. To learn more about how to implement new algorithms, see [Plugin Algorithms](#).

You must register each new algorithm before you can use it. To register an algorithm, you add the required metadata for the algorithms in the .ini file of the instance of Analysis Services. You must add the information to each instance where you plan to use the new algorithm. After you have added the algorithm, you can restart the instance, and use the MINING_SERVICES schema rowset to view the new algorithm, including the options and providers that the algorithm supports.

[Processing a multidimensional model \(Analysis Services\)](#)

[Data Mining Extensions \(DMX\) Reference](#)

Physical Architecture (Analysis Services - Data Mining)

10/22/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Microsoft Analysis Services uses both server and client components to supply data mining functionality for business intelligence applications:

- The server component is implemented as a Microsoft Windows service. You can have multiple instances on the same computer, with each instance of Analysis Services implemented as a separate instance of the Windows service.
- Clients communicate with Analysis Services using the public standard XML for Analysis (XMLA), a SOAP-based protocol for issuing commands and receiving responses, exposed as a Web service. Client object models are also provided over XMLA, and can be accessed either by using a managed provider, such as ADOMD.NET, or a native OLE DB provider.
- Query commands can be issued using Data Mining Extensions (DMX), an industry standard query language oriented toward data mining. Analysis Services Scripting Language (ASSL) can also be used to manage Analysis Services database objects.

Architectural Diagram

An Analysis Services instance runs as a stand-alone service and communication with the service occurs through XML for Analysis (XMLA), by using either HTTP or TCP.

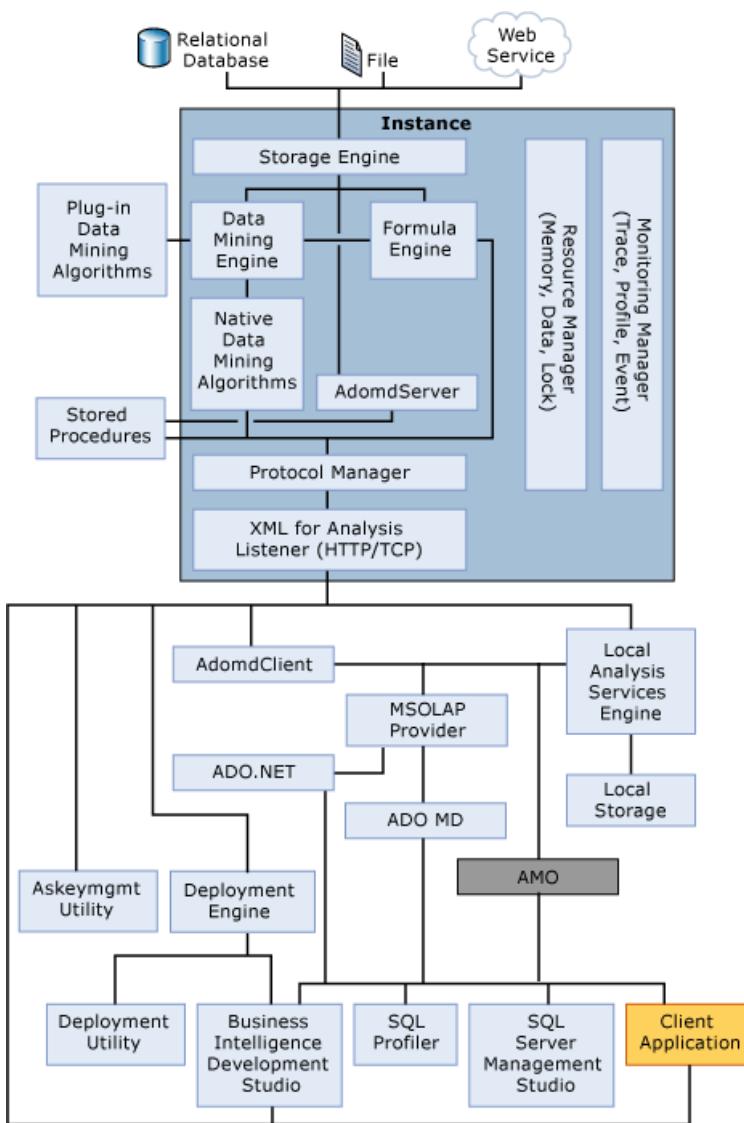

AMO is a layer between the user application and the Analysis Services instance that provides access to Analysis Services administrative objects. AMO is a class library that takes commands from a client application and converts those commands into XMLA messages for the Analysis Services instance. AMO presents Analysis Services instance objects as classes to the end user application, with method members that run commands and property members that hold the data for the Analysis Services objects.

The following illustration shows the Analysis Services components architecture, including services within the Analysis Services instance and user components that interact with the instance.

The illustration shows that the only way to access the instance is by using the XML for Analysis (XMLA) Listener, either by using HTTP or TCP.

WARNING

DSO has been deprecated. You should not use DSO to develop solutions.

Server Configuration

One server instance can support multiple Analysis Services databases, each with its own instance of the Analysis Services service that responds to client requests and processes objects.

Separate instances must be installed if you want to work with both tabular models and data mining and/or multidimensional models. Analysis Services supports side-by-side installation of instances running in tabular mode (which uses the VertiPaq in-memory analytics engine) and instances running in one of the conventional OLAP, MOLAP, or ROLAP configurations. For more information, see [Determine the Server Mode of an Analysis Services Instance](#).

All communications between a client and the Analysis Services server use XMLA, which is a platform-independent and language-independent protocol. When a request is received from a client, Analysis Services determines whether the request relates to OLAP or data mining, and routes the request appropriately. For more information, see [OLAP Engine Server Components](#).

[Logical Architecture \(Analysis Services - Data Mining\)](#)

Data Mining Services and Data Sources

9/6/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Data mining requires a connection to an instance of SQL Server Analysis Services. Data from a cube is not required for data mining and the use of relational sources is recommended; however, data mining uses components provided by the Analysis Services engine.

This topic provides information that you need to know when connecting to an instance of SQL Server Analysis Services to create, process, deploy, or query data mining models.

Data Mining Services

The server component of Microsoft SQL Server Analysis Services is the msmdsrv.exe application, which ordinarily runs as a Windows service. This application consists of security components, an XML for Analysis (XMLA) listener component, a query processor component and numerous other internal components that perform the following functions:

- Parsing statements received from clients
- Managing metadata
- Handling transactions
- Processing calculations
- Storing dimension and cell data
- Creating aggregations
- Scheduling queries
- Caching objects
- Managing server resources

XMLA Listener

The XMLA listener component handles all XMLA communications between Analysis Services and its clients. The Analysis Services **Port** configuration setting in the msmdsrv.ini file can be used to specify a port on which an Analysis Services instance listens. A value of 0 in this file indicates that Analysis Services listen on the default port. Unless otherwise specified, Analysis Services uses the following default TCP ports:

PORT	DESCRIPTION
2383	Default instance of SQL Server Analysis Services.
2382	Redirector for other instances of SQL Server Analysis Services.
Dynamically assigned at server startup	Named instance of SQL Server Analysis Services.

For more information about controlling the ports used by this service, see [Configure the Windows Firewall to Allow Analysis Services Access](#).

Connecting to Data Sources

Whenever you create or update a data mining structure or model, you use data that is defined by a data source. The data source does not contain the data, which might include Excel workbooks, text files, and SQL Server databases; it only defines the connection information. A data source view (DSV) serves as an abstraction layer on top of that source, modifying or mapping the data that is obtained from the source.

It is beyond the scope of this topic to describe the connection requirements for each of these sources. For more information, see the documentation for the provider. However, in general, you should be aware of the following requirements of Analysis Services, when interacting with providers:

- Because data mining is a service provided by a server, the Analysis Services instance must be given access to the data source. There are two aspects to access: location and identity.

Location means that, if you build a model using data that is stored only on your computer and then deploy the model to a server, the model would fail to process because the data source cannot be found. To resolve this problem, you might need to transfer data into the same SQL Server instance where Analysis Services is running, or move files to a shared location.

Identity means that the services on Analysis Services must be able to open the data file or data source with the appropriate credentials. For example, when you built the model, you might have had unlimited permissions to view the data, but the user who is processing and updating the models on the server might have limited or no access to the data, which can cause failure to process or affect the contents of a model. At minimum, the account used for connecting to the remote data source must have read permissions to the data.

- When you move a model, the same requirements apply: you must set up appropriate access to the location of the old data source, copy the data sources, or configure a new data source. Also, you must transfer logins and roles, or set up permissions to allow data mining objects to be processed and updated in the new location.

Configuring Permissions and Server Properties

Data mining requires additional permissions on an Analysis Services database. Most data mining properties can be set by using the [Analysis Server Properties Dialog Box \(Analysis Services\)](#).

For more information about the properties that you can configure, see [Server properties in Analysis Services](#).

The following server properties are of particular relevance to data mining:

- AllowAdHocOpenRowsetQueries** Controls ad hoc access to OLE DB providers, which are loaded directly into server memory space.

IMPORTANT

To improve security, we recommend that you set this property to **false**. The default value is **false**. However, even if this property is set to **false**, users can continue to create singleton queries, and can use OPENQUERY on permitted data sources.

- AllowedProvidersInOpenRowset** Specifies the provider, if ad hoc access is enabled. You can specify multiple providers, by entering a comma-separated list of ProgIDs.
- MaxConcurrentPredictionQueries** Controls the load on the server caused by predictions. The default value of 0 allows unlimited queries for SQL Server Enterprise, and a maximum of five concurrent queries for SQL Server Standard. Queries above the limit are serialized and may time out.

The server provides additional properties that control which data mining algorithms are available, including any

restrictions on the algorithms, and the defaults for all data mining services. However, there are no settings that allow you to control access to data mining stored procedures specifically. For more information, see [Data Mining Properties](#).

You can also set properties that let you tune the server and control security for client usage. For more information, see [Feature Properties](#).

NOTE

For more information about Support for plug-in algorithms by the editions of SQL Server, see [Features Supported by the Editions of SQL Server 2012](#) (<https://go.microsoft.com/fwlink/?LinkId=232473>).

Programmatic Access to Data Mining Objects

You can use the following object models to create a connection to an Analysis Services database and work with data mining objects:

ADO Uses OLE DB to connect to an Analysis Services server. When you use ADO, the client is limited to schema rowset queries and DMX statements.

ADO.NET Interacts with SQL Server providers better than other providers. Uses data adaptors to store dynamic rowsets. Uses the dataset object, which is a cache of the server data stored as data tables that can be updated or saved as XML.

ADOMD.NET A managed data provider that is optimized for working with data mining and OLAP. ADOMD.NET is faster and more memory-efficient than ADO.NET. ADOMD.NET also lets you retrieve metadata about server objects. Recommended for client applications except when .NET is not available.

Server ADOMD Object model for accessing Analysis Services objects directly on the server. Used by Analysis Services stored procedures; not for client use.

AMO Management interface for Analysis Services that replaces Decision Support Objects (DSO). Operations such as iterating objects require higher permissions when using AMO than when using other interfaces. That is because AMO accesses metadata directly, whereas ADOMD.NET and other interfaces access only the database schemas.

Browse and Query Access to Servers

You can perform all kinds of predictions by using a instance of Analysis Services in OLAP/Data Mining mode, with the following restrictions:

- If you use server ADOMD, you can use DMX to access the server without making a connection. You can then copy the results directly into a data table. However, you cannot use Server ADOMD with remote instances; you can query only the local server.
- ADO.NET does not support named parameters for data mining. You must use ADOMD.NET.
- ADOMD.NET lets you pass an entire table to use as the parameter; therefore, you can use data on the client, or data that is unavailable to the server. You can also use shaped tables as prediction input.

Using Data Mining Stored Procedures

A common use of stored procedures is to encapsulate queries for reuse. The client can use CALL to run stored procedures, including Analysis Services system stored procedures.

If the procedure returns a dataset, the client will receive a dataset or datatable with a nested table containing the rows. For example, if you create a query against the model content, the query returns the entire model. To avoid bringing back too many rows, you can write stored procedures by using the ADOMD+ object model.

To write a server stored procedure, you must reference the Microsoft.AnalysisServices.AdomdServer namespace.

For more information about how to create and use stored procedures, see [User Defined Functions and Stored Procedures](#).

NOTE

Stored procedures cannot be used to change security on data server objects. When you execute a stored procedure, the user's current context is used to determine access to all server objects. Therefore, users must have appropriate permissions on any database objects that they access.

[Management of Data Mining Solutions and Objects](#)

Management of Data Mining Solutions and Objects

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

SQL Server 2017 provides client tools that you can use to manage existing mining structures and mining models. This section describes the management operations that you can perform using each environment.

In addition to these tools, you can manage data mining objects programmatically, by using AMO, or use other clients that connect to an Analysis Services database, such as the Data Mining Add-ins for Microsoft Excel 2007.

In this Section

[Moving Data Mining Objects](#)

[Processing Requirements and Considerations \(Data Mining\)](#)

[Using SQL Server Profiler to Monitor Data Mining \(Analysis Services - Data Mining\)](#)

Location of Data Mining Objects

Mining structures and models that have been processed are stored in an instance of Analysis Services.

If you create a connection to an Analysis Services database in **Immediate** mode when developing your data mining objects, any objects that you create are immediately added to the server as you work. However, if you design data mining objects in **Offline** mode, which is the default when you work in Visual Studio with Analysis Services projects, the mining objects that you create are only metadata containers until you deploy them to an instance of Analysis Services. Therefore, any time that you make a change to an object, you must redeploy the object to the Analysis Services server. For more information about data mining architecture, see [Physical Architecture \(Analysis Services - Data Mining\)](#).

NOTE

Some clients, such as the Data Mining Add-ins for Microsoft Excel 2007, also let you create session mining models and mining structures, which use a connection to an instance but store the mining structure and models on the server only for the duration of the session. You can still manage these models through the client, the same as you would structures and models stored in an Analysis Services database, but the objects are not persisted after you disconnect from the instance of Analysis Services.

Managing Data Mining Objects in SQL Server Data Tools

Visual Studio with Analysis Services projects offers features that make it easy to create, browse, and edit data mining objects.

The following links provide information on how you can modify data mining objects by using Visual Studio with Analysis Services projects:

- [Edit the Data Source View used for a Mining Structure](#)
- [Change the Properties of a Mining Structure](#)
- [Change the Properties of a Mining Model](#)

- [View or Change Modeling Flags \(Data Mining\)](#)
- [View or Change Algorithm Parameters](#)

Typically you will use Visual Studio with Analysis Services projects as a tool for developing new projects and adding to existing projects, and then manage projects and objects that have been deployed by using tools such as SQL Server Management Studio.

However, you can directly modify objects that are already deployed to an instance of ssASnoversion by using the **Immediate** option and connecting to the server in Online mode. For more information, see [Connect in Online Mode to an Analysis Services Database](#).

WARNING

All changes to a mining structure or mining model, including changes to metadata such as a name or description, require that the structure or model be reprocessed.

If you do not have the solution file that was used to create the data mining project or objects, you can import the existing project from the server using the Analysis Services Import wizard, make modifications to the objects, and then redeploy using the **Incremental** option. For more information, see [Import a Data Mining Project using the Analysis Services Import Wizard](#).

Managing Data Mining Objects in SQL Server Management Studio

In SQL Server Management Studio, you can script, process, or delete mining structures and mining models. You can view only a limited set of properties by using Object Explorer; however, you can view additional metadata about mining models by opening a **DMX Query** window and selecting a mining structure.

- [Create a DMX Query in SQL Server Management Studio](#)

Managing Data Mining Objects Programmatically

You can create, alter, process, and delete data mining objects by using the following programming languages. Each language is designed for different tasks and as a result, there might be restrictions on the type of operations that you can perform. For example, some properties of data mining objects cannot be changed by using Data Mining Extensions (DMX); you must use XMLA or AMO.

Analysis Management Objects (AMO)

Analysis Management Objects (AMO) is an object model built on top of XMLA that gives you full control over data mining objects. By using AMO, you can create, deploy, and monitor mining structures and mining models.

- [AMO Concepts and Object Model](#)
- [Microsoft.AnalysisServices](#)

Restrictions: None.

Data Mining Extensions (DMX)

Data Mining Extensions (DMX) can be used with other command interfaces such as ADO.NET or ADOMD.Net to create, delete, and query mining structures and mining models.

- [Data Mining Extensions \(DMX\) Data Definition Statements](#)

Restrictions: Some properties cannot be changed by using DMX.

XML for Analysis (XMLA)

XML for Analysis (XMLA) is the data definition language for all of Analysis Services. XMLA gives you control

over most data mining objects and server operations. All management operations between the client and the server can be performed by using XMLA. For convenience, you can use the Analysis Services Scripting Language (ASSL) to wrap the XML.

Restrictions: Visual Studio with Analysis Services projects generates some XMLA statements that are supported for internal use only, and cannot be used in XML DDL scripts.

[Analysis Services Developer Documentation](#)

Moving Data Mining Objects

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The most common scenarios for moving data mining objects are to deploy a model from a testing or analysis environment to a production environment, or to share models with other users.

This topic describes how you can use the tools and scripting languages provided by Analysis Services, for moving data mining objects.

Moving Data Mining Objects between Databases or Servers

You can move data mining objects between Analysis Services databases or between instances of Analysis Services in the following ways:

- Re-deploying the solution to a different database.
- Scripting individual objects.
- Backing up and then restoring a copy of the database.
- Exporting and importing structures and models.

The following section explains these options in more detail.

Deploying

Deploying the solution to a different server or database requires that you have the solution file that was created by using Visual Studio with Analysis Services projects.

For more information about deploying Analysis Services solutions, see [Deploy Analysis Services Projects \(SSDT\)](#).

Scripting

Analysis Services provides several languages that you can use to script objects.

- **XMLA:** You can script objects using XMLA by right-clicking objects in SQL Server Management Studio. To execute the script, open it in an **XMLA Query** window on the target server.
- **DMX:** You can create scripts by using templates or one of the query builders provided in Visual Studio with Analysis Services projects and SQL Server Management Studio.

Note, however, that there are differences in the tasks that you can perform with each scripting language:

- Properties such as the object description and data bindings can only be created or changed by using Analysis Services DDL languages, not by using DMX.
- Only DMX supports the import and export of mining objects.
- Only DMX supports generating PMML or importing model definitions from PMML.
- Only DMX supports training a model with application data. Moreover, the DMX INSERT INTO statement supports training a model without providing values for a key column.

For more information, see [Developing with Analysis Services Scripting Language \(ASSL\)](#).

Backup and Restore

Backup and restore of an entire Analysis Services database is the method of choice if your data mining solution relies on OLAP objects. SQL Server 2017 provides backup and restore functionality that makes database backups faster and easier.

For more information about backup, see [Backup and Restore of Analysis Services Databases](#).

Exporting and Importing

Exporting and then re-importing mining models and structures by using DMX statements is the easiest way to move or back up individual relational data mining objects. For more information about the DMX syntax for these operations, see the following topics:

- [EXPORT \(DMX\)](#)
- [IMPORT \(DMX\)](#)

If you specify the INCLUDE DEPENDENCIES option, Analysis Services will also export the definition of any required data source views, and when you import the model or structure, it will re-create the data source view on the target server. After you have finished importing the model, make sure to set the necessary mining permissions on the object.

NOTE

You cannot export and import OLAP models by using DMX. If your mining model is based on an OLAP cube, you must use the functionality provided by Analysis Services for backing up and restoring an entire database, or redeploy the cube and its models.

Processing Requirements and Considerations (Data Mining)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

This topic describes some technical considerations to keep in mind when processing data mining objects. For a general explanation of what processing is, and how it applies to data mining, see [Processing Data Mining Objects](#).

[Queries on Relational Store](#)

[Processing Mining Structures](#)

[Processing Mining Models](#)

Queries on the Relational Store during Processing

For data mining, there are three phases to processing: querying the source data, determining raw statistics, and using the model definition and algorithm to train the mining model.

The Analysis Services server issues queries to the database that provides the raw data. This database might be an instance of SQL Server 2017 or an earlier version of the SQL Server database engine. When you process a data mining structure, the data in the source is transferred to the mining structure and persisted on disk in a new, compressed format. Not every column in the data source is processed: only the columns that are included in the mining structure, as defined by the bindings.

Using this data, Analysis Services builds an index of all data and discretized columns, and creates a separate index for continuous columns. One query is issued for each nested table to create the index, and an additional query per nested table is generated to process relationships between each pair of a nested table and case table. The reason for creating multiple queries is to process a special internal multidimensional data store. You can limit the number of queries that Analysis Services sends to the relational store by setting the server property, **DatabaseConnectionPoolMax**. For more information, see [OLAP Properties](#).

When you process the model, the model does not reread the data from the data source, but instead gets the summary of the data from the mining structure. Using the cube that was created, together with the cached index and case data has been cached, the server creates independent threads to train the models.

For more information about the editions of SQL Server that support Parallel Model Processing, see [Features Supported by the Editions of SQL Server 2012](#) (<https://go.microsoft.com/fwlink/?linkid=232473>).

Processing Mining Structures

A mining structure can be processed together with all dependent models, or separately. Processing a mining structure separately from models can be useful when some models are expected to take a long time to process and you want to defer that operation.

For more information, see [Process a Mining Structure](#).

If you are concerned about conserving hard disk space, note that Analysis Services retains mining structure caches locally. That is, it writes out all the training data to your local hard disk. If you do not want the data cached, you can change the default by setting the **MiningStructureCacheMode** property on the mining structure

to **ClearAfterProcessing**. This will destroy the cache after models are processed; however, it will also disable drillthrough on the mining structure. For more information, see [Drillthrough Queries \(Data Mining\)](#).

Also, if you clear the cache, you will not be able to use the holdout test set, if you defined one, and the definition of the test set partition will be lost. For more information about holdout test sets, see [Training and Testing Data Sets](#).

Processing Mining Models

You can process a mining model separately from its associated mining structure, or you can process all models that are based on the structure, together with the structure.

For more information, see [Process a Mining Model](#).

However, in Visual Studio with Analysis Services projects and SQL Server Management Studio, you cannot multiselect mining models to process with the structure. If you need to control which models are processed, you must select them individually, or use XMLA or DMX to process models serially.

When Reprocessing is Required

You must process the Analysis Services models that you define before you can start to work with them. You must also reprocess the mining models whenever you change the mining model structure, update the training data, change an existing mining model, or add a new mining model to the structure.

Mining models are also processed in these scenarios:

Deployment of a project: Depending on the project settings and the current state of the project, the mining models in the project are typically processed in full when the project is deployed.

When you initiate deployment, processing starts automatically, unless there is a previously processed version on the Analysis Services server and there have been no structural changes. You can deploy a project by selecting **Deploy solution** from the drop-down list or by pressing the F5 key. You can

For more information about how to set Analysis Services deployment properties that control how mining models are deployed, see [Deployment of Data Mining Solutions](#).

Moving a mining model: When you move a mining model by using the EXPORT command, only the definition of the model is exported, which includes the name of the mining structure that is expected to provide data to the model.

Reprocessing requirements for the following scenarios using the EXPORT and IMPORT commands:

- The mining structure exists on the target instance and the mining structure is in an unprocessed state.
Both the structure and model must be reprocessed.
- The mining structure exists on the target instance and the mining structure has been processed. Only the mining model was exported.

The model can be used without processing.

- The mining structure definition was also exported by using the WITH DEPENDENCIES keyword.
Both the structure and model must be reprocessed.

For more information, see [Export and Import Data Mining Objects](#).

[Processing a multidimensional model \(Analysis Services\)](#)

Using SQL Server Profiler to Monitor Data Mining (Analysis Services - Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If you have the necessary permissions, you can use SQL Server Profiler to monitor data mining activities that are issued as requests sent to an instance of SQL Server Analysis Services. Data mining activity can include the processing of models or structures, prediction queries or content queries, or the creation of new models or structures.

SQL Server Profiler uses a **trace** to monitor requests sent from multiple clients, including Visual Studio with Analysis Services projects, SQL Server Management Studio, Web services, or the Data Mining Add-ins for Excel, so long as the activities all use the same instance of SQL Server Analysis Services. You must create a separate trace for each instance of SQL Server Analysis Services that you want to monitor. For general information about traces, and how to use SQL Server Profiler, see [Use SQL Server Profiler to Monitor Analysis Services](#).

For specific guidance about the types of events to capture, see [Create Profiler Traces for Replay \(Analysis Services\)](#).

Using Traces to Monitor Data Mining

When you capture information in a trace, you can specify whether the information is saved in a file or in a table on an instance of SQL Server. Regardless of the method you use to store the data, you can use SQL Server Profiler to view the trace and filter by events. The following table lists some of the events and subclasses in the default Analysis Services trace that are of interest for data mining.

EVENTCLASS	EVENTSUBCLASS	DESCRIPTION
Query Begin	0 - MDXQuery	Contains the text of all calls to Analysis Services stored procedures.
Query End		
Query Begin	1 - DMXQuery	Contains the text and results of Data Mining Extensions (DMX) statements.
Query End		
Progress Report Begin	34 - DataMiningProgress	Provides information about the progress of the data mining algorithm: for example, if you are building a clustering model, the progress message tells you which candidate cluster is being built
Progress Report End		
Query Begin	EXECUTESQL	Contains the text of the Transact-SQL query that is being executed
Query End		
Query Begin	2- SQLQuery	Contains the text of any queries against the schema rowsets in the form of system tables.
Query End		

EVENTCLASS	EVENTSUBCLASS	DESCRIPTION
DISCOVER Begin	Multiple	Contains the text of DMX function calls or DISCOVER statements, encapsulated in XMLA.
DISCOVER End		
Error	(none)	<p>Contains the text of errors sent by the server to the client.</p> <p>Error messages prefaced with Error (Data Mining): or Informational (Data Mining): are generated specifically in response to DMX requests. However, it is not sufficient to view only these error messages. Other errors, such as those generated by the parser, may be related to data mining but do not have this prefix.</p>

By viewing the command statements in the trace log, you can also see the syntax of complex statements sent by the client to the Analysis Services server, including calls to system stored procedures. This information can be useful for debugging, or you can use valid statements as a template for creating new prediction queries or models. For some examples of stored procedure calls that you can capture via a trace, see [Clustering Model Query Examples](#).

Security Overview (Data Mining)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The process of securing Microsoft SQL Server Analysis Services occurs at multiple levels. You must secure each instance of Analysis Services and its data sources to make sure that only authorized users have read or read/write permissions to selected dimensions, mining models, and data sources. You must also secure underlying data sources to prevent unauthorized users from maliciously compromising sensitive business information. The process of securing an instance of Analysis Services is described in the following topics.

Security Architecture

See the following resources to learn about the basic security architecture of an instance of Analysis Services, including how Analysis Services uses Microsoft Windows Authentication to authenticate user access.

- [Security Roles \(Analysis Services - Multidimensional Data\)](#)
- [Security Properties](#)
- [Configure Service Accounts \(Analysis Services\)](#)
- [Authorizing access to objects and operations \(Analysis Services\)](#)

Configuring the Logon Account for Analysis Services

You must select an appropriate logon account for Analysis Services and specify the permissions for this account. You must make sure that the Analysis Services logon account has only those permissions that are necessary to perform necessary tasks, including appropriate permissions to the underlying data sources.

For data mining, you need a different set of permissions to build and process models than you need to view or query the models. Making predictions against a model is a kind of query and does not require administrative permissions.

Securing an Analysis Services Instance

Next you must secure the Analysis Services computer, the Windows operating system on the Analysis Services computer, Analysis Services itself, and the data sources that Analysis Services uses.

Configuring Access to Analysis Services

When you set up and define authorized users for an instance of Analysis Services, you need to determine which users should also have permission to administer specific database objects, which users can view the definition of objects or browse the models, and which users are able to access data sources directly.

Special Considerations for Data Mining

To enable an analyst or developer to create and test data mining models, you must give that analyst or developer administrative permissions on the database where the mining models are stored. As a consequence, the data mining analyst or developer can potentially create or delete other objects that are not related to data mining, including data mining objects that were created and are being used by other analysts or developers, or OLAP objects that are not included in the data mining solution.

Accordingly, when you create a solution for data mining, you must balance the needs of the analyst or developer to develop, test and tune models, against the needs of other users, and take measures to protect existing database objects. One possible approach is to create a separate database dedicated to data mining, or to create separate databases for each analyst.

Although the creation of models requires the highest level of permissions, you can control the user's access to data mining models for other operations, such as processing, browsing, or querying, by using role-based security. When you create a role, you set permissions that are specific to data mining objects. Any user who is a member of a role automatically has all permissions associated with that role.

Additionally, data mining models often reference data sources that contain sensitive information. If the mining structure and mining model has been configured to allow users to drill through from the model to the data in the structure, you must take precautions to mask sensitive information, or to limit the users who have access to the underlying data.

If you use Integration Services packages to clean data, to update mining models, or to make predictions, you must ensure that the Integration Services service has the appropriate permissions on the database where the model is stored, and appropriate permissions on the source data.

[Roles and Permissions \(Analysis Services\)](#)

Data Mining Tools

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Microsoft SQL Server Analysis Services provides the following tools that you can use to create data mining solutions:

- The **Data Mining Wizard** in Visual Studio with Analysis Services projects makes it easy to create mining structures and mining models, using either relational data sources or multidimensional data in cubes. In the wizard, you choose data to use, and then apply specific data mining techniques, such as clustering, neural networks, or time series modeling.
- **Model viewers** are provided in both SQL Server Management Studio and Visual Studio with Analysis Services projects, for exploring your mining models after they are created. You can browse models using viewers tailored to each algorithm, or go deeper into analysis by using the model content viewer.
- The **Prediction Query Builder** is provided in both SQL Server Management Studio and Visual Studio with Analysis Services projects to help you create prediction queries. You can also test the accuracy of models against a holdout data set or external data, or use cross-validation to assess the quality of your data set.
- SQL Server Management Studio is the interface where you manage existing data mining solutions that have been deployed to an instance of Analysis Services. You can reprocess structures and models to update the data in them.
- SQL Server Integration Services contains tools that you can use to clean data, to automate tasks such as creating predictions and updating models, and to create text mining solutions.

The following sections provide more information about the data mining tools in SQL Server.

Data Mining Wizard

Use the Data Mining Wizard to get started creating data mining solutions. The wizard is quick and easy, and guides you through the process of creating a data mining structure and an initial related mining model, and includes the tasks of selecting an algorithm type and a data source, and defining the case data used for analysis.

For More Information: [Data Mining Wizard \(Analysis Services - Data Mining\)](#)

Data Mining Designer

After you have created a mining structure and mining model by using the Data Mining Wizard, you can use the Data Mining Designer from either Visual Studio with Analysis Services projects or SQL Server Management Studio to work with existing models and structures.

The designer includes tools for these tasks:

- Modify the properties of mining structures, add columns and create column aliases, change the binning method or expected distribution of values.
- Add new models to an existing structure; copy models, change model properties or metadata, or define filters on a mining model.

- Browse the patterns and rules within the model; explore associations or decision trees. Get detailed statistics about

Custom viewers are provided for each different type of model, to help you analyze your data and explore the patterns revealed by data mining.

- Validate models by creating lift charts, or analyzing the profit curve for models. Compare models using classification matrices, or validate a data set and its models by using cross-validation.
- Create predictions and content queries against existing mining models. Build one-off queries, or set up queries to generate predictions for entire tables of external data.

SQL Server Management Studio

After you create and deploy mining models to a server, you can use SQL Server Management Studio to manage the Analysis Services database that hosts the data mining objects. You can also continue to perform tasks that use the model, such as exploring the models, processing new data, and creating predictions.

Management Studio also contains query editors that you can use to design and execute Data Mining Extensions (DMX) queries, or to work with data mining objects by using XMLA.

Integration Services Data Mining Tasks and Transformations

SQL Server Integration Services provides many components that support data mining.

Some tools in Integration Services are designed to help automate common data mining tasks, including prediction, model building, and processing. For example:

- Create an Integration Services package that automatically updates the model every time the dataset is updated with new customers
- Perform custom segmentation or custom sampling of case records.
- Automatically generate models based on parameters.

However, you can also use data mining in a package workflow, as an input to other processes. For example:

- Use probability values generated by the model to weight scores for text mining or other classification tasks.
- Automatically generate predictions based on prior data and use those values to assess the validity of new data.
- Using logistic regression to segment incoming customers by risk.

Data Mining Wizard (Analysis Services - Data Mining)

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Data Mining Wizard in Microsoft SQL Server Analysis Services starts every time that you add a new mining structure to a data mining project. The wizard helps you choose a data source and set up a data source view that defines the data to be used for analysis, and then helps you create an initial model.

In the final phase of the wizard, you can optionally divide your data into training and testing sets, and enable features such as drillthrough.

What to Know Before You Start

Here are the things you need to know before you start the wizard.

- Will you build the data mining structure and models from a relational database or from an existing cube in an OLAP database?
- Which columns contain the keys that uniquely identify a case record?
- Which columns or attributes do you want to use for prediction? Which columns or attributes are good to use as input for analysis?
- Which algorithm should you use? The algorithms provided in SQL Server Analysis Services all have different characteristics and produce different results. Fortunately you are not limited to one model for each set of data, so feel free to experiment by adding different models.
- Do you need to be able to test your models on a unified data set? If so, consider using the option to set some data aside for testing. You can choose a percentage, and cap that by a specified number of rows if desired.

Starting the Data Mining Wizard

To use the Data Mining Wizard, you must have opened a solution in Visual Studio with Analysis Services projects that contains at least one data mining or OLAP project.

- If your solution is ready for data mining, you can simply right-click the **Mining Structures** node in Solution Explorer and select **New Mining Structure** to start the wizard.
- If your solution does not contain any existing projects, you can add a new data mining project. From the **File** menu, select **New**, and then select **Project**. Be sure to choose the template, **Analysis Services Multidimensional and Data Mining Project**.
- You can also use the Analysis Services Import Wizard to obtain metadata from an existing data mining solution. However, you cannot select the individual objects to import; the entire database is imported, including any cubes, data source views, etc. Also note that the new solution that is created via import is automatically configured to use the local default database. You might need to change this to another instance before you can process or browse the objects, and if you are importing from a previous version of Analysis Services, you might need to update references to providers.

Next, you will create the mining structure and one associated data mining model. You can also create just the

mining structure and add models later, but it is generally easiest to create a test model first.

Relational vs. OLAP Mining Models

The next important option that you have is whether to use a relational data source, or to base your model on multidimensional (OLAP) data.

The Data Mining Wizard branches into two paths at this point, depending on whether your data source is relational or in a cube. Everything else except the data selection process is the same—the choice of algorithm, the ability to add a holdout data set, etc.—but selecting cube data is a bit more complex than using relational data. (You also get some additional options at the end if you create a model based on a cube.)

See the following topics for a walkthrough of each option in more detail:

[Create a Relational Mining Structure](#)

Walks you through the decisions you make when building a relational data mining model.

[Create an OLAP Mining Structure](#)

Describes the additional options and selections to make when choosing data from an OLAP cube.

NOTE

You do not need to have a cube or an OLAP database to do data mining. Unless your data is already stored in a cube, or you want to mine OLAP dimensions or the results of OLAP aggregations or calculations, we recommend that you use a relational table or data source for data mining.

Choosing an Algorithm

Next, you must decide on which algorithm to use in processing your data. This decision can be difficult to make. Each algorithm provided in Analysis Services has different features and produces different results, so you can experiment and try several different models before determining which is most appropriate for your data and your business problem. See the following topic for an explanation of the tasks to which each algorithm is best suited:

[Data Mining Algorithms \(Analysis Services - Data Mining\)](#)

Again, you can create multiple models using different algorithms, or change parameters for the algorithms to create different models. You are not locked into your choice of algorithm, and it is good practice to create several different models on the same data.

Define the Data Used for Modeling

In addition to choosing the data from a source, you must specify which of the table in the data source view contains the *case data*. The case table will be used to train the data mining model, and as such should contain the entities that you want to analyze: for example, customers and their demographic information. Each case must be unique, and must be identifiable by a *case key*.

In addition to specifying the case table, you can include *nested tables* in your data. A nested table usually contains additional information about the entities in the case table, such as transactions conducted by the customer, or attributes that have a many-to-one relationship with the entity. For example, a nested table joined to the

Customers case table might include a list of products purchased by each customer. In a model that analyzes traffic to a Web site, the nested table might include the sequences of pages that the user visited. For more information, see [Nested Tables \(Analysis Services - Data Mining\)](#)

Additional Features

To assist you in choosing the right data, and configuring the data sources correctly, the Data Mining Wizard provides these additional features:

- **Auto -detection of data types:** The wizard will examine the uniqueness and distribution of column values and then recommend the best data type, and suggest a usage type for the data. You can override these

suggestions by selecting values from a list.

- **Suggestions for variables:** You can click on a dialog box and start an analyzer that calculates correlations across the columns included in the model, and determines whether any columns are likely predictors of the outcome attribute, given the configuration of the model so far. You can override these suggestions by typing different values.
- **Feature selection:** Most algorithms will automatically detect columns that are good predictors and use those preferentially. In columns that contain too many values, *feature selection* will be applied, to reduce the cardinality of the data and improve the chances for finding a meaningful pattern. You can affect feature selection behavior by using model parameters.
- **Automatic cube slicing:** If your mining model is based on an OLAP data source, the ability to slice the model by using cube attributes is automatically provided. This is handy for creating models based on subsets of cube data.

Completing the Wizard

The last step in the wizard is to name the mining structure and the associated mining model. Depending on the type of model you created, you might also have the following important options:

- If you select **Allow drill through**, the ability to *drill through* is enabled in the model. With drillthrough, users who have the appropriate permissions can explore the source data that is used to build the model.
- If you are building an OLAP model, you can select the options, **Create a new data mining cube, or Create a data mining dimension**. Both these options make it easier to browse the completed model and drill through to the underlying data.

After you complete the Data Mining Wizard, you use Data Mining Designer to modify the mining structure and models, to view the accuracy of the model, view characteristics of the structure and models, or make predictions by using the models.

Create a Relational Mining Structure

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Most data mining models are based on relational data sources. The advantages of creating a relational data mining model are that you can assemble ad hoc data and train and update a model without the complexity of creating a cube.

A relational mining structure can draw data from disparate sources. The raw data can be stored in tables, files, or relational database systems, so long as the data can be defined as part of data source view. For example, you should use a relational mining structure if your data is in Excel, a SQL Server data warehouse or SQL Server reporting database, or in external sources that are accessed via the OLE DB or ODBC providers.

This topic provides an overview of how to use the Data Mining Wizard to create a relational mining structure.

Requirements

[Process for Creating a Relational Mining Structure](#)

[How to Choose Data Sources](#)

[How to Specify Content Type and Data Type](#)

[Why and How to Create a Holdout Data Set](#)

[Why and How to Enable Drillthrough](#)

Requirements

First, you must have an existing data source. You can use the Data Source designer to set up a data source, if one does not already exist. For more information, see [Create a Data Source \(SSAS Multidimensional\)](#).

Next, use the Data Source View Wizard to assemble required data into a single data source view. For more information about how you can select, transform, filter, or manage data with data source views, see [Data Source Views in Multidimensional Models](#).

Overview of Process

Start the Data Mining Wizard, by right-clicking the **Mining Structures** node in Solution Explorer, and selecting **Add New Mining Structure**. The wizard guides you through the following steps to create the structure for a new relational mining model:

1. **Select the Definition Method:** Here you select a data source type, and choose **From relational database or data warehouse**.
2. **Create the Data Mining Structure:** Determine whether you will build just a structure, or a structure with a mining model.

You also choose an appropriate algorithm for your initial model. For guidance on which algorithm is best for certain tasks, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

3. **Select Data Source View:** Choose a data sources view to use in training your model. The data source view can also contain data used for testing, or unrelated data. You get to pick and choose which data is actually used in the structure and in the model. You can also apply filters to the data later on.

4. **Specify Table Types:** Select the table that contains the cases used for analysis. For some data sets, especially ones used for building market basket models, you might also include a related table, to use as a nested table.

For each table, you must specify the key, so that the algorithm knows how to identify a unique record, and related records if you have added a nested table.

For more information, see [Mining Structure Columns](#).

5. **Specify the Training Data:** On this page, you choose as the *case table*, which is the table that contains the most important data for analysis.

For some data sets, especially ones used for building market basket models, you might also include a related table. The values in that nested table will be handled as multiple values that are all related to a single row (or case) in the main table.

6. **Specify Columns Content and Data Types:** For each column that you use in the structure, you must choose both a *data type* and a *content type*.

The wizard will automatically detect possible data types, but you don't need to use the data type recommended by the wizard. For example, even if your data contains numbers, they might be representative of categorical data. Columns that you specify as keys are automatically assigned the correct data type for that particular model type. For more information, see [Mining Model Columns](#) and [Data Types \(Data Mining\)](#).

The *content type* that you choose for each column that you use in the model tells the algorithm how the data should be processed.

For example, you might decide to discretize numbers, rather than use continuous values. You can also ask the algorithm to automatically detect the best content type for the column. For more information, see [Content Types \(Data Mining\)](#).

7. **Create Testing Set:** On this page, you can tell the wizard how much data should be set aside for use in testing the model. If your data will support multiple models, it is a good idea to create a holdout data set, so that all models can be tested on the same data.

For more information, see [Testing and Validation \(Data Mining\)](#).

8. **Completing the Wizard:** On this page, you give a name to the new mining structure and the associated mining model, and save the structure and model.

You also can set some important options, depending on the model type. For example, you can enable drillthrough on the structure.

At this point the mining structure and its model are just metadata; you will need to process them both to get results.

How to Choose Relational Data

Relational mining structures can be based on any data that is available through an OLE DB data source. If the source data is contained within multiple tables, you use a data source view to assemble the tables and columns that you need in one place.

If the tables include any one-to-many relationships—for example, you have multiple purchase records for each customer that you want to analyze—you can add both tables, and then use one table as the case table, linking data on the many side of the relationship as a nested table.

The data in a mining structure is derived from whatever is in the existing data source view. You can modify data as you need within the data source view, adding relationships or derived columns that might not be present in the

underlying relational data. You can also create named calculations or aggregations within the data source view. These features are very handy if you do not have control over the arrangement of data in the data source, or if you want to experiment with different aggregations of data for your data mining models.

You do not have to use all the data that is available; you can pick and choose which columns to include in the mining structure. All models that are based on that structure then can use those columns, or you can flag certain columns as **Ignore** for a particular model. You can enable users of a data mining model to drill down from the results of the mining model to see additional mining structure columns that were not included in the mining model itself.

How to Specify Content Type and Data Type

The data type is pretty much the same as the data types you specify in SQL Server or other application interfaces: dates and times, numbers of different sizes, Boolean values, text and other discrete data.

However, content types are important for data mining and affect the outcome of analysis. The content type tells the algorithm what it should do with the data: should numbers be treated on a continuous scale, or binned? How many potential values are there? Is each value distinct? If the value is a key, what kind of key is it - does it indicate a date/time value, a sequence, or some other kind of key?

Note that the choice of data type can limit your choice of content types. For example, you cannot discretize values that are not numeric. If you cannot see the content type that you want, you can click **Back** to return to the data type page and try a different data type.

You need not worry too much about getting the content type wrong. It is very easy to create a new model and change the content type within the model, as long as the new content type is supported by the data type set in the mining structure. It is also very common to create multiple models using different content types, either as an experiment, or to meet the requirements of a different algorithm.

For example, if your data contains an income column, you could create two different models when using the Microsoft Decision Trees algorithm, and configure the column alternately as either continuous numbers or discrete ranges. However, if you added a model using the Microsoft Naïve Bayes algorithm, you would be forced to change the column to discretized values only, because that algorithm does not support continuous numbers.

Why and How to Split Data into Training and Testing Sets

Near the end of the wizard, you must decide whether to partition your data into training and testing sets. The ability to provision a randomly sampled portion of the data for testing is very convenient, as it ensures that a consistent set of test data is available for use with all mining models associated with the new mining structure.

WARNING

Note that this option is not available for all model types. For example, if you create a forecasting model, you won't be able to use holdout, because the time series algorithm requires that there be no gaps in data. For a list of the model types that support holdout data sets, see [Training and Testing Data Sets](#).

To create this holdout data set, you specify the percentage of the data you want to use for testing. All remaining data will be used for training. Optionally, you can set a maximum number of cases to use for testing, or set a seed value to use in starting the random selection process.

The definition of the holdout test set is stored with the mining structure, so that whenever you create a new model based on the structure, the testing data set will be available for assessing the accuracy of the model. If you delete the cache of the mining structure, the information about which cases were used for training and which were used for testing will be deleted as well.

Why and How to Enable Drillthrough

Almost at the very end of the wizard, you have the option to enable *drillthrough*. It is easy to miss this option, but it's an important one. Drillthrough lets you view source data in the mining structure by querying the mining model.

Why is this useful? Suppose you are viewing the results of a clustering model, and want to see the customers who were put into a specific cluster. By using drillthrough, you can view details such as contact information.

WARNING

To use drillthrough, you must enable it when you create the mining structure. You can enable drillthrough on models later, by setting a property on the model, but mining structures require that this option be set at the beginning. For more information, see [Drillthrough Queries \(Data Mining\)](#).

Create an OLAP Mining Structure

7/16/2019 • 11 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

There are many advantages to creating a data mining model based on an OLAP cube or other multidimensional data store. An OLAP solution already contains huge amounts of data that is well organized, cleaned and properly formatted; however, the complexity of the data is such that users are unlikely to find meaningful patterns by ad hoc exploration. Data mining offers the ability to discover new correlations and provide actionable insight.

This topic describes how to create an OLAP mining structure, based on a dimension and related measures in an existing multidimensional solution.

Requirements

[Overview of OLAP Data Mining Process](#)

[Scenarios for Using Data Mining in OLAP Solutions](#)

Filters

[Using Nested Tables](#)

[Data Mining Dimensions](#)

Requirements for OLAP Mining Structure and Models

If you are designing an OLAP mining model, your data source already exists, in the database that was used to build the cube. You cannot connect to a remote cube and build data mining objects; the cube objects must be available within the same solution as the database as the mining structure that you will build.

If you do not have the original project files, or do not wish to alter them, you can use the option in Visual Studio, **Import from Server (Multidimensional or Data Mining)**, to get a copy of the metadata and solution objects. You can then modify the deployment target, edit data sources, and work with the cube objects without affecting the existing objects.

For more information, see [Import a Data Mining Project using the Analysis Services Import Wizard](#).

Overview of OLAP Data Mining Process

Start the Data Mining Wizard by right-clicking the **Mining Structures** node in Solution Explorer, and selecting **New Mining Structure**. The wizard guides you through the following steps to create the structure for a new structure and model:

1. **Select the Definition Method:** Here you select a data source type, and choose **From existing cube**.

NOTE

The OLAP cube that you use as a source must exist within the same database as the mining structure, as described above. Also, you cannot use a cube created by the Power Pivot for Excel add-in as a source for data mining.

2. **Create the Data Mining Structure:** Determine whether you will build just a structure, or a structure with a mining model.

You must also choose an appropriate algorithm for analyzing your data. For guidance on which algorithm is best for certain tasks, see [HYPERLINK "ms-help://SQL111033/as_1devconc/html/ed1fc83b-b98c-437e-bf53-4ff001b92d64.htm"](ms-help://SQL111033/as_1devconc/html/ed1fc83b-b98c-437e-bf53-4ff001b92d64.htm) Data Mining Algorithms (Analysis Services - Data Mining).

3. **Select the Source Cube Dimension:** This step is the same as selecting a data source. You need to choose the single dimension that contains the most important data used for training your model. You can add data from other dimensions later, or filter the dimension.
4. **Select the Case Key:** Within the dimension that you just selected, choose an attribute (column) to serve as the unique identifier for your case data.

Typically a column will be pre-selected for you, but you can change the column if in fact there are multiple keys.

5. **Selecting Case Level Columns:** Here you choose the attributes from the selected dimension, and the related measures, that are relevant to your analysis. This step is equivalent to selecting columns from a table.

The wizard automatically includes for your review and selection any measures that were created using attributes from the selected dimension.

For example, if your cube contains a measure that calculates freight cost based on the customer's geographical location, and you chose the Customer dimension as your main data source for modeling, the measure will be proposed as a candidate for adding to the model. Beware of adding too many measures that are already directly based on attributes, as there is already one implicit relationship between the columns, as defined in the measure formula, and the strength of this (expected) correlation can obscure other relationships that you might otherwise discover.

6. **Specify Mining Model Column Usage:** For each attribute or measure that you added to the structure, you must specify whether the attribute should be used for prediction, or used as input. If you do not select either of these options, the data will be processed but will not be used for analysis; however, it will be available as background data in case you later enable drillthrough.
7. **Add nested tables:** Click to add related tables. In the **Select a Measure Group Dimension** dialog box, you can choose a single dimension from among the dimensions that are related to the current dimension.

Next, you use the **Select a Nested Table Key** dialog box to define how the new dimension is related to the dimension that contains the case data.

Use the **Select Nested Table Columns** dialog box to choose the attributes and measures from the new dimension that you want to use in analysis. You must also specify whether the nested attribute will be used for prediction.

After you have added all the nested attributes you might need, return to the page, **Specify Mining Model Column Usage**, and click **Next**.

8. **Specify Columns Content and Data Type:** By this point, you have added all the data that will be used for analysis, and must specify the *data type* and *content type* for each attribute.

In an OLAP model, you do not have the option to automatically detect data types, because the data type is already defined by the multidimensional solution and cannot be changed. Keys are also automatically identified. For more information, see [Data Types \(Data Mining\)](#).

The *content type* that you choose for each column that you use in the model tells the algorithm how the data should be processed. For more information, see [Content Types \(Data Mining\)](#).

9. **Slicing the source cube:** Here you can define filters in a cube to select just a subset of data and train models that are more targeted.

You filter a cube by choosing the dimension to filter on, selecting the level of the hierarchy that contains the criteria you want to use, and then typing a condition to use as the filter.

10. **Create Testing Set:** On this page, you can tell the wizard how much data should be set aside for use in testing the model. If your data will support multiple models, it is a good idea to create a holdout data set, so that all models can be tested on the same data.

For more information, see [Testing and Validation \(Data Mining\)](#).

11. **Completing the Wizard:** On this page, you give a name to the new mining structure and the associated mining model, and save the structure and model.

On this page, you can also can set the following options:

- **Allow drillthrough**
- **Create mining model dimension**
- **Create cube using mining model dimension**

To learn more about these options, see the section later in this topic, [Understanding Data Mining Dimensions and Drillthrough](#).

At this point the mining structure and its model are just metadata; you will need to process them both to get results.

Scenarios for Use of Data Mining with OLAP Data

OLAP cubes frequently contain so many members and dimensions that it can be difficult to know where to begin with data mining. To help identify the patterns that the cubes contain, typically you identify a single dimension of interest, and then begin to explore patterns related to that dimension. The following table lists several common OLAP data mining tasks, describes sample scenarios in which you might apply each task, and identifies the data mining algorithm to use for each task.

TASK	SAMPLE SCENARIO	ALGORITHM
Group members into clusters	Segment a customer dimension based on customer member properties, the products that the customers buy, and the amount of money that the customers spend.	Microsoft Clustering Algorithm
Find interesting or abnormal members	Identify interesting or abnormal stores in a store dimension based on sales, profit, store location, and store size.	Microsoft Decision Trees Algorithm
Find interesting or abnormal cells	Identify store sales that go against typical trends over time.	Microsoft Time Series Algorithm
Find correlations	Identify factors that are related to server downtime, including region, machine type, OS, or purchase date.	Microsoft Naïve Bayes algorithm

Slicing a Cube vs. Filtering Models

Slicing the cube while you are building a model is like creating a filter on a relational mining model. In a relational model, the filter on the data source is defined as a WHERE clause on a SQL statement; in a cube, you use the editor to create filter statements using MDX.

For example, a cube might contain information about purchases of products worldwide, but for your marketing campaign, you want to create a model based on analysis of female customers over 30 who live in the United Kingdom.

In this scenario, you would create two filters:

- For the first filter, you would choose the Geography dimension, choose the hierarchy for Region, and then use the **Filter Expression** list to choose "United Kingdom" from the possible values.
- For the second filter, you would choose the Customer dimension, select the Gender attribute, and select "Female" from the list of attribute values.

After the mining structure has been created, you can modify both the definition of the cube data and the filter criteria. For more information, see [Filters for Mining Models](#).

Both the **Mining Structure** tab and the **Mining Model** tab provide an option to add a filter to an existing mining structure, by clicking **Define a Cube Slice**. The **Slice Cube** dialog box helps you build a valid MDX filter expression by choosing value from dropdown lists.

WARNING

Note that the interface for designing and browsing cubes has been changed in SQL Server 2017. For more information, see [Browse data and metadata in Cube](#).

You can add as many filters on the cube as are required to return the data that you need for the mining model. You can also define slices on individual cube slices. For example, if your structure contains two nested tables that are based on products, you could slice one table on March 2004 and the other table on April 2004. The resulting model could then be used to predict purchases made in April based on the purchases that were made in March.

Using Nested Tables in an OLAP Mining Model

When you use the Data Mining Wizard to build a model based on cube data, you can add nested tables by specifying the names of related dimensions and then choosing the attributes or measures to add to the model.

For example, if the main dimension used for case data is Customer, you might add as a related dimension the Products dimension, because you expect that a customer might have ordered multiple products over time, and the cube already links each customer to the many products via the order fact tables.

You add nested tables in the **Specify Mining Model Column Usage** page of the wizard, by clicking **Add Nested Tables**. A dialog box opens that guides you through process of choosing a related dimension, as well as any measures. The case and nested dimensions must be related by a foreign key, and measures must use one of the attributes that are already included in the case or nested tables. Unfortunately, these restrictions really don't do much to narrow the scope, so you must be careful to select only those attributes that are useful for modeling.

For each attribute or measure that you add to the nested table, you must specify whether the nested attribute will be used for prediction or not, by selecting **Predictable** or **Input** in the **Select Nested Table Columns** dialog box. If you do not select either of these options, the data will be added to the mining structure but not used for analysis.

For each attribute and measure, you must also specify whether the attribute is discrete, discretized, or continuous. The wizard will preselect a default based on the data type of the attribute, but you might need to change these, depending on the algorithm requirements. If you choose a content type that is not compatible with the algorithm you have chosen (for example, you use a continuous numeric type with a Naïve Bayes model), you won't get an error message till you try to process the model.

When you are done setting these options, the wizard adds the nested table to the case table. The default name for

the nested table is the nested dimension name, but you can rename the nested table and its columns. You can repeat this process to add multiple nested tables to the mining structure.

The ability to use nested table data like this is a feature of SQL Server data mining that is particularly powerful, and in a cube, there are almost limitless possibilities for using related subsets of data.

Understanding Data Mining Dimensions and Drillthrough

The option, **Allow drillthrough**, lets you run queries against the underlying cube data while you are browsing the model. The data is not contained in the new data mining dimension, but the Analysis Services database can use the data bindings to retrieve the information from the source cube.

The option, **Create mining model dimension**, lets you generate a new dimension within the existing cube that contains the patterns discovered by the algorithm. The hierarchy within the new dimension is determined largely by the model type. For example, the representation of a clustering model is fairly flat, with the (All) node at the top of the hierarchy and each cluster in the next level. In contrast, the dimension that is created for a decision tree model might have a very deep hierarchy, representing the branching of the tree.

The option, **Create cube using mining model dimension**, lets you export the new data mining dimension into a new cube. Any objects that are required for drillthrough on the data mining dimension will be included automatically.

WARNING

Only these model types support the creation of data mining dimensions: models based on the Microsoft Clustering algorithm, the Microsoft Decision Trees algorithm, or the Microsoft Association algorithm.

[Properties for Mining Structure and Structure Columns](#)

Add Mining Models to a Structure (Analysis Services - Data Mining)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A mining structure is intended to support multiple mining models. Therefore, after you finish the wizard, you can open the structure and add new mining models. Each time that you create a model, you can use a different algorithm, change the parameters, or apply filters to use a different subset of the data.

Adding New Mining Models

When you use the Data Mining Wizard to create a new mining model, by default you must always create a mining structure first. The wizard then gives you the option to add an initial mining model to the structure. However, you don't need to create a model right away. If you create the structure only, you do not need to make a decision about which column to use as the predictable attribute, or how to use the data in a particular model. Instead, you just set up the general data structure that you want to use in future, and later you can use [Data Mining Designer](#) to add new mining models that are based on the structure.

NOTE

In DMX, the CREATE MINING MODEL statement begins with the mining model. That is, you define your choice of mining model, and Analysis Services automatically generates the underlying structure. Later you can continue to add new mining models to that structure, by using the ALTER STRUCTURE... ADD MODEL statement.

Choosing an Algorithm

When you add a new model to an existing structure, the first thing you should do is select a data mining algorithm to use in that model. Choosing the algorithm is important because each algorithm performs a different type of analysis and has different requirements.

When you select an algorithm that is incompatible with your data, you will get a warning. In some cases, you might need to ignore columns that cannot be processed by the algorithm. In other cases, the algorithm will automatically make the adjustments for you. For example, if your structure contains numeric data, and the algorithm can only work with discrete values, it will group the numeric values into discrete ranges for you. In some cases, you might need to manually fix the data first, by choosing a key or choosing a predictable attribute.

You do not need to change the algorithm when you create a new model. Often you can get very different results by using the same algorithm, but filtering the data, or changing a parameter such as the clustering method or the minimum itemset size. We recommend that you experiment with multiple models to see which parameters produce the best results.

Note that all new models need to be processed before you can use them.

Specifying the Usage of Columns in a New Mining Model

When you add new mining models to an existing mining structure, you must specify how each column of data should be used by the model. Depending on the type of algorithm you choose for the model, some of these choices may be made by default. If you do not specify a usage type for a column, the column will not be included in the mining structure. However, the data in the column can still be available for drillthrough, if the model

supports it.

Columns from the mining structure that are used by the model (if not set to Ignore) must be a key, an input column, a predictable column, or a predictable column the values of which are also used as inputs to the model.

- Key columns contain a unique identifier for each row in a table. Some mining models, such as those based on the sequence clustering or time series algorithms, can contain multiple key columns. However, these multiple keys are not compound keys in the relational sense, but instead must be selected so as to provide support for time series and sequence clustering analysis.
- Input columns provide the information from which predictions are made. The Data Mining Wizard provides the **Suggest** feature, which is enabled when you select a predictable column. If you click this button, the wizard will sample the predictable values and determine which of the other columns in the structure make good variables. It will reject key columns or other columns with many unique values, and suggest columns that appear to be correlated with the outcome.

This feature is particularly handy when datasets contain more columns than you really need to build a mining model. The **Suggest** feature calculates a numeric score, from 0 to 1, that describes the relationship between each column in the dataset and the predictable column. Based on this score, the feature suggests columns to use as input for the mining model. If you use the **Suggest** feature, you can use the suggested columns, modify the selections to fit your needs, or ignore the suggestions.

- Predictable columns contain the information that you try to predict in the mining model. You can select multiple columns as the predictable attributes. Clustering models are the exception in that a predictable attribute is optional.

Depending on the model type, the predictable column might need to be a specific data type: for example, a linear regression model requires a numeric column as the predicted value; Naïve Bayes algorithm requires a discrete value (and all the inputs must be discrete as well).

Specifying Column Content

For some columns, you might also need to specify the *column content*. In SQL Server data mining, the Content Type property of each data column tells the algorithm how it should process the data in that column. For example, if your data has an Income column, you must specify that the column contains continuous numbers by setting the content type to Continuous. However, you could also specify that the numbers in the Income column be grouped into buckets by setting the content type to Discretized and optionally specifying the exact number of buckets. You can create different models that handle columns differently: for example, you might try one model that buckets customers into three age groups, and another model that buckets customers into 10 age groups.

[Mining Model Properties](#)

[Mining Model Columns](#)

Customize Mining Models and Structure

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

After you have selected an algorithm that meets your business needs, you can customize the mining model in the following ways to potentially improve results.

- Use different columns of data in the model, or change the usage, content type, or discretization method for the columns.
- Create filters on the mining model to restrict the data used in training the model.
- Change the algorithm that was used to analyze data.
- Set algorithm parameters to control thresholds, tree splits, and other important conditions.

This topic describes these options.

Changing Data Used by the Model

The decisions that you make about which columns of data to use in the model, and how to use and process that data, greatly affect the results of analysis. The following topics provide information to help you understand these choices.

Using Feature Selection

Most data mining algorithms in Analysis Services use a process called *feature selection* to select only the most useful attributes for addition to a model. Reducing the number of columns and attributes can improve performance and the quality of the model. The feature selection methods that are available differ depending on the algorithm that you choose.

[Feature Selection \(Data Mining\)](#).

Changing Usage

You can change which columns are included in a mining model and how each column is used. If you do not get the results you expect, you should examine the columns you used as input, and ask yourself whether the columns are a good choice, and whether there is anything you can do to improve the handling of data, including:

- Identifying categorical variables that have mistakenly labeled as numbers.
- Adding categories to collapse the number of attributes and make it easier to find correlations.
- Changing the way that numbers are binned, or discretized.
- Removing columns that have a lot of unique values, or columns that are really reference data and not useful for analysis, such as addresses or middle names.

You don't need to physically remove columns from the mining structure; you can just flag the column as **Ignore**. The column is removed from the mining model, but can still be used by other mining models in the structure, or referenced in a drillthrough query.

Creating Aliases for Model Columns

When Analysis Services creates the mining model, it uses the same column names that are in the mining structure. You can add an alias to any column in the mining model. This might make it easier to understand the

column contents or usage, or make the name shorter for convenience in creating queries. Aliases are also helpful when you want to create a copy of a column and name it something descriptive.

You create an alias by editing the **Name** property of the mining model column. Analysis Services continues to use the original name as the ID of the column, and the new value that you type for **Name** becomes the column alias, and appears in the grid in parentheses next to the column usage.

Structure	Target Mail - Deciles	Target Mail - Quartiles	Target Mail - Continuous
	Microsoft_Decision_Trees	Microsoft_Decision_Trees	Microsoft_Decision_Trees
Age	Input	Input	Input
Bike Buyer	PredictOnly	PredictOnly	PredictOnly
Customer Key	Key	Key	Key
Total Children	Input	Input	Input
Income Deciles	Input (Income)	Ignore	Ignore
Yearly Income	Ignore	Ignore	Input (Income)
Income Quartiles	Ignore	Input (Income)	Ignore

The graphic shows related models that have multiple copies of a mining structure column, all related to Income. Each copy of the structure column has been discretized in a different way. The models in the diagram each use a different column from the mining structure; however, for convenience in comparing the columns across the models, the column in each model has been renamed to **[Income]**.

Adding Filters

You can add a filter to a mining model. A filter is a set of WHERE conditions that restrict the data in the model cases to some subset. The filter is used when training the model, and can optionally be used when you test the model or create accuracy charts.

By adding filters, you can reuse mining structures but create models based on very different subsets of the data. Or, you can simply use filters to eliminate certain rows and improve the quality of analysis.

For more information, see [Filters for Mining Models \(Analysis Services - Data Mining\)](#).

Changing the Algorithm

Although new models that you add to a mining structure share the same data set, you can get different results by using a different algorithm (if the data supports it), or by changing the parameters for the algorithm. You can also set modeling flags.

The choice of algorithm determines what kind of results you will get. For general information about how a specific algorithm works, or the business scenarios where you would benefit from using a particular algorithm, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

See the technical reference topic for each algorithm for a description of the requirements and restrictions, as well as detailed information about the customizations that each algorithm supports.

Data Mining Designer

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Data Mining Designer is the primary environment in which you work with mining models in Microsoft SQL Server Analysis Services. You can access the designer either by selecting an existing mining structure, or by using the Data Mining Wizard to create a new mining structure and mining model. You can use Data Mining Designer to perform the following tasks:

- Modify the mining structure and the mining model that were initially created by the Data Mining Wizard.
- Create new models based on an existing mining structure.
- Train and browse mining models.
- Compare models by using accuracy charts.
- Create prediction queries based on mining models.

Mining Structure Tab

Use the **Mining Structure** tab to add columns and modify the properties of an existing mining structure. The following tasks and topics provide more information about working with mining structures:

[Mining Structures \(Analysis Services - Data Mining\)](#)

[Mining Structure Tasks and How-tos](#)

Mining Models Tab

Use the **Mining Models** tab to manage existing mining models and to create new models. Mining models are always based on an existing mining structure .

In the **Mining Models** tab, you can change the algorithm type, add or remove columns that are associated with the model structure, adjust algorithm-specific column properties, specify the mining model column usage, and adjust algorithm parameters that are associated with the mining model. You can also process the mining structure together with selected models or with all the associated models.

See the following topics for more information about working with mining models:

[Mining Models \(Analysis Services - Data Mining\)](#)

[Mining Model Tasks and How-tos](#)

Mining Model Viewer Tab

Use the **Mining Model Viewer** tab to visually explore your mining models. Each mining model is associated with a custom viewer that displays content that is specific to that model. You can also view mining model content by using the content viewer.

See the following topics for more information about exploring mining models with the data mining viewers:

[Data Mining Model Viewers](#)

[Mining Model Viewer Tasks and How-tos](#)

Mining Accuracy Chart Tab

Use the **Mining Accuracy Chart** tab to test the predictive accuracy of a single mining model, or to compare the effectiveness of multiple mining models contained within a mining structure. The tab contains tools for filtering the data, selecting mining models, and displaying the results in a lift chart, profit chart, or classification matrix.

See the following topics for more information about testing and validating mining models:

[Testing and Validation \(Data Mining\)](#)

[Testing and Validation Tasks and How-tos \(Data Mining\)](#)

Mining Model Prediction Tab

The **Mining Model Prediction** tab includes Prediction Query Builder, which you can use to create a Data Mining Extensions (DMX) prediction query. The tab contains tools for specifying mining models and input tables, mapping the columns in the mining model to columns in the input table, adding functions to a query, and specifying criteria for each column.

After you design a query, you can use different views in the tab to display the results of the query and to modify the query manually. You can also save the results of the query to a table in a database.

See the following topics for more information about creating data mining queries:

[Data Mining Queries](#)

[Data Mining Solutions](#)

Data Mining Model Viewers

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

After you train a data mining model in Microsoft SQL Server Analysis Services, you can explore the model to look for interesting trends. Because the results of mining models are complex and can be difficult to understand in a raw format, visually investigating the data is often the easiest way to understand the rules and relationships that algorithms discover within the data.

Each algorithm that you use to build a model returns a different type of results. Therefore, Analysis Services provides a separate viewer for each algorithm. When you browse a mining model in Visual Studio with Analysis Services projects, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer, using the appropriate viewer for the model.

How to Use the Model Viewers

First you select the mining model and then you select a viewer. Each model always has two viewers available: a custom viewer, which can include multiple tabs, and the generic viewer.

Depending on the type of the model that you selected, you will see very different options for exploring the model. The custom viewers associated with each model type are tailored to the algorithm that you used to create the selected data mining model. Each custom viewer has a variety of tools and dialog boxes for helping you explore the statistics and patterns in the model, view charts, or interactively work with probability thresholds or filter out items by name.

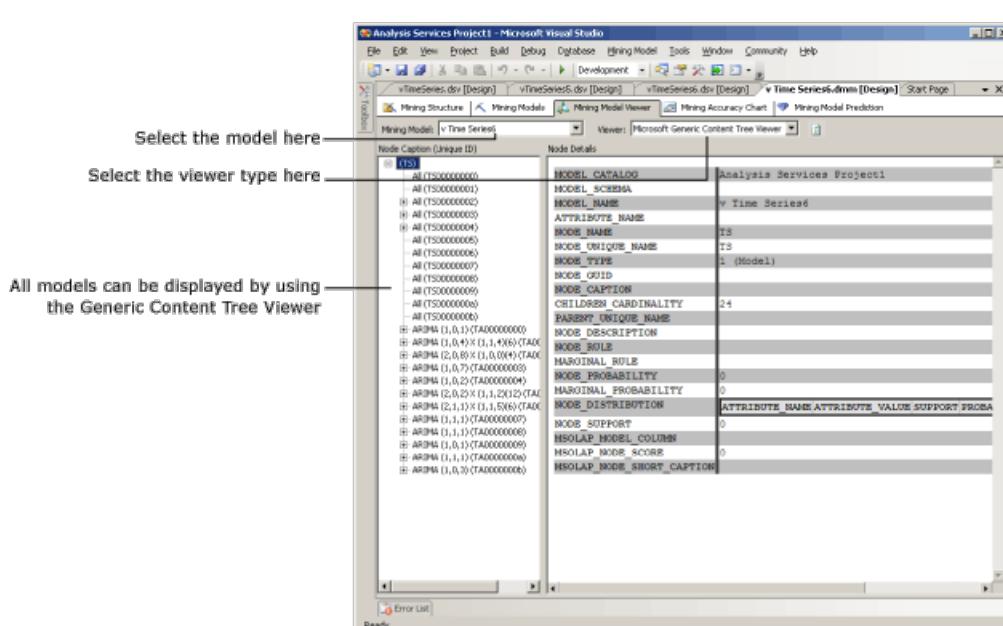

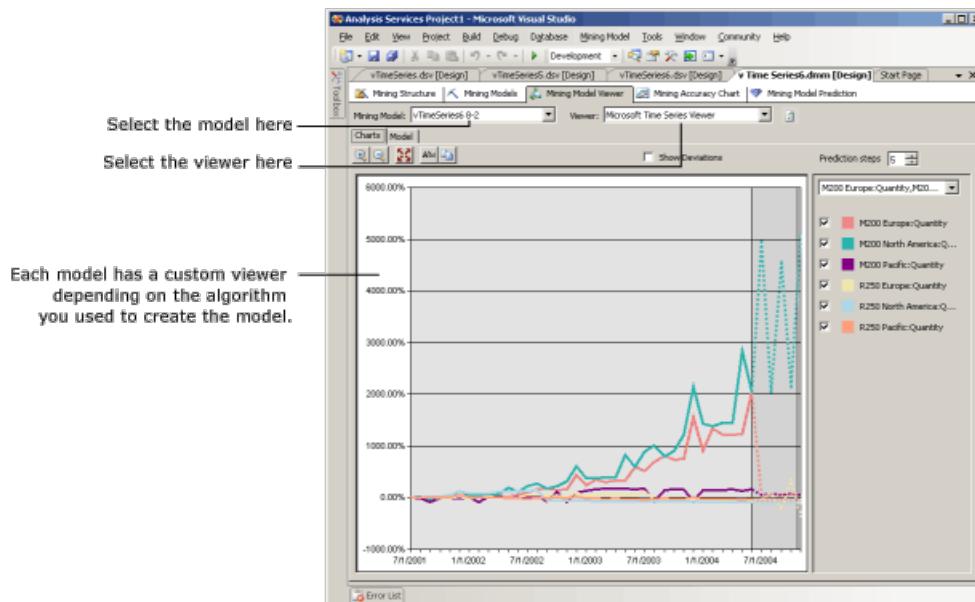

The following diagram illustrates the difference when you choose a custom viewer and the generic viewer for the same model.

1. First, you see the custom viewer that is displayed when you select a mining model based on the Microsoft Time Series algorithm.

This particular custom viewer automatically creates a graph of the time series and provides five predictions.

2. Next, you see the same model, displayed using the **Microsoft Generic Content Tree Viewer**.

On the left, the generic viewer displays a list of the nodes in the model. You can click a node to view its contents in the right-hand pane.

More about the Microsoft Generic Content Tree Viewer

Each model can also be viewed using the [Microsoft Generic Content Tree Viewer \(Data Mining\)](#). This viewer presents the contents of the mining model according to a standard HTML table format. However, the arrangement of the nodes and the content of each node will differ greatly depending on the algorithm used to generate the results.

Whereas the custom viewers are designed for exploring and understanding the model, the generic viewer is more useful when you already understand the model and want to extract statistics or rules from a specific node. For example, you would use the generic viewer when you want to view detailed information about the patterns and statistics that Analysis Services captured during analysis, such as the probability of a node, or a regression formula.

You can also write *content queries* using DMX to get all of the information that is presented in this viewer. For more information, see [Content Queries \(Data Mining\)](#).

In This Section

The following topics describe in more detail each of the viewers, and how to interpret the information in them.

[Browse a Model Using the Microsoft Tree Viewer](#)

Describes the Microsoft Tree Viewer. This viewer displays mining models that are built with the Microsoft Decision Trees algorithm and the Microsoft Linear Regression algorithm.

[Browse a Model Using the Microsoft Cluster Viewer](#)

Describes the Microsoft Cluster Viewer. This viewer displays mining models that are built with the Microsoft Clustering algorithm.

[Browse a Model Using the Microsoft Time Series Viewer](#)

Describes the Microsoft Time Series Viewer. This viewer displays mining models that are built with the Microsoft Time Series algorithm.

[Browse a Model Using the Microsoft Naïve Bayes Viewer](#)

Describes the Microsoft Naïve Bayes viewer. This viewer displays mining models that are built with the Microsoft Naïve Bayes algorithm.

[Browse a Model Using the Microsoft Sequence Cluster Viewer](#)

Describes the Microsoft Sequence Cluster Viewer. This viewer displays mining models that are built with the Microsoft Sequence Clustering algorithm.

[Browse a Model Using the Microsoft Association Rules Viewer](#)

Describes the Microsoft Association Rules Viewer. This viewer displays mining models that are built with the Microsoft Association algorithm.

[Browse a Model Using the Microsoft Neural Network Viewer](#)

Describes the Microsoft Neural Network Viewer. This viewer displays mining models that are built with the Microsoft Neural Network algorithm, including models that use the Microsoft Logistic Regression algorithm.

[Browse a Model Using the Microsoft Generic Content Tree Viewer](#)

Describes the detailed information that is available in the generic viewer for all data mining models and provides examples of how to interpret the information for each algorithm.

[Data Mining Designer](#)

Browse a Model Using the Microsoft Tree Viewer

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Tree Viewer in Microsoft SQL Server Analysis Services displays decision trees that are built with the Microsoft Decision Trees algorithm. The Microsoft Decision Trees algorithm is a hybrid decision tree algorithm that supports both classification and regression. Therefore, you can also use this viewer to view models based on the Microsoft Linear Regression algorithm. The Microsoft Decision Trees algorithm is used for predictive modeling of both discrete and continuous attributes. For more information about this algorithm, see [Microsoft Decision Trees Algorithm](#).

NOTE

To view detailed information about the equations used in the model and the patterns that were discovered, use the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Tree Viewer includes the following tabs and panes:

- [Decision Tree](#)
- [Dependency Network](#)
- [Mining Legend](#)

Decision Tree

When you build a decision tree model, Analysis Services builds a separate tree for each predictable attribute. You can view an individual tree by selecting it from the **Tree** list on the **Decision Tree** tab of the viewer.

A decision tree is composed of a series of splits, with the most important split, as determined by the algorithm, at the left of the viewer in the **All** node. Additional splits occur to the right. The split in the **All** node is most important because it contains the strongest split-causing conditional in the dataset, and therefore it caused the first split.

You can expand or collapse individual nodes in the tree to show or hide the splits that occur after each node. You can also use the options on the **Decision Tree** tab to affect how the tree is displayed. Use the **Show Level** slider to adjust the number of levels that are shown in the tree. Use **Default Expansion** to set the default number of levels that are displayed for all trees in the model.

Predicting Discrete Attributes

When a tree is built with a discrete predictable attribute, the viewer displays the following on each node in the tree:

- The condition that caused the split.
- A histogram that represents the distribution of the states of the predictable attribute, ordered by popularity.

You can use the **Histogram** option to change the number of states that appear in the histograms in the tree. This is useful if the predictable attribute has many states. The states appear in a histogram in order of popularity from left to right; if the number of states that you choose to display is fewer than the total number of states in the attribute, the least popular states are displayed collectively in gray. To see the exact count for each state for a node, pause the pointer over the node to view an InfoTip, or select the node to view its details in the **Mining Legend**.

The background color of each node represents the concentration of cases of the particular attribute state that you select by using the **Background** option. You can use this option to highlight nodes that contain a particular target in which you are interested.

Predicting Continuous Attributes

When a tree is built with a continuous predictable attribute, the viewer displays a diamond chart, instead of a histogram, for each node in the tree. The diamond chart has a line that represents the range of the attribute. The diamond is located at the mean for the node, and the width of the diamond represents the variance of the attribute at that node. A thinner diamond indicates that the node can create a more accurate prediction. The viewer also displays the regression equation, which is used to determine the split in the node.

Additional Decision Tree Display Options

When drill through is enabled for a decision tree model, you can access the training cases that support a node by right-clicking the node in the tree and selecting **Drill Through**. You can enable drill through within the Data Mining Wizard, or by adjusting the drill through property on the mining model in the **Mining Models** tab.

You can use the zoom options on the **Decision Tree** tab to zoom in or out of a tree, or use **Size to Fit** to fit the whole model in the viewer screen. If a tree is too large to be sized to fit the screen, you can use the **Navigation** option to navigate through the tree. Clicking **Navigation** opens a separate navigation window that you can use to select sections of the model to display.

You can also copy the tree view image to the Clipboard, so that you can paste it into documents or into image manipulation software. Use **Copy Graph View** to copy only the section of the tree that is visible in the viewer, or use **Copy Entire Graph** to copy all the expanded nodes in the tree.

[Back to Top](#)

Dependency Network

The **Dependency Network** displays the dependencies between the input attributes and the predictable attributes in the model. The slider at the left of the viewer acts as a filter that is tied to the strengths of the dependencies. If you lower the slider, only the strongest links are shown in the viewer.

When you select a node, the viewer highlights the dependencies that are specific to the node. For example, if you choose a predictable node, the viewer also highlights each node that helps predict the predictable node.

If the viewer contains numerous nodes, you can search for specific nodes by using the **Find Node** button. Clicking **Find Node** opens the **Find Node** dialog box, in which you can use a filter to search for and select specific nodes.

The legend at the bottom of the viewer links color codes to the type of dependency in the graph. For example, when you select a predictable node, the predictable node is shaded turquoise, and the nodes that predict the selected node are shaded orange.

[Back to Top](#)

Mining Legend

The **Mining Legend** displays the following information when you select a node in the decision tree model:

- The number of cases in the node, broken down by the states of the predictable attribute.
- The probability of each case of the predictable attribute for the node.

- A histogram that includes a count for each state of the predictable attribute.
- The conditions that are required to reach a specific node, also known as the *node path*.
- For linear regression models, the regression formula.

You can dock and work with the **Mining Legend** in a similar manner as with Solution Explorer.

[Data Mining Model Viewers](#)

Browse a Model Using the Microsoft Cluster Viewer

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Cluster Viewer in Microsoft SQL Server Analysis Services displays mining models that are built with the Microsoft Clustering algorithm. The Microsoft Clustering algorithm is a segmentation algorithm for use in exploring data to identify anomalies in the data and to create predictions. For more information about this algorithm, see [Microsoft Clustering Algorithm](#).

NOTE

To view detailed information about the equations used in the model and the patterns that were discovered, use the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Cluster Viewer provides the following tabs for use in exploring clustering mining models:

- [Cluster Diagram](#)
- [Cluster Profiles](#)
- [Cluster Characteristics](#)
- [Cluster Discrimination](#)

Cluster Diagram

The **Cluster Diagram** tab of the Microsoft Cluster Viewer displays all the clusters that are in a mining model. The shading of the line that connects one cluster to another represents the strength of the similarity of the clusters. If the shading is light or nonexistent, the clusters are not very similar. As the line becomes darker, the similarity of the links becomes stronger. You can adjust how many lines the viewer shows by adjusting the slider to the right of the clusters. Lowering the slider shows only the strongest links.

By default, the shade represents the population of the cluster. By using the **Shading****Variable** and **State** options, you can select which attribute and state pair the shading represents. The darker the shading, the greater the attribute distribution is for a specific state. The distribution decreases as the shading gets lighter.

To rename a cluster, right-click its node and select **Rename Cluster**. The new name is persisted to the server.

To copy the visible section of the diagram to the Clipboard, click **Copy Graph View**. To copy the complete diagram, click **Copy Entire Graph**. You can also zoom in and out by using **Zoom In** and **Zoom Out**, or you can fit the diagram to the screen by using **Scale Diagram to Fit in Window**.

[Back to Top](#)

Cluster Profiles

The **Cluster Profiles** tab provides an overall view of the clusters that the algorithm in your model creates. This view displays each attribute, together with the distribution of the attribute in each cluster. An InfoTip for each cell displays the distribution statistics, and an InfoTip for each column heading displays the cluster population.

Discrete attributes are shown as colored bars, and continuous attributes are shown as a diamond chart that represents the mean and standard deviation in each cluster. The **Histogram bars** option controls the number of bars that are visible in the histogram. If more bars exist than you choose to display, the bars of highest importance are retained, and the remaining bars are grouped together into a gray bucket.

You can change the default names of the clusters, to make the names more descriptive. Rename a cluster by right-clicking its column heading and selecting **Rename cluster**. You can also hide clusters by selecting **Hide column**.

To open a window that provides a larger, more detailed view of the clusters, double-click either a cell in the **States** column or a histogram in the viewer.

Click a column heading to sort the attributes in order of importance for that cluster. You can also drag columns to reorder them in the viewer.

[Back to Top](#)

Cluster Characteristics

To use the **Cluster Characteristics** tab, select a cluster from the **Cluster** list. After you select a cluster, you can examine the characteristics that make up that specific cluster. The attributes that the cluster contains are listed in the **Variables** columns, and the state of the listed attribute is listed in the **Values** column. Attribute states are listed in order of importance, described by the probability that they will appear in the cluster. The probability is shown in the **Probability** column.

[Back to Top](#)

Cluster Discrimination

You can use the **Cluster Discrimination** tab to compare attributes between two clusters. Use the **Cluster 1** and **Cluster 2** lists to select the clusters to compare. The viewer determines the most important differences between the clusters, and displays the attribute states that are associated with the differences, in order of importance. A bar to the right of the attribute shows which cluster the state favors, and the size of the bar shows how strongly the state favors the cluster.

[Data Mining Model Viewers](#)

Browse a Model Using the Microsoft Time Series Viewer

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Time Series Viewer in Microsoft SQL Server Analysis Services displays mining models that are built with the Microsoft Time Series algorithm. The Microsoft Time Series algorithm is a regression algorithm that creates data mining models for prediction of continuous columns, such as product sales, in a forecasting scenario. These time series models can include information based on different algorithms:

- The ARTxp algorithm, which is optimized for short-term prediction.
- The ARIMA algorithm, which is optimized for long-term prediction.
- A blend of the ARTxp and ARIMA algorithms.

For more information about these algorithms, see [Microsoft Time Series Algorithm](#) and [Microsoft Time Series Algorithm Technical Reference](#).

NOTE

To view detailed information about the equations used in the model and the patterns that were discovered, use the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Time Series Viewer provides the following tabs:

- [Model](#)
- [Charts](#)

Note The information shown for the model content and in the Mining Legend depends on the algorithm that the model uses. However, the **Model** and **Charts** tabs are the same regardless of the algorithm mix.

Model

When you build a time series model, Analysis Services presents the completed model as a tree. If your data contains multiple case series, Analysis Services builds a separate tree for each series. For example, you are predicting sales for the Pacific, North America, and Europe regions. The predictions for each of these regions are case series. Analysis Services builds a separate tree for each of these series. To view a particular series, select the series from the **Tree** list.

For each tree, the time series model contains an **All** node, and then splits into a series of nodes that represent periodic structures discovered by the algorithm. You can click each node to display statistics such as the number of cases and the equation.

If you created the model using ARTxp only, the **Mining Legend** for the root node contains only the total number of cases. For each non-root node, the **Mining Legend** contains more detailed information about the tree split:

for example, it might show the equation for the node and the number of cases. The **rule** in the legend contains information that identifies the series, and the time slice to which the rule applies. For example, the legend text **M200 Europe Amount -2** indicates that the node represents the model for the M200 Europe series, at a period two time slices ago.

If you created the model using ARIMA only, the **Model** tab contains a single node with the caption, **All**. The **Mining Legend** for the root node contains the ARIMA equation.

If you created a mixed model, the root node contains the number of cases and the ARIMA equation only. After the root node, the tree splits into separate nodes for each periodic structure. For each non-root node, the Mining Legend contains both the ARTxp and ARIMA algorithms, the equation for the node, and the number of cases in the node. The ARTxp equation is listed first, and is labeled as the tree node equation. This is followed by the ARIMA equation. For more information about how to interpret this information, see [Microsoft Time Series Algorithm Technical Reference](#).

In general, the decision tree graph shows the most important split, the **All** node, at the left of the viewer. In decision trees, the split after the **All** node is the most important because it contains the condition that most strongly separates the cases in the training data. In a time series model, the main branching indicates the most likely seasonal cycle. Splits after the **All** node appear to the right of the branch.

You can expand or collapse individual nodes in the tree to show or hide the splits that occur after each node. You can also use the options on the **Decision Tree** tab to affect how the tree is displayed. Use the **Show Level** slider to adjust the number of levels that are shown in the tree. Use **Default Expansion** to set the default number of levels that are displayed for all trees in the model.

The shading of the background color for each node signifies the number of cases that are in the node. To find the exact number of cases in a node, pause the pointer over the node to view an InfoTip for the node.

[Back to Top](#)

Charts

The **Charts** tab displays a graph that shows the behavior of the predicted attribute over time, together with five predicted future values. The vertical axis of the chart represents the value of the series, and the horizontal axis represents time.

NOTE

The time slices used on the time axis depend on the units used in your data: they could represent days, months, or even seconds.

Use the **Abs** button to toggle between absolute and relative curves. If your chart contains multiple models, the scale of the data for each model might be very different. If you use an absolute curve, one model might appear as a flat line, whereas another model shows significant changes. This occurs because the scale of one model is greater than the scale of the other model. By switching to a relative curve, you change the scale to show the percentage of change instead of absolute values. This makes it easier to compare models that are based on different scales.

If the mining model contains multiple time series, you can select one or multiple series to display in the chart. Just click the list at the right of the viewer and select the series you want from the list. If the chart becomes too complex, you can filter the series that are displayed by selecting or clearing the series check boxes in the legend.

The chart displays both historical and future data. Future data appears shaded, to differentiate it from historical data. The data values appear as solid lines for historical data and as dotted lines for predictions. You can change the color of the lines that are used for each series by setting properties in Visual Studio with Analysis Services projects or SQL Server Management Studio. For more information, see [Change the Colors Used in the Data Mining Viewer](#).

You can adjust the range of time that is displayed by using the zoom options. You can also view a specific time range by clicking the chart, dragging a time selection across the chart, and then clicking again to zoom in on the selected range.

You can select how many future time **steps** that you want to see in the model by using **Prediction Steps**. If you select the **Show Deviations** check box, the viewer provides error bars so that you can see how accurate the predicted value is.

[Data Mining Model Viewers](#)

Browse a Model Using the Microsoft Naïve Bayes Viewer

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The Microsoft Naïve Bayes Viewer in Microsoft SQL Server Analysis Services displays mining models that are built with the Microsoft Naïve Bayes algorithm. The Microsoft Naïve Bayes algorithm is a classification algorithm that is highly adaptable to predictive modeling tasks. For more information about this algorithm, see [Microsoft Naïve Bayes Algorithm](#).

Because one of the main purposes of a naïve Bayes model is to provide a way to quickly explore the data in a dataset, the Microsoft Naïve Bayes Viewer provides several methods for displaying the interaction between predictable attributes and input attributes.

NOTE

If you want to view detailed information about the equations used in the model and the patterns that were discovered, you can switch to the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Naïve Bayes Viewer provides the following tabs for exploring data:

- [Dependency Network](#)
- [Attribute Profiles](#)
- [Attribute Characteristics](#)
- [Attribute Discrimination](#)

Dependency Network

The **Dependency Network** tab displays the dependencies between the input attributes and the predictable attributes in a model. The slider at the left of the viewer acts as a filter that is tied to the strengths of the dependencies. Lowering the slider shows only the strongest links.

When you select a node, the viewer highlights the dependencies that are specific to the node. For example, if you choose a predictable node, the viewer also highlights each node that helps predict the predictable node.

The legend at the bottom of the viewer links color codes to the type of dependency in the graph. For example, when you select a predictable node, the predictable node is shaded turquoise, and the nodes that predict the selected node are shaded orange.

[Back to Top](#)

Attribute Profiles

The **Attribute Profiles** tab displays histograms in a grid. You can use this grid to compare the predictable attribute that you select in the **Predictable** box to all other attributes that are in the model. Each column in the tab represents a state of the predictable attribute. If the predictable attribute has many states, you can change the number of states that appear in the histogram by adjusting the **Histogram bars**. If the number you choose is less than the total number of states in the attribute, the states are listed in order of support, with the remaining states collected into a single gray bucket.

To display a Mining Legend that relates the colors of the histogram to the states of an attribute, click the **Show Legend** check box. The Mining Legend also displays the distribution of cases for each attribute-value pair that you select.

To copy the contents of the grid to the Clipboard as an HTML table, right-click the **Attribute Profiles** tab and select **Copy**.

[Back to Top](#)

Attribute Characteristics

To use the **Attribute Characteristics** tab, select a predictable attribute from the **Attribute** list and select a state of the selected attribute from the **Value** list. When you set these variables, the **Attribute Characteristics** tab displays the states of the attributes that are associated with the selected case of the selected attribute. The attributes are sorted by importance.

[Back to Top](#)

Attribute Discrimination

To use the **Attribute Discrimination** tab, select a predictable attribute and two of its states from the **Attribute**, **Value 1**, and **Value 2** lists. The grid on the **Attribute Discrimination** tab then displays the following information in columns:

Attribute

Lists other attributes in the dataset that contain a state that highly favors one state of the predictable attribute.

Values

Shows the value of the attribute in the **Attribute** column.

Favors <value 1>

Shows a colored bar that indicates how strongly the attribute value favors the predictable attribute value shown in **Value 1**.

Favors <value 2>

Shows a colored bar that indicates how strongly the attribute value favors the predictable attribute value shown in **Value 2**.

[Data Mining Model Viewers](#)

Browse a Model Using the Microsoft Sequence Cluster Viewer

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Sequence Cluster Viewer in Microsoft SQL Server Analysis Services displays mining models that are built with the Microsoft Sequence Clustering algorithm. The Microsoft Sequence Clustering algorithm is a sequence analysis algorithm for use in exploring data that contains events that can be linked by following paths, or *sequences*. For more information about this algorithm, see [Microsoft Sequence Clustering Algorithm](#).

NOTE

To view detailed information about the equations used in the model and the patterns that were discovered, use the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

NOTE

The Microsoft Sequence Cluster Viewer provides functionality and options that are similar to the Microsoft Cluster Viewer. For more information, see [Browse a Model Using the Microsoft Cluster Viewer](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Sequence Cluster Viewer provides the following tabs for use in exploring sequence clustering mining models:

- [Cluster Diagram](#)
- [Cluster Profiles](#)
- [Cluster Characteristics](#)
- [Cluster Discrimination](#)
- [Cluster Transitions](#)

Cluster Diagram

The **Cluster Diagram** tab of the Microsoft Sequence Cluster Viewer displays all the clusters that are in a mining model. The shading of the line that connects one cluster to another represents the strength of the similarity of the clusters. If the shading is light or nonexistent, the clusters are not very similar. As the line becomes darker, the similarity of the links becomes stronger. You can adjust how many lines the viewer shows by adjusting the slider to the right of the clusters. Lowering the slider shows only the strongest links.

By default, the shade represents the population of the cluster. By using the **Shading****Variable** and **State** options, you can select which attribute and state pair the shading represents. The darker the shading, the greater the attribute distribution is for a specific state. The distribution decreases as the shading gets lighter.

To rename a cluster, right-click its node and select **Rename Cluster**. The new name is persisted to the server.

To copy the visible section of the diagram to the Clipboard, click **Copy Graph View**. To copy the complete diagram, click **Copy Entire Graph**. You can also zoom in and out by using **Zoom In** and **Zoom Out**, or you can fit the diagram to the screen by using **Scale Diagram to Fit in Window**.

[Back to Top](#)

Cluster Profiles

The **Cluster Profile** tab provides an overall view of the clusters that the algorithm in your model creates. Each column that follows the **Population** column in the grid represents a cluster that the model discovered. The <attribute>.samples row represents different sequences of data that exist in the cluster, and the <attribute> row describes all the items that the cluster contains and their overall distribution.

The **Histogram bars** option controls the number of bars that are visible in the histogram. If more bars exist than you choose to display, the bars of highest importance are retained, and the remaining bars are grouped together into a gray bucket.

You can change the default names of the clusters, to make the names more descriptive. Rename a cluster by right-clicking its column heading and selecting **Rename cluster**. You can hide clusters by selecting **Hide column**, and you can also drag columns to reorder them in the viewer.

To open a window that provides a larger, more detailed view of the clusters, double-click either a cell in the **States** column or a histogram in the viewer.

[Back to Top](#)

Cluster Characteristics

To use the **Cluster Characteristics** tab, select a cluster from the **Cluster** list. After you select a cluster, you can examine the characteristics that make up that specific cluster. The attributes that the cluster contains are listed in the **Variables** columns, and the state of the listed attribute is listed in the **Values** column. Attribute states are listed in order of importance, described by the probability that they will appear in the cluster. The probability is shown in the **Probability** column.

[Back to Top](#)

Cluster Discrimination

You can use the **Cluster Discrimination** tab to compare attributes between two clusters, to determine how items in a sequence favor one cluster over another. Use the **Cluster 1** and **Cluster 2** lists to select the clusters to compare. The viewer determines the most important differences between the clusters, and displays the attribute states that are associated with the differences, in order of importance. A bar to the right of the attribute shows which cluster the state favors, and the size of the bar shows how strongly the state favors the cluster.

[Back to Top](#)

Cluster Transitions

By selecting a cluster on the **Cluster Transitions** tab, you can browse the transitions between sequence states in the selected cluster. Each node in the viewer represents a state of the sequence column. An arrow represents a transition between two states and the probability that is associated with the transition. If a transition returns back to the originating node, an arrow can point back to the originating node.

An arrow that originates from a dot represents the probability that the node is the start of a sequence. An ending edge that leads to a null represents the probability that the node is the end of the sequence.

You can filter the edge of the nodes by using the slider at the left of the tab.

[Browse a Model Using the Microsoft Cluster Viewer](#)

Browse a Model Using the Microsoft Association Rules Viewer

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Association Rules Viewer in Microsoft SQL Server Analysis Services displays mining models that are built with the Microsoft Association algorithm. The Microsoft Association algorithm is an association algorithm for use in creating data mining models that you can use for market basket analysis. For more information about this algorithm, see [Microsoft Association Algorithm](#).

Following are the primary reasons for using the Microsoft Association algorithm:

- To find itemsets that describe items that are typically found together in a transaction.
- To discover rules that predict the presence of other items in a transaction based on existing items.

NOTE

To view detailed information about the equations used in the model and the patterns that were discovered, use the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

For a walkthrough of how to create, explore, and use an association mining model, see [Lesson 3: Building a Market Basket Scenario \(Intermediate Data Mining Tutorial\)](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Association Rules Viewer includes the following tabs:

- [Itemsets](#)
- [Rules](#)
- [Dependency Net](#)

Each tab contains the **Show long name** check box, which you can use to show or hide the table from which the itemset originates in the rule or itemset.

Itemsets

The **Itemsets** tab displays the list of itemsets that the model identified as frequently found together. The tab displays a grid with the following columns: **Support**, **Size**, and **Itemset**. For more information about support, see [Microsoft Association Algorithm](#). The **Size** column displays the number of items in the itemset. The **Itemset** column displays the actual itemset that the model discovered. You can control the format of the itemset by using the **Show** list, which you can set to the following options:

- **Show attribute name and value**
- **Show attribute value only**
- **Show attribute name only**

You can filter the number of itemsets that are displayed in the tab by using **Minimum support** and **Minimum itemset size**. You can limit the number of displayed itemsets even more by using **Filter Itemset** and entering an itemset characteristic that must exist. For example, if you type "Water Bottle = existing", you can limit the itemsets to only those that contain a water bottle. The **Filter Itemset** option also displays a list of the filters that you have used previously.

You can sort the rows in the grid by clicking a column heading.

[Back to Top](#)

Rules

The **Rules** tab displays the rules that the association algorithm discovered. The **Rules** tab includes a grid that contains the following columns: **Probability**, **Importance**, and **Rule**. The probability describes how likely the result of a rule is to occur. The importance is designed to measure the usefulness of a rule. Although the probability that a rule will occur may be high, the usefulness of the rule may in itself be unimportant. The importance column addresses this. For example, if every itemset contains a specific state of an attribute, a rule that predicts state is trivial, even though the probability is very high. The greater the importance, the more important the rule is.

You can use **Minimum probability** and **Minimum importance** to filter the rules, similar to the filtering you can do on the **Itemsets** tab. You can also use **Filter Rule** to filter a rule based on the states of the attributes that it contains.

You can sort the rows in the grid by clicking a column heading.

[Back to Top](#)

Dependency Net

The **Dependency Net** tab includes a dependency network viewer. Each node in the viewer represents an item, such as "state = WA". The arrow between nodes represents the association between items. The direction of the arrow dictates the association between the items according to the rules that the algorithm discovered. For example, if the viewer contains three items, A, B, and C, and C is predicted by A and B, if you select node C, two arrows point toward node C - A to C and B to C.

The slider at the left of the viewer acts as a filter that is tied to the probability of the rules. Lowering the slider shows only the strongest links.

Browse a Model Using the Microsoft Neural Network Viewer

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Microsoft Neural Network Viewer in Microsoft SQL Server Analysis Services displays mining models that are built with the Microsoft Neural Network algorithm. The Microsoft Neural Network algorithm creates classification and regression mining models that can analyze multiple inputs and outputs, and is very useful for open-ended analyses and exploration. For more information about this algorithm, see [Microsoft Neural Network Algorithm](#).

When you explore a model using the Microsoft Neural Network Viewer, you typically pick some target attribute and state, and then use the viewer to see how input attributes affect the outcome.

For example, suppose you know these facts about a class of potential customers:

- Middle aged (40 to 50 years old).
- Owns a home.
- Has two children who still live at home.

How can you correlate these attributes with the likelihood that the customer will make a purchase?

By building a neural network model using purchasing behavior as the target outcome, you can explore multiple combinations on customer attributes, such as high income, and discover which combination of attributes is most likely to influence purchasing behavior. For example, you might discover that the determining factor is the distance that they commute to work.

If you need to view detailed information, such as the equations that represent each pattern that was discovered, you can switch views and use the Microsoft Generic Content Tree viewer. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#) or [Microsoft Generic Content Tree Viewer \(Data Mining\)](#).

Viewer Tabs

When you browse a mining model in Analysis Services, the model is displayed on the **Mining Model Viewer** tab of Data Mining Designer in the appropriate viewer for the model. The Microsoft Neural Network Viewer provides the following tabs for use in exploring neural network mining models:

- [Inputs](#)
- [Outputs](#)
- [Variables](#)

Inputs

Use the **Inputs** tab to choose the attributes and values that the model used as inputs. By default, the viewer opens with all attributes included. In this default view, the model chooses which attribute values are the most important to display.

To select an input attribute, click inside the **Attribute** column of the **Input** grid, and select an attribute from the drop-down list. (Only attributes that are included in the model are included in the list.)

The first distinct value appears under the **Value** column. Clicking the default value reveals a list that contains all the possible states of the associated attribute. You can select the state that you want to investigate. You can select as many attributes as you want.

[Back to Top](#)

Outputs

Use the **Outputs** tab to choose the outcome attribute to investigate. You can choose any two outcome states to compare, assuming the columns were defined as predictable attributes when the model was created.

Use the **OutputAttribute** list to select an attribute. You can then select two states that are associated with the attribute from the **Value 1** and **Value 2** lists. These two states of the output attribute will be compared in the **Variables** pane.

[Back to Top](#)

Variables

The grid in the **Variables** tab contains the following columns: **Attribute**, **Value**, **Favors [value 1]**, and **Favors [value 2]**. By default, the columns are sorted by the strength of **Favors [value 1]**. Clicking a column heading changes the sort order to the selected column.

A bar to the right of the attribute shows which state of the output attribute the specified input attribute state favors. The size of the bar shows how strongly the output state favors the input state.

Browse a Model Using the Microsoft Generic Content Tree Viewer

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The Microsoft Generic Mining Model Content Viewer provides detailed information about the patterns found by the mining algorithm, and also provides access to various statistics generated during the analysis process. The amount and type of information depends on the algorithm that was used, but can include the following categories:

- Segments of data, and their characteristics.
- Descriptive statistics about each group or about the whole set of data.
- The number of branches or child nodes in a tree.
- Calculations, such as variance and mean, for a cluster or a whole set of data.

Viewing this information can help you better understand the results of your analysis. You can also identify ways to fine-tune, and then retrain, your model. Or, you might decide to retrain by using a different algorithm.

Viewing Mining Model Content

The Microsoft Generic Content Viewer displays the columns, rules, properties, attributes, nodes, and other content from the *content schema rowset* of the mining model. The content schema rowset is a generic framework for presenting detailed information about the content of a data mining model.

This detailed information is contained in an HTML table that represents the patterns, clusters, or trees in the model as nodes. You can click on each node and expand it to see more detail, such as the formulas or the count of distinct values for a numeric attribute. You can also explore the child-parent relationships among the nodes.

For more information about the general meaning of the terms used in the mining model content, see [Mining Model Content \(Analysis Services - Data Mining\)](#). The topic also contains links to information about mining model content for specific types of models. Each type of mining model contains information that is highly specific to the algorithm and the patterns found in the data, so we recommend that you consult the technical reference topic for each model type in order to fully understand each model type.

Querying Mining Model Content

The same information that is provided by the Microsoft Generic Content Tree Viewer is also available by querying the mining model. You can create queries against mining model content by using Data Mining Extensions (DMX) statements. For example, in SQL Server Management Studio, you can run a content query by executing the following DMX statement:

```
SELECT * FROM [<mining model name>].CONTENT
```

For more information, see [Data Mining Queries](#).

Mining Model Viewer Tasks and How-tos

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Data Mining Designer in Visual Studio with Analysis Services projects contains several tools that you can use to explore mining models. The following topics provide step-by-step instructions on how to complete tasks that are specific to using the **Mining Model Viewer** tab in the designer.

In This Section

- [Select a Mining Model and a Data Mining Viewer](#)
- [Copy a View of a Mining Model](#)
- [Find a Specific Node in a Dependency Network](#)
- [Filter a Rule in an Association Rules Model](#)
- [Filter an Itemset in an Association Rules Model](#)
- [Drill Through to Case Data from a Mining Model](#)
- [View the Formula for a Time Series Model \(Data Mining\)](#)
- [Change the Colors Used in the Data Mining Viewer](#)

See Also

[Basic Data Mining Tutorial](#)

[Mining Model Viewers \(Data Mining Model Designer\)](#)

Select a Mining Model and a Data Mining Viewer

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

You can explore a mining model by using one of the viewers on the **Mining Model Viewer** tab of Data Mining Designer. You can easily switch between models, or change the viewer that is used.

- The **Mining Model** drop-down list box on the **Mining Model Viewer** tab of Data Mining Designer in Visual Studio with Analysis Services projects contains a list of all the mining models that are in the current mining structure.
- Custom viewers are provided for each type of model. For an overview of all the custom viewers, see [Mining Model Viewers \(Data Mining Model Designer\)](#). For a walkthrough of how to use the custom viewers to understand a model, see [Lesson 4: Exploring the Targeted Mailing Models \(Basic Data Mining Tutorial\)](#).
- The Microsoft Generic Content Viewer shows the patterns discovered by the algorithm in a standard representation of nodes in a tree. Although the generic tree view shows all the content for the model in rich detail, it is more difficult to interpret. For more information, see [Browse a Model Using the Microsoft Generic Content Tree Viewer](#).

To select a viewer type

- Select the viewer that is provided for the specific type of model that you created, using the **Viewer** list at the top of the **Mining Model Viewer** tab.
- Or, use the **Microsoft Generic Mining Content Viewer**

To select a mining model to view

- On the **Mining Model Viewer** tab in Data Mining Designer, select the mining model that you want to view from the **Mining Model** list.

The selected mining model opens in the viewer that is provided for that model type.

[Mining Model Viewer Tasks and How-tos](#)

Copy a View of a Mining Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The **Mining Model Viewer** tab of Data Mining Designer in Visual Studio with Analysis Services projects uses a separate viewer for each type of mining model. Several of the viewers have components from which you can copy the contents to the Clipboard, and from there paste the contents into a document or into image manipulation software. The following components make this functionality available:

- Cluster Diagram in the Microsoft Cluster Viewer and the Microsoft Sequence Cluster Viewer
- Decision Tree in the Microsoft Tree Viewer and the Microsoft Time Series Viewer
- State Transitions in the Microsoft Sequence Cluster Viewer
- Dependency Network in the Microsoft Association Rules Viewer, the Microsoft Naïve Bayes Viewer, and the Microsoft Tree Viewer
- Mining model content, from the Node Details pane of the Microsoft Generic Content Tree Viewer

You can copy the complete representation of the mining model, or just the part that is visible in the viewer.

WARNING

When you copy a model using the viewer, it does not create a new model object. To create a new model, you must use either the wizard, or the Data Mining Designer,. For more information, see [Make a Copy of a Mining Model](#).

To copy the complete model to the Clipboard

1. From the **Mining Model** list on the **Mining Model Viewer** tab, select the mining model that you want to view.
2. Select the appropriate tab, such as the **Dependency Network** tab, and then click **Copy Entire Graph** on the toolbar of that tab.

To copy the visible piece of the model to the Clipboard

1. From the **Mining Model** list on the **Mining Model Viewer** tab, select the mining model that you want to view.
2. Select the appropriate tab, such as the **Dependency Network** tab, and then zoom in or out to view the model at the level that you want.
3. Click **Copy Graph View** on the toolbar of the selected tab.

To copy the mining model content to the Clipboard

1. From the **Mining Model** list on the **Mining Model Viewer** tab, select the mining model that you want to view.
2. From the **Viewer** drop-down list, select **Microsoft Generic Content Tree Viewer**.
3. In the **Node Caption (Unique ID)** pane, click a node.
4. Right-click the **Node Details** pane and then select **Select All**.
5. Right-click the **Node Details** pane again and select **Copy**.

[Mining Model Viewer Tasks and How-tos](#)

Find a Specific Node in a Dependency Network

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A dependency network in a Microsoft SQL Server Analysis Services mining model can contain many nodes, making it difficult to locate the data you are interested in. To solve this problem, you can use the **Find Node** dialog box on the **Dependency Network** tab of Data Mining Designer to search for a specific node.

To find a specific node in a dependency network

1. On the **Mining Model Viewer** tab of **Data Mining Designer** in Visual Studio with Analysis Services projects, click **Find Node** on the toolbar of the **Dependency Network** tab of the mining model viewer.

The **Find Node** dialog box opens.

2. In the **Node name contains** box, enter part of the name of the node for which you want to search.

The list of nodes is filtered to display only those nodes that contain part of the search path.

3. Select the correct node from the list, and then click **OK**.

See Also

[Mining Model Viewer Tasks and How-tos](#)

Filter a Rule in an Association Rules Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can use filtering with association models to restrict the results to just the associations that interest you. For example, you might filter the rules to show only those that include a specific product.

In Data Mining Designer, you use the controls on the **Rules** tab of the Microsoft Association Rules Viewer to filter the rules that are displayed. You can also create a query on the model to see only itemset that contains a particular value.

NOTE

This option is available only for mining models that have been created by using the Microsoft Association Algorithm.

Filter a rule in an association model

1. Open the mining model by using the **Association Rules Viewer**. To do this in SQL Server Management Studio, right click the model name and select **Browse**. To do this in Visual Studio with Analysis Services projects, double-click the mining structure that contains the model, and then click the **Mining Model Viewer** tab of **Data Mining Designer**.
2. Click the **Rules** tab of the **Association Rules Viewer**.
3. Type a rule condition into the **Filter Rule** box. For example, a rule condition might be "Bike Stand", which also returns "Bike Stands".
The **Filter Rule** text box supports regular expressions as defined by the .NET language. Therefore, you can use expressions such as the following: `((.Helmets.*Fenders.*)|(.*Fenders.*Helmets.*))`. This expression would return any itemsets that include attributes with the words Helmets and Fenders, in any order.
4. For **Minimum probability**, increase the value of probability to see fewer rules, or decrease the value to see more rules.
5. For **Minimum importance**, increase the value of importance to see fewer rules, or decrease the value to see more rules.
6. For **Show**, select one of the following options: **Show attribute name and value**, **Show attribute name only**, or **Show attribute value only**.
7. For **Maximum rows**, increase the value to increase the total number of rules that meet the specified conditions, or decrease the value to limit the number of rules returned. Rules are ordered by probability, so you might eliminate additional rules that meet the specified conditions for probability or importance.
8. Select or deselect the **Show long name** check box to toggle the way that the rules names are displayed.

The rules are now filtered to only display rules that contain the indicated item. The filter condition applies to attribute values either before or after the rule delimiter, "->".

NOTE

The viewer caches the initial list of rules, based on a query to the mining model, and does not refresh the list of rules unless you change the conditions of the query by setting the maximum rows, the probability, importance, or the display of long names. Therefore, if you type a condition and the display does not immediately refresh, you can force the viewer to refresh the data by selecting and then deselecting the **Show long names** check box.

Create a query on the itemsets in an association model

- [Association Model Query Examples](#)

See Also

[Mining Model Viewer Tasks and How-tos](#)

[Browse a Model Using the Microsoft Association Rules Viewer](#)

[Lesson 3: Building a Market Basket Scenario \(Intermediate Data Mining Tutorial\)](#)

Filter an Itemset in an Association Rules Model

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

In Microsoft SQL Server Analysis Services, you can filter the itemsets that are displayed in the **Itemsets** tab of the Microsoft Association Rules Viewer.

To filter an itemset

1. On the **Mining Model Viewer** tab of Data Mining Designer in Visual Studio with Analysis Services projects, click the **Itemsets** tab of the **Association Rules Viewer**.
2. Enter a rule condition in the **Filter itemset** box. For example, a rule condition might be "Touring-1000 = existing"
3. Click **Enter**.

The itemsets are now filtered to display only those itemsets that contain the selected items. The box is not case-sensitive. Filters are stored in memory so that you can select an old filter from the list.

[Mining Model Viewer Tasks and How-tos](#)

Use Drillthrough from the Model Viewers

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Depending on the model type, you can use drillthrough from the browse viewers on the **Mining Model Viewer** tab of Data Mining Designer to explore the cases used in the mining model or to see additional columns in the mining structure. Although many model types do not support drillthrough because the patterns in the model cannot be directly linked to specific cases, the following model types do support drillthrough.

Note that drillthrough must have been enabled on the model, and you must have the appropriate permissions. The drillthrough option might also be disabled if the model is in an unprocessed state, regardless of whether the model was previously processed and has content. To retrieve model case data by using drillthrough, the cache of the structure and model must be current.

Use drillthrough in the Microsoft Tree Viewer

1. In Data Mining Designer, select a decision trees model, and select **Browse Model** to open the model in the **Microsoft Tree Viewer**. In SQL Server Management Studio, right-click the model, and select **Browse**.
2. Right-click any node in the tree graph, and select **Drill through**.
3. Select one of the following options: **Model Columns Only** or **Model and Structure Columns**. If you do not have permissions, an option might not be available.
4. The **Drill Through** dialog box opens, displaying the case data and/or structure data. The title bar of the dialog box also contains a description that identifies the node from which the drillthrough query was executed.
5. Right-click anywhere in the results and select **Copy All** to save the results to the Clipboard.

Use drillthrough in the Microsoft Cluster Viewer

1. In Data Mining Designer, select a clustering model, and select **Browse Model** to open the model in the **Microsoft Cluster Viewer**. In SQL Server Management Studio, right-click the model, and select **Browse**.
2. On the **Cluster** tab, right-click any node.
3. Select **Drill through**, and then select one of the following options: **Model Columns Only** or **Model and Structure Columns**. If you do not have permissions, an option might not be available.
4. The **Drill Through** dialog box opens, displaying the case data and/or structure data. The title bar of the dialog box also contains a description that identifies the cluster for the cases.
5. Right-click anywhere in the results and select **Copy All** to save the results to the Clipboard.

Use drillthrough in the Microsoft Association Rules Viewer

1. In Data Mining Designer, select an association model, and select **Browse Model** to open the model in the **Microsoft Association Rules Viewer**. In SQL Server Management Studio, right-click the model, and select **Browse**.
2. On the **Rules** tab, right-click any row that represents a rule. On the **Itemsets** tab, click on any row that contains an itemset.
3. Select **Drill through**, and then select one of the following options: **Model Columns Only** or **Model and Structure Columns**. If you do not have permissions, an option might not be available.

4. The **Drill Through** dialog box opens, displaying the case data and/or structure data. The title bar of the dialog box also contains a description that identifies the rule name.
5. Right-click anywhere in the results and select **Copy All** to save the complete case results to the Clipboard. You can also select **Copy** to copy just the selected case. If the model contains a nested table column, only the name of the nested table column is pasted; to retrieve the data values inside the nested table column for each case you must create a query on the model content.

Use drillthrough in the Microsoft Sequence Cluster Viewer

1. In Data Mining Designer, select a clustering model, and select **Browse Model** to open the model in the **Microsoft Cluster Viewer**. In SQL Server Management Studio, right-click the model, and select **Browse**.
2. On the **Cluster Diagram tab**, right-click any node that represents a cluster. From the **Cluster Profiles** tab, click anywhere in a cluster profile or in the cluster representing the total model population.
3. Select **Drill through**, and then select one of the following options: **Model Columns Only** or **Model and Structure Columns**. If you do not have permissions, an option might not be available.
4. The **Drill Through** dialog box opens, displaying the case data and/or structure data. The title bar of the dialog box also contains a description that identifies the cluster for the cases.
5. Right-click anywhere in the results and select **Copy All** to save the results to the Clipboard. If the model contains a nested table column, only the name of the nested table column is pasted; to retrieve the data values inside the nested table column for each case you must create a query on the model content.

[Mining Model Viewer Tasks and How-tos](#)

[Drillthrough on Mining Models](#)

[Drillthrough on Mining Structures](#)

View the Formula for a Time Series Model (Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If you created a time series model using SQL Server Data Mining, the easiest way to see the regression equation for the model is to use the **Mining Legend** of the [Microsoft Time Series Viewer](#), which presents all the constants in a readable format.

To view the ARTXP regression formula for a time series model

1. In SQL Server Management Studio, select the time series model that you want to view, and click **Browse**.

-- or --

In Visual Studio with Analysis Services projects, select the time series model, and then click the **Mining Model Viewer** tab.

2. Click the **Model** tab.
3. If the model contains multiple trees, select a single tree from the **Tree** drop-down list.

NOTE

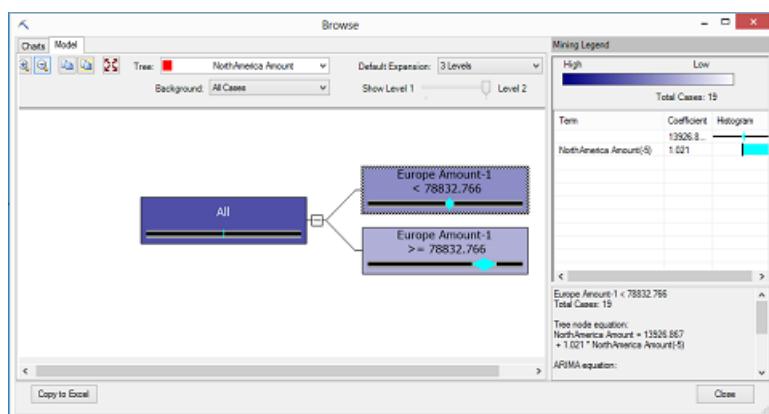

A model will always have multiple trees if you have more than one data series. However, you will not see as many trees in the **Time Series viewer** as you will see in the [Microsoft Generic Content Tree Viewer](#). That is because the Time Series viewer combines the ARIMA and ARTXP information for each data series into a single representation.

4. Click any leaf node in the tree.

Nodes that are labeled as **Data Series** are always leaf nodes and can contain an equation. If an **(All)** node has no child nodes, it can also contain an equation.

5. If the **Mining Legend** is not available, right-click the node, and select **Show Legend**.

The ARTXP formula is displayed in the first half of the **Mining Legend**, as the **Tree node equation**.

To view the ARIMA formula for a time series model

1. In SQL Server Management Studio, select the time series model that you want to view, and click **Browse**.

-- or --

In Visual Studio with Analysis Services projects, select the time series model, and then click the **Mining Model Viewer** tab.

2. Click the **Model** tab.
3. If the model contains multiple trees, select a single tree from the **Tree** drop-down list.

NOTE

The model will always have multiple trees if you include more than one data series.

4. Click any node in the tree.

The ARIMA formula is displayed in the second half of the **Mining Legend**, as the **ARIMA equation**.

5. If the **Mining Legend** is not available, right-click the node, and select **Show Legend**.

To get the coefficients and terms for the equation

1. You can also get the terms and coefficients of the regression formula for a time series model by creating a **content query** on the model content.

For more information, see [Time Series Model Query Examples](#)

2. You can also browse the time series models and find the terms and coefficients by using the [Microsoft Generic Content Tree Viewer](#).

For more information, see [Mining Model Content for Time Series Models \(Analysis Services - Data Mining\)](#).

NOTE

If you browse the content of a mixed model that uses both the ARIMA and ARTXP models, the two models are in separate trees, joined at the root node representing the model. Even though the ARIMA and ARTXP models are presented in one viewer for convenience, the structures are very different, as are the equations, which cannot be combined or compared. The ARTXP tree is more like a decision tree, whereas the ARIMA tree represents a series of moving averages.

Change the Colors Used in the Data Mining Viewer

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

You can change the colors that are used in the data mining viewers to display data series, nodes, or clusters. You do this by setting options in Visual Studio with Analysis Services projects or SQL Server Management Studio. After you have changed the settings, the color selections apply to all models that you view by using Visual Studio with Analysis Services projects; however, you must close Visual Studio with Analysis Services projects and reopen the model in the viewer to see the new colors.

To change the colors used in the data mining viewers

1. On the **Tools** menu of Visual Studio with Analysis Services projects or SQL Server Management Studio, select **Options**.
2. In the **Options** dialog box, expand **Designers**, and then expand **Data Mining Viewers**.
3. Find the viewer property that you want to change, and click the current color selection.
4. Select a new color from the dropdown list. Click the **Custom** tab to select a color from the palette of custom colors available on the current computer, or click **System** to select a color from among the colors specified in the Windows color scheme.

NOTE

If you use a custom color, the color is represented by a color icon and the RGB values of the color. If you use a System color or Web color, the color is represented by a color icon and the name of the color.

SQL Server Data Mining Add-Ins for Office

7/16/2019 • 2 minutes to read • [Edit Online](#)

SQL Server 2012 (11.x) Data Mining Add-ins for Office is a lightweight set of tools for predictive analytics that lets you use data in Excel to build analytical models for prediction, recommendation, or exploration.

IMPORTANT

The data mining add-in for Office is not supported in Office 2016 or later.

The wizards and data management tools in the add-ins provide step-by-step instruction for these common data mining tasks:

- **Organize and clean your data prior to modeling.** Use data stored in Excel or any Excel data source. You can create and save connections to re-use data sources, repeat experiments, or re-train models.
- **Profile, sample, and prepare.** Many experienced data miners say that as much as 70-90 percent of a data mining project is spent on data preparation. The add-ins can make this task go faster, by providing visualizations in Excel and wizards that help you with these common tasks:
 - Profile data and understand its distribution and characteristics.
 - Create training and testing sets through random sampling or oversampling.
 - Find outliers and remove or replace them.
 - Re-label data to improve the quality of analysis.
- **Analyze patterns through supervised or unsupervised learning.** Click through friendly wizards to perform some of the most popular data mining tasks, including clustering analysis, market basket analysis, and forecasting.

Among the well-known machine learning algorithms included in the add-ins are Naïve Bayes, logistic regression, clustering, time series, and neural networks.

If you are new to data mining, get help building prediction queries from the **Query** wizard.

Advanced users can build custom DMX queries with the drag-and-drop **Advanced Query Editor**, or automate predictions using Excel VBA.

- **Document and manage.** After you've created a data set and built some models, document your work and your insights by generating a statistical summary of the data and model parameters.
- **Explore and visualize.** Data mining is not an activity that can be fully automated - you need to explore and understand your results to take meaningful action. The add-ins help you with exploration by providing interactive viewers in Excel, Visio templates that let you customize model diagrams, and the ability to export charts and tables to Excel for additional filtering or modification.
- **Deploy and integrate.** When you've created a useful model, put your model into production, by using the management tools to export the model from your experimental server to another instance of Analysis Services.

You can also leave the model on the server where you created it, but refresh the training data and run predictions using Integration Services or DMX scripts.

Power users will appreciate the **Trace** functionality, that lets you see the XMLA and DMX statements sent to the server.

Getting Started

For more information, see [What's Included in the Data Mining Add-Ins for Office](#)

Support and Requirements

The SQL Server Data Mining Add-Ins for Office is a free download. You must have one of the following versions of Office already installed to use these tools:

- Office 2010, 32-bit or 64-bit version
- Office 2013, 32-bit or 64-bit version

WARNING

Be sure to download the version of the add-ins that matches your version of Excel.

The Data Mining Add-ins requires a connection to one of the following editions of SQL Server Analysis Services:

- Enterprise
- Business Intelligence
- Standard

Depending on the edition of SQL Server Analysis Services that you connect to, some of the advanced algorithms might not be available. For information, see [Features Supported by the Editions of SQL Server 2016](#).

For additional help with installation, see this page on the Download Center:

<https://www.microsoft.com/download/details.aspx?id=29061>

Data Mining Stored Procedures (Analysis Services - Data Mining)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Beginning in SQL Server 2005 (9.x), Analysis Services supports stored procedures that can be written in any managed language. The managed languages that are supported include Visual Basic .NET, C#, and managed C++. In SQL Server Management Studio, you can call the stored procedures directly by using the **CALL** statement, or as part of a Data Mining Extensions (DMX) query.

For more information about calling Analysis Services stored procedures, see [Calling Stored Procedures](#).

For general information about programmability, see [Data Mining Programming](#).

For additional information about how to program data mining objects, see the article, "[SQL Server Data Mining Programmability](#)", in the MSDN library.

NOTE

When you query mining models, especially when you test new data mining solutions, you might find it convenient to call the system stored procedures that are used internally by the data mining engine. You can view the names of these system stored procedures by using SQL Server Profiler to create a trace on the Analysis Services server, and then creating, browsing, and querying the data mining models. However, Microsoft does not guarantee the compatibility of system stored procedures between versions, and you should never use calls to the system stored procedures in a production system. Instead, for compatibility, you should create your own queries by using DMX or XML/A.

In This Section

- [SystemGetCrossValidationResults \(Analysis Services - Data Mining\)](#)
- [SystemGetClusterCrossValidationResults \(Analysis Services - Data Mining\)](#)
- [SystemGetAccuracyResults \(Analysis Services - Data Mining\)](#)
- [SystemGetClusterAccuracyResults \(Analysis Services - Data Mining\)](#)

[Cross-Validation Tab \(Mining Accuracy Chart View\)](#)
[Calling a Stored Procedure](#)

SystemGetCrossValidationResults (Analysis Services - Data Mining)

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Partitions the mining structure into the specified number of cross-sections, trains a model for each partition, and then returns accuracy metrics for each partition.

NOTE

This stored procedure cannot be used to cross-validate clustering models, or models that are built by using the Microsoft Time Series algorithm or the Microsoft Sequence Clustering algorithm. To cross-validate clustering models, you can use the separate stored procedure, [SystemGetClusterCrossValidationResults \(Analysis Services - Data Mining\)](#).

Syntax

```
SystemGetCrossValidationResults(  
    <mining structure>  
    [, <mining model list>]  
    ,<fold count>  
    ,<max cases>  
    ,<target attribute>  
    [,<target state>]  
    [,<target threshold>]  
    [,<test list>])
```

Arguments

mining structure

Name of a mining structure in the current database.

(required)

mining model list

Comma-separated list of mining models to validate.

If a model name contains any characters that are not valid in the name of an identifier, the name must be enclosed in brackets.

If a list of mining models is not specified, cross-validation is performed against all models that are associated with the specified structure and that contain a predictable attribute.

NOTE

To cross-validate clustering models, you must use a separate stored procedure, [SystemGetClusterCrossValidationResults \(Analysis Services - Data Mining\)](#).

(optional)

fold count

Integer that specifies the number of partitions into which to separate the data set. The minimum value is 2. The maximum number of folds is **maximum integer** or the number of cases, whichever is lower.

Each partition will contain roughly this number of cases: *max cases/fold count*.

There is no default value.

NOTE

The number of folds greatly affects the time that is required to perform cross-validation. If you select a number that is too high, the query might run for a very long time, and in some cases the server can become unresponsive or time out.

(required)

max cases

Integer that specifies the maximum number of cases that can be tested across all folds.

A value of 0 indicates that all the cases in the data source will be used.

If you specify a value that is greater than the actual number of cases in the data set, all cases in the data source will be used.

There is no default value.

(required)

target attribute

String that contains the name of the predictable attribute. A predictable attribute can be a column, nested table column, or nested table key column of a mining model.

NOTE

The existence of the target attribute is validated only at run time.

(required)

target state

Formula that specifies the value to predict. If a target value is specified, metrics are collected for the specified value only.

If a value is not specified or is **null**, the metrics are computed for the most probable state for each prediction.

The default is **null**.

An error is raised during validation if the specified value is not valid for the specified attribute, or if the formula is not the correct type for the specified attribute.

(optional)

target threshold

Double greater than 0 and less than 1. Indicates the minimum probability score that must be obtained for the prediction of the specified target state to be counted as correct.

A prediction that has a probability less than or equal to this value is considered incorrect.

If no value is specified or is **null**, the most probable state is used, regardless of its probability score.

The default is **null**.

NOTE

Analysis Services will not raise an error if you set *state threshold* to 0.0, but you should never use this value. In effect, a threshold of 0.0 means that predictions with a 0 percent probability are counted as correct.

(optional)

test list

A string that specifies testing options.

Note This parameter is reserved for future use.

(optional)

Return Type

The rowset that is returned contains scores for each partition in each model.

The following table describes the columns in the rowset.

COLUMN NAME	DESCRIPTION
ModelName	The name of the model that was tested.
AttributeName	The name of the predictable column.
AttributeState	A specified target value in the predictable column. If this value is null , the most probable prediction was used. If this column contains a value, the accuracy of the model is assessed against this value only.
PartitionIndex	An 1-based index that identifies to which partition the results apply.
PartitionSize	An integer that indicates how many cases were included in each partition.
Test	Category of the test that was performed. For a description of the categories and the tests that are included in each category, see Measures in the Cross-Validation Report .
Measure	The name of the measure returned by the test. Measures for each model depend on the type of the predictable value. For a definition of each measure, see Cross-Validation (Analysis Services - Data Mining) . For a list of measures returned for each predictable type, see Measures in the Cross-Validation Report .
Value	The value of the specified test measure.

Remarks

To return accuracy metrics for the complete data set, use [SystemGetAccuracyResults \(Analysis Services - Data Mining\)](#).

If the mining model has already been partitioned into folds, you can bypass processing and return only the results of cross-validation by using [SystemGetAccuracyResults \(Analysis Services - Data Mining\)](#).

Examples

The following example demonstrates how to partition a mining structure for cross-validation into two folds, and then test two mining models that are associated with the mining structure, `[v Target Mail]`.

Line three of the code lists the mining models that you want to test. If you do not specify the list, all non-clustering models associated with the structure are used. Line four of the code specifies the number of partitions. Because no value is specified for *max cases*, all cases in the mining structure are used and distributed evenly across the partitions.

Line five specifies the predictable attribute, Bike Buyer, and line six specifies the value to predict, 1 (meaning "yes, will buy").

The NULL value in line seven indicates that there is no minimum probability bar that must be met. Therefore, the first prediction that has a non-zero probability will be used in assessing accuracy.

```
CALL SystemGetCrossValidationResults(
[v Target Mail],
[Target Mail DT], [Target Mail NB],
2,
'Bike Buyer',
1,
NULL
)
```

Sample results:

MODELNAME	ATTRIBUTENAME	ATTRIBUTESTATE	PARTITIONINDEX	PARTITIONSIZE	TEST	MEASURE	VALUE
Target Mail DT	Bike Buyer	1	1	500	Classification	True Positive	144
Target Mail DT	Bike Buyer	1	1	500	Classification	False Positive	105
Target Mail DT	Bike Buyer	1	1	500	Classification	True Negative	186
Target Mail DT	Bike Buyer	1	1	500	Classification	False Negative	65
Target Mail DT	Bike Buyer	1	1	500	Likelihood	Log Score	-0.6190428 07138345
Target Mail DT	Bike Buyer	1	1	500	Likelihood	Lift	0.0740963 734002671
Target Mail DT	Bike Buyer	1	1	500	Likelihood	Root Mean Square Error	0.3469462 79977653

ModelName	Attribute Name	Attribute State	PartitionIndex	PartitionSize	Test	Measure	Value
Target Mail DT	Bike Buyer	1	2	500	Classification	True Positive	162
Target Mail DT	Bike Buyer	1	2	500	Classification	False Positive	86
Target Mail DT	Bike Buyer	1	2	500	Classification	True Negative	165
Target Mail DT	Bike Buyer	1	2	500	Classification	False Negative	87
Target Mail DT	Bike Buyer	1	2	500	Likelihood	Log Score	-0.654117781086519
Target Mail DT	Bike Buyer	1	2	500	Likelihood	Lift	0.038997399132084
Target Mail DT	Bike Buyer	1	2	500	Likelihood	Root Mean Square Error	0.342721344892651

Requirements

Cross-validation is available only in SQL Server Enterprise beginning with SQL Server 2008.

SystemGetClusterCrossValidationResults (Analysis Services - Data Mining)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Partitions the mining structure into the specified number of cross-sections, trains a model for each partition, and then returns accuracy metrics for each partition.

Note This stored procedure can be used only with a mining structure that contains at least one clustering model. To cross-validate non-clustering models, you must use [SystemGetCrossValidationResults \(Analysis Services - Data Mining\)](#).

Syntax

```
SystemGetClusterCrossValidationResults(  
    <structure name>,  
    [,<mining model list>]  
    ,<fold count>}  
    ,<max cases>  
    <test list>])
```

Arguments

mining structure

Name of a mining structure in the current database.

(required)

mining model list

Comma-separated list of mining models to validate.

If a list of mining models is not specified, cross-validation is performed against all clustering models that are associated with the specified structure.

NOTE

To cross-validate models that are not clustering models, you must use a separate stored procedure, [SystemGetCrossValidationResults \(Analysis Services - Data Mining\)](#).

(optional)

fold count

Integer that specifies the number of partitions into which to separate the data set. The minimum value is 2. The maximum number of folds is **maximum integer** or the number of cases, whichever is lower.

Each partition will contain roughly this number of cases: *max cases/fold count*.

There is no default value.

NOTE

The number of folds greatly affects the time required to perform cross-validation. If you select a number that is too high, the query may run for a very long time, and in some cases the server may become unresponsive or time out.

(required)

max cases

Integer that specifies the maximum number of cases that can be tested.

A value of 0 indicates that all the cases in the data source will be used.

If you specify a number that is higher than the actual number of cases in the data set, all cases in the data source will be used.

(required)

test list

A string that specifies testing options.

Note This parameter is reserved for future use.

(optional)

Return Type

The Return Type table contains scores for each individual partition and aggregates for all models.

The following table describes the columns returned.

COLUMN NAME	DESCRIPTION
ModelName	The name of the model that was tested.
AttributeName	The name of the predictable column. For cluster models, always null .
AttributeState	A specified target value in the predictable column. For cluster models, always null .
PartitionIndex	An 1-based index that identifies which partition the results apply to.
PartitionSize	An integer that indicates how many cases were included in each partition.
Test	The type of test that was performed.
Measure	The name of the measure returned by the test. Measures for each model depend on the type of the predictable value. For a definition of each measure, see Cross-Validation (Analysis Services - Data Mining) . For a list of measures returned for each predictable type, see Measures in the Cross-Validation Report .
Value	The value of the specified test measure.

Remarks

To return accuracy metrics for the entire data set, use [SystemGetClusterAccuracyResults \(Analysis Services - Data Mining\)](#).

Also, if the mining model has already been partitioned into folds, you can bypass processing and return only the results of cross-validation by using [SystemGetClusterAccuracyResults \(Analysis Services - Data Mining\)](#).

Examples

The following example demonstrates how to partition a mining structure into three folds, and then test two clustering models that are associated with the mining structure.

Line three of the code lists the specific mining models that you want to test. If you do not specify the list, all clustering models associated with the structure are used.

Line four of the code specifies the number of folds, and line five specifies the maximum number of cases to use.

Because these are clustering models, you do not need to specify a predictable attribute or value.

```
CALL SystemGetClusterCrossValidationResults(
    [v Target Mail],
    [Cluster 1], [Cluster 2],
    3,
    10000
)
```

Sample results:

MODELNAME	ATTRIBUTENAME	ATTRIBUTESTATE	PARTITIONINDEX	PARTITIONSIZE	TEST	MEASURE	VALUE
Cluster 1			1	3025	Clustering	Case Likelihood	0.9305245 11864121
Cluster 1			2	3025	Clustering	Case Likelihood	0.9191841 78430778
Cluster 1			3	3024	Clustering	Case Likelihood	0.9296511 20490248
Cluster 2			1	1289	Clustering	Case Likelihood	0.9227897 26933607
Cluster 2			2	1288	Clustering	Case Likelihood	0.9348655 35691068
Cluster 2			3	1288	Clustering	Case Likelihood	0.9247245 95688798

SystemGetAccuracyResults (Analysis Services - Data Mining)

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Returns cross-validation accuracy metrics for a mining structure and all related models, excluding clustering models.

This stored procedure returns metrics for the whole data set as a single partition. To partition the dataset into cross-sections and return metrics for each partition, use [SystemGetCrossValidationResults \(Analysis Services - Data Mining\)](#).

NOTE

This stored procedure is not supported for models that are built by using the Microsoft Time Series algorithm or the Microsoft Sequence Clustering algorithm. Also, for clustering models, use the separate stored procedure, [SystemGetClusterAccuracyResults \(Analysis Services - Data Mining\)](#).

Syntax

```
SystemGetAccuracyResults(<mining structure>,
[,<mining model list>]
,<data set>
,<target attribute>
[,<target state>]
[,<target threshold>]
[,<test list>])
```

Arguments

mining structure

Name of a mining structure in the current database.

(Required)

model list

Comma-separated list of models to validate.

The default is **null**. This means that all applicable models are used. When the default is used, clustering models are automatically excluded from the list of candidates for processing.

(Optional)

data set

A integer value that indicates which partition in the mining structure is used for testing. The value is derived from a bitmask that represents the sum of the following values, where any single value is optional:

Training cases	0x0001
Test cases	0x0002
Model filter	0x0004

For a complete list of possible values, see the Remarks section of this topic.

(required)

target attribute

String that contains the name of a predictable object. A predictable object can be a column, nested table column, or nested table key column of a mining model.

(required)

target state

String that contains a specific value to predict.

If a value is specified, the metrics are collected for that specific state.

If no value is specified, or if null is specified, the metrics are computed for the most probable state for each prediction.

The default is **null**.

(optional)

target threshold

Number between 0.0 and 1 that specifies the minimum probability in which the prediction value is counted as correct.

The default is **null**, which means that all predictions are counted as correct.

(optional)

test list

A string that specifies testing options. This parameter is reserved for future use.

(optional)

Return Type

The rowset that is returned contains scores for each partition and aggregates for all models.

The following table lists the columns returned by **GetValidationResults**.

COLUMN NAME	DESCRIPTION
Model	The name of the model that was tested. All indicates that the result is an aggregate for all models.
AttributeName	The name of the predictable column.

COLUMN NAME	DESCRIPTION
AttributeState	<p>A target value in the predictable column.</p> <p>If this column contains a value, metrics are collected for the specified state only.</p> <p>If this value is not specified, or is null, the metrics are computed for the most probable state for each prediction.</p>
PartitionIndex	<p>Denotes the partition to which the result applies.</p> <p>For this procedure, always 0.</p>
PartitionCases	An integer that indicates the number of rows in the case set, based on the < <i>data set</i> > parameter.
Test	The type of test that was performed.
Measure	<p>The name of the measure returned by the test. Measures for each model depend on the model type, and the type of the predictable value.</p> <p>For a list of measures returned for each predictable type, see Measures in the Cross-Validation Report.</p> <p>For a definition of each measure, see Cross-Validation (Analysis Services - Data Mining).</p>
Value	The value for the specified measure.

Remarks

The following table provides examples of the values that you can use to specify the data in the mining structure that is used for cross-validation. If you want to use test cases for cross-validation, the mining structure must already contain a testing data set. For information about how to define a testing data set when you create a mining structure, see [Training and Testing Data Sets](#).

INTEGER VALUE	DESCRIPTION
1	Only training cases are used.
2	Only test cases are used.
3	Both the training cases and testing cases are used.
4	Invalid combination.
5	Only training cases are used, and the model filter is applied.
6	Only test cases are used, and the model filter is applied.
7	Both the training and testing cases are used, and the model filter is applied.

For more information about the scenarios in which you would use cross-validation, see [Testing and Validation](#)

(Data Mining).

Examples

This example returns accuracy measures for a single decision tree model, `v Target Mail DT`, that is associated with the `vTargetMail` mining structure. The code on line four indicates that the results should be based on the testing cases, filtered for each model by the filter specific to that model. `[Bike Buyer]` specifies the column that is to be predicted, and the 1 on the following line indicates that the model is to be evaluated only for the specific value 1, meaning "Yes, will buy".

The final line of the code specifies that the state threshold value is 0.5. This means that predictions that have a probability greater than 50 percent should be counted as "good" predictions when calculating accuracy.

```
CALL SystemGetAccuracyResults (
    [vTargetMail],
    [vTargetMail DT],
    6,
    'Bike Buyer',
    1,
    0.5
)
```

Sample Results:

MODELNAME	ATTRIBUTENAME	ATTRIBUTES STATE	PARTITIONINDEX	PARTITIONSIZE	TEST	MEASURE	VALUE
v Target Mail DT	Bike Buyer	1	0	1638	Classification	True Positive	605
v Target Mail DT	Bike Buyer	1	0	1638	Classification	False Positive	177
v Target Mail DT	Bike Buyer	1	0	1638	Classification	True Negative	501
v Target Mail DT	Bike Buyer	1	0	1638	Classification	False Negative	355
v Target Mail DT	Bike Buyer	1	0	1638	Likelihood	Log Score	-0.5984546 38753028
v Target Mail DT	Bike Buyer	1	0	1638	Likelihood	Lift	0.0936717 116894395
v Target Mail DT	Bike Buyer	1	0	1638	Likelihood	Root Mean Square Error	0.3616308 00104946

Requirements

Cross-validation is available only in SQL Server Enterprise beginning with SQL Server 2008.

SystemGetClusterAccuracyResults (Analysis Services - Data Mining)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Returns cross-validation accuracy metrics for a mining structure and related clustering models.

This stored procedure returns metrics for the entire data set as a single partition. To partition the dataset into cross-sections and return metrics for each partition, use [SystemGetClusterCrossValidationResults \(Analysis Services - Data Mining\)](#).

NOTE

This stored procedure works only for clustering models. For non-clustering models, use [SystemGetAccuracyResults \(Analysis Services - Data Mining\)](#).

Syntax

```
SystemGetClusterAccuracyResults(  
    <mining structure>  
    [, <mining model list>]  
    ,<data set>  
    ,<test list>])
```

Arguments

mining structure

Name of a mining structure in the current database.

(Required)

mining model list

Comma-separated list of models to validate.

The default is **null**, meaning that all applicable models are used. When the default is used, non-clustering models are automatically excluded from the list of candidates for processing.

(Optional)

data set

An integer value that indicates which partition in the mining structure is to be used for testing. The value is derived from a bitmask that represents the sum of the following values, where any single value is optional:

Training cases	0x0001
Test cases	0x0002

Model filter	0x0004
--------------	--------

For a complete list of possible values, see the Remarks section of this topic.

(Required)

test list

A string that specifies testing options. This parameter is reserved for future use.

(optional)

Return Type

A table that contains scores for each individual partition and aggregates for all models.

The following table lists the columns returned by **SystemGetClusterAccuracyResults**. To learn more about how to interpret the information returned by the stored procedure, see [Measures in the Cross-Validation Report](#).

COLUMN NAME	DESCRIPTION
ModelName	The name of the model that was tested. All indicates that the result is an aggregate for all models.
AttributeName	Not applicable to clustering models.
AttributeState	Not applicable to clustering models.
PartitionIndex	A number that indicates the partition. For this stored procedure, the number is always 0.
PartitionCases	An integer that indicates how many cases have been tested.
Test	The type of test that was performed.
Measure	The name of the measure returned by the test. Measures for each model depend on the model type, and the type of the predictable value. For a list of measures returned for each predictable type, see Measures in the Cross-Validation Report . For a definition of each measure, see Cross-Validation (Analysis Services - Data Mining) .
Value	A probability score that indicates the cluster case likelihood.

Remarks

The following table provides examples of the values that you can use to specify the data in the mining structure that is used for cross-validation. If you want to use test cases for cross-validation, the mining structure must already contain a testing data set. For information about how to define a testing data set when you create a mining structure, see [Training and Testing Data Sets](#).

INTEGER VALUE	DESCRIPTION
1	Only training cases are used.
2	Only test cases are used.
3	Both the training cases and testing cases are used.
4	Invalid combination.
5	Only training cases are used, and the model filter is applied.
6	Only test cases are used, and the model filter is applied.
7	Both the training and testing cases are used, and the model filter is applied.

For more information about the scenarios in which you would use cross-validation, see [Testing and Validation \(Data Mining\)](#).

Examples

This example returns accuracy measures for two clustering models, named `[Cluster 1]` and `[Cluster 2]`, that are associated with the `vTargetMail` mining structure. The code on line four indicates that the results should be based on the testing cases alone, without using any filters that might be associated with each model.

```
CALL SystemGetClusterAccuracyResults (
    [vTargetMail],
    [Cluster 1], [Cluster 2],
    2
)
```

Sample Results:

MODELNAME	ATTRIBUTE NAME	ATTRIBUTES STATE	PARTITIONINDEX	PARTITIONSIZE	TEST	MEASURE	VALUE
Cluster 1			0	5545	Clustering	Case Likelihood	0.7965143 42249313
Cluster 2			0	5545	Clustering	Case Likelihood	0.7321224 71228572

Requirements

Cross-validation is available only in SQL Server Enterprise beginning in SQL Server 2008.

SQL Server Analysis Services server management

9/12/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

For Azure Analysis Services, see [Manage Azure Analysis Services](#).

Instances

A server instance of Analysis Services is a copy of the **msmdsrv.exe** executable that runs as an operating system service. Each instance is fully independent of other instances on the same server, having its own configuration settings, permissions, ports, startup accounts, file storage, and server mode properties.

Each instance runs as Windows service, Msmdsrv.exe, in the security context of a defined logon account.

- The service name of default instance is MSSQLServerOLAPService.
- The service name of each named instance of is MSOLAP\$InstanceName.

NOTE

If multiple instances are installed, Setup also installs a redirector service, which is integrated with the SQL Server Browser service. The redirector service is responsible for directing clients to the appropriate named instance of Analysis Services. The SQL Server Browser service always runs in the security context of the Local Service account, a limited user account used by Windows for services that do not access resources outside the local computer.

Multi-instance means that you can scale-up by installing multiple server instances on the same hardware. For Analysis Services in particular, it also means that you can support different server modes by having multiple instances on the same server, each one configured to run in a specific mode.

Server mode

Server mode is a server property that determines which storage and memory architecture is used for that instance. A server that runs in Multidimensional mode uses the resource management layer that was built for multidimensional cube databases and data mining models. In contrast, Tabular server mode uses the VertiPaq in-memory analytics engine and data compression to aggregate data as it is requested.

Differences in storage and memory architecture mean that a single instance of Analysis Services will run either tabular databases or multidimensional databases, but not both. The server mode property determines which type of database runs on the instance.

Server mode is set during installation when you specify the type of database that will run on the server. To support all available modes, you can install multiple instances of Analysis Services, each deployed in a server mode that corresponds to the projects you are building.

As a general rule, most of the administrative tasks you must perform do not vary by mode. As an Analysis Services system administrator, you can use the same procedures and scripts to manage any Analysis Services instance on your network regardless of how it was installed.

NOTE

The exception is Power Pivot for SharePoint. Server administration of a Power Pivot deployment is always within the context of a SharePoint farm. Power Pivot differs from other server modes in that it is always single-instance, and always managed through SharePoint Central Administration or the Power Pivot Configuration Tool. Although it is possible to connect to Power Pivot for SharePoint in SQL Server Management Studio or Visual Studio with Analysis Services projects, it is not desirable. A SharePoint farm includes infrastructure that synchronizes server state and oversees server availability. Using other tools can interfere with these operations. For more information about Power Pivot server administration, see [Power Pivot for SharePoint](#).

[Determine the Server Mode of an Analysis Services Instance](#)

High availability and Scalability in Analysis Services

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This article describes the most commonly used techniques for making Analysis Services databases highly available and scalable. While each objective could be addressed separately, in reality they often go hand in hand: a scalable deployment for large query or processing workloads typically comes with expectations of high availability.

The reverse case is not always true, however. High availability, without scale, can be the sole objective when stringent service level agreements exist for mission-critical, but moderate, query workloads.

Techniques for making Analysis Services highly available and scalable tend to be the same for all server modes (Multidimensional, Tabular, and SharePoint integrated mode). Unless specifically noted otherwise, you should assume the information in this article applies to all modes.

Key Points

Because the techniques for availability and scale differ from those of the relational database engine, a short summary of key points is an effective introduction to techniques used with Analysis Services:

- Analysis Services utilizes the high availability and scalability mechanisms built into the Windows server platform: network load balancing (NLB), Window Server Failover Clustering (WSFC), or both.

NOTE

The Always On feature of the relational database engine does not extend to Analysis Services. You cannot configure an Analysis Services instance to run in an Always On availability group.

Although Analysis Services does not run in Always On Availability Groups, it can both retrieve and process data from Always On relational databases. For instructions on how to configure a highly available relational database so that it can be used by Analysis Services, see [Analysis Services with Always On Availability Groups](#).

- High availability, as a sole objective, can be achieved via server redundancy in a failover cluster
Replacement nodes are assumed to have identical hardware and software configuration as the active node.
By itself, WSFC gives you high availability, but without scale.
- Scalability, with or without availability, is achieved via NLB over read-only databases. Scalability is usually a concern when query volumes are large or subject to sudden spikes.

Load balancing, coupled with multiple read-only databases, give you both scale and high availability because all nodes are active, and when a server goes down, requests are automatically redistributed among the remaining nodes. When you need both scalability and availability, an NLB cluster is the right choice.

For processing, objectives of high availability and scalability are less of a concern because you control the timing and scope of operations. Processing can be both partial and incremental across portions of a model, although at some point, you will need to process a model in full on a single server to ensure data consistency across all indexes and aggregations. A robust scalable architecture relies on hardware that can accommodate full processing at whatever cadence is required. For large solutions, this work is structured as an independent operation, with its own hardware resources.

Single vs. multi-server configurations

In a regular single-server deployment, processing and query workloads run concurrently, assuming system resources are sufficient for both activities. Analysis Services keeps existing data structures intact for query support while an updated version is being processed in the background. Having sufficient memory and disk space to handle temporary data structures is a hardware requirement that exists for all server modes, although each mode places different demands on system resources and comes with different levels of NUMA-awareness.

Single servers and scalability

A single high-end, multi-core server might provide sufficient scale on its own. On high end system with a large number of cores, RAM, and disk space, you can potentially scale-up within a single system.

For Multidimensional databases, you can adjust server configuration properties to create affinity between processes and processors. See [Thread Pool Properties](#) for more information.

Multi-server deployments

Sometimes operational requirements dictate the use of multiple servers. For example, failover clusters are multi-server by definition, with each node running on identical hardware and software configurations.

Similarly, a serious requirement for high availability of query workloads typically calls for multiple servers. In this scenario, the recommended configuration for Analysis Services is to use a mix of read-only and read-write databases, running on separate instances of Analysis Services, on dedicated hardware. Read-only databases handle query requests. Read-write databases are used for processing. An expanded description of this commonly used technique is provided in the next section.

Virtual machines and high availability

Another strategy for meeting a high availability requirement could include the use of virtual machines. If availability can be satisfied by standing up a replacement server within hours rather than minutes, you might be able to use virtual machines that can be started on demand, and loaded with updated databases retrieved from a central location.

Scalability using read-only and read-write databases

Network load balancing is recommended for high or escalating query and processing workloads. Analysis Services databases in a NLB solution are defined as read-only databases to ensure consistency across queries.

Although the guidance in [Scale-out querying for Analysis Services using read-only databases](#) (published in 2008) is dated, it's still generally valid. While server operating systems and computer hardware have evolved, and references to specific platforms and CPU limits are obsolete, the basic technique of using read-only and read-write databases for large query volumes is unchanged.

The approach can be summarized as follows:

- Use dedicated hardware and instances of Analysis Services to process the database. Set the database to read-only after processing is finished. See [Switch an Analysis Services database between ReadOnly and ReadWrite modes](#) for instructions.
- Use multiple, identical query servers to run copies of the same read-only Analysis Services database. Servers are deployed in an NLB cluster, accessed via one virtual server name that serves as a single point of entry to the cluster.
- Use robocopy to copy an entire data directory from the processing server to each query server and attach the same database in read-only mode to all query servers. You can also use SAN snapshots, synchronize, or any other tool or method you use for moving production databases.

Resource demands for Tabular and Multidimensional workloads

The following table is a high-level summary of how Analysis Services uses system resources for queries and processing, separated out by server mode and storage. This summary might help you understand what to emphasize in a multi-server deployment that handles a distributed workload.

Server and storage mode	Impact on system resource
Tabular in-memory (default) where queries are executed as table scans of in-memory data structures.	Emphasize RAM and CPUs with fast clock speeds.
Tabular in DirectQuery mode, where queries are offloaded to backend relational database servers and processing is limited to constructing metadata in the model.	Focus on relational database performance, lowering network latency, and maximizing throughput. Faster CPUs can also improve performance of the Analysis Services query processor.
Multidimensional models using MOLAP storage	Choose a balanced configuration that accommodates disk IO for loading data quickly and sufficient RAM for cached data.
Multidimensional models using ROLAP storage.	Maximize disk IO and minimize network latency.

High availability and redundancy through WSFC

Analysis Services can be installed into an existing Windows Server Failover Cluster (WSFC) to achieve high availability that restores service within the shortest time possible.

Failover clusters provide full access (read and writeback) to the database, but only one node at a time. Secondary databases run on additional nodes in the cluster, as replacement servers if the first node goes down.

The primary advantage of failover clustering is fast recovery from a service failure. This advantage comes with certain limitations. For one, if failover is never needed, dedicated resources in the cluster are idle. Second, in the event of a failover, all connections are lost, with the corresponding loss of uncommitted work. Most client applications should be able to handle this situation; often, hitting the refresh button in the application will bring the results back.

When considering a WSFC, keep the following points in mind:

- Active/Active is not currently supported. Active/Passive (failover) is the only supported WSFC configuration for Analysis Services.
- When clustering Analysis Services, make sure that any nodes participating in the cluster run on identical or highly similar hardware, and that the operational context of each node is the same in terms of operating system version and service packs, Analysis Services version and service packs (or cumulative updates), and server mode.
- Avoid repurposing a Passive node as another workload's Active node. Any short-term gains in computer utilization will be lost in the event of an actual failover situation if the node is unable to handle both workloads.

In-depth instructions and background information for deploying Analysis Services in a failover cluster are provided in this whitepaper: [How to Cluster SQL Server Analysis Services](#). Although written for SQL Server 2012, this guidance still applies to newer versions of Analysis Services.

[An Analysis Services Case Study: Using Tabular Models in a Large-scale Commercial Solution](#)

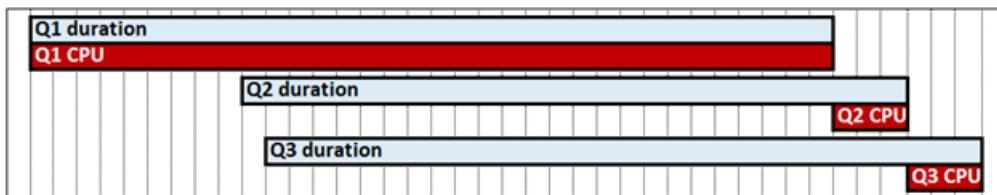

Query interleaving

11/8/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: ✓ SQL Server 2019 and later Analysis Services ✓ Azure Analysis Services ✗ Power BI Premium

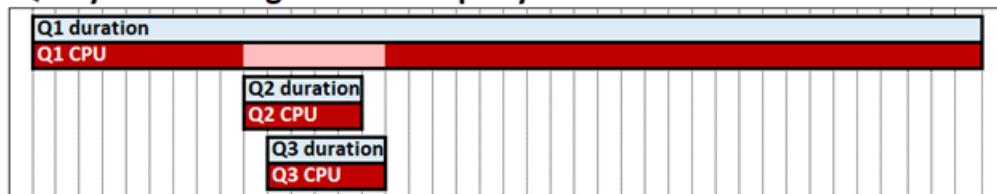

Query interleaving is a tabular mode system configuration that can improve query performance in high-concurrency scenarios. By default, the Analysis Services tabular engine works in a first-in, first-out (FIFO) fashion with regards to CPU. This means, for example, if one resource expensive and possibly slow storage-engine query is received, and then followed by two otherwise fast queries, the fast queries can potentially get blocked waiting for the expensive query to complete. This is shown in the following diagram, which shows Q1, Q2 and Q3 as the respective queries, their duration, and CPU time.

FIFO

Query interleaving with *short query bias* allows concurrent queries to share CPU resources. This means fast queries are not blocked behind slow queries. The time it takes to complete all three queries is still about the same, but in our example Q2 and Q3 are not blocked until the end. Short-query bias means fast queries, defined by how much CPU each query has already consumed at a given point in time can be allocated a higher proportion of resources than long-running queries. In the following diagram, Q2 and Q3 queries are deemed *fast* and allocated more CPU than Q1.

Query interleaving with short query bias

Query interleaving is intended to have little or no performance impact on queries that run in isolation; a single query can still consume as much CPU as it does with the FIFO model.

Important considerations

Before determining if query interleaving is right for your scenario, keep the following in mind:

- Query interleaving applies only for import models. It does not affect DirectQuery models.
- Query interleaving only considers CPU consumed by VertiPaq storage engine queries. It does not apply to formula engine operations.
- A single DAX query can result in multiple VertiPaq storage engine queries. A DAX query is deemed *fast* or *slow* based on CPU consumed by its storage engine queries. The DAX query is the unit of measurement.
- Refresh operations are by default protected from query interleaving. Long-running refresh operations are categorized differently to long-running queries.

Enable query interleaving

To enable query interleaving, set the **SchedulingBehavior** property. This property can be specified with the following values:

VALUE	DESCRIPTION
-1	Automatic. The engine will choose the queue type.
0 (default)	First in, first out (FIFO).
1	Short query bias. The engine gradually throttles long running queries when under pressure in favor of fast queries.

At this time, the SchedulingBehavior property can be set only by using XMLA. In SQL Server Management Studio, the following XMLA snippet sets the **SchedulingBehavior** property to **1**, short query bias.

```
<Alter AllowCreate="true" ObjectExpansion="ObjectProperties"
xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object />
  <ObjectDefinition>
    <Server xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xmlns:ddl2="http://schemas.microsoft.com/analysisservices/2003/engine/2"
    xmlns:ddl2_2="http://schemas.microsoft.com/analysisservices/2003/engine/2/2"
    xmlns:ddl100_100="http://schemas.microsoft.com/analysisservices/2008/engine/100/100"
    xmlns:ddl200="http://schemas.microsoft.com/analysisservices/2010/engine/200"
    xmlns:ddl200_200="http://schemas.microsoft.com/analysisservices/2010/engine/200/200"
    xmlns:ddl300="http://schemas.microsoft.com/analysisservices/2011/engine/300"
    xmlns:ddl300_300="http://schemas.microsoft.com/analysisservices/2011/engine/300/300"
    xmlns:ddl400="http://schemas.microsoft.com/analysisservices/2012/engine/400"
    xmlns:ddl400_400="http://schemas.microsoft.com/analysisservices/2012/engine/400/400"
    xmlns:ddl500="http://schemas.microsoft.com/analysisservices/2013/engine/500"
    xmlns:ddl500_500="http://schemas.microsoft.com/analysisservices/2013/engine/500/500">
      <ID>myserver</ID>
      <Name>myserver</Name>
      <ServerProperties>
        <ServerProperty>
          <Name>ThreadPool\SchedulingBehavior</Name>
          <Value>1</Value>
        </ServerProperty>
      </ServerProperties>
    </Server>
  </ObjectDefinition>
</Alter>
```

IMPORTANT

A restart of the server instance is required. In Azure Analysis Services, you must pause and then resume the server, effectively restarting.

Additional properties

In most cases, SchedulingBehavior is the only property you need to set. The following additional properties have defaults that should work in most scenarios with short query bias, however they can be changed if needed. The following properties *have no effect* unless query interleaving is enabled by setting the SchedulingBehavior property.

ReservedComputeForFastQueries - Sets the number of reserved logical cores for *fast* queries. All queries are deemed *fast* until they decay because they have used up a certain amount of CPU.

ReservedComputeForFastQueries is an integer between 0 and 100. The default value is 75.

The unit of measure for ReservedComputeForFastQueries is the percentage of cores. For example, a value of 80 on a server with 20 cores attempts to reserve 16 cores for fast queries (while no refresh operations are being performed). ReservedComputeForFastQueries rounds up to the nearest whole number of cores. It's recommended you do not set this property value below 50. This is because fast queries could be deprived and is counter to the overall design of the feature.

DecayIntervalCPUTime - An integer representing the CPU time in milliseconds that a query spends before it decays. If the system is under CPU pressure, decayed queries are limited to the remaining cores not reserved for fast queries. The default value is 60,000. This represents 1 minute of CPU time, not elapsed calendar time.

ReservedComputeForProcessing - Sets the number of reserved logical cores for each processing (data refresh) operation. The property value is an integer between 0 and 100, with a default value of 75 expressed. The value represents a percentage of the cores determined by the ReservedComputeForFastQueries property. A value of 0 (zero) means processing operations are subject to the same query interleaving logic as queries, so can be decayed.

While no processing operations are being performed, ReservedComputeForProcessing has no effect. For example, with a value of 80, ReservedComputeForFastQueries on a server with 20 cores reserves 16 cores for fast queries. With a value of 75, ReservedComputeForProcessing will then reserve 12 of the 16 cores for refresh operations, leaving 4 for fast queries while processing operations are running and consuming CPU. As described in the **Decayed queries** section below, the remaining 4 cores (not reserved for fast queries or processing operations) will still be used for fast queries and processing if idle.

Decayed queries

The constraints described in this section apply only if the system is under CPU pressure. For example, a single query, if it's the only one running in the system at a given time, can consume all the available cores regardless of whether it has decayed or not.

Each query may require many storage-engine jobs. When a core in the pool for decayed queries becomes available, the scheduler will check the oldest running query based on elapsed calendar time to see if it has already used up its **Maximum Core Entitlement** (MCE). If no, its next job is executed. If yes, the next oldest query is evaluated. The query MCE is determined by how many decay intervals it has already used. For each decay interval used, the MCE is reduced based on the algorithm shown in the table below. This continues until either the query completes, times out, or the MCE is reduced to a single core.

In the following example, the system has 32 cores, and the system's CPU is under pressure.

ReservedComputeForFastQueries is 60 (60%).

- 20 cores (19.2 rounded up) is reserved for fast queries.
- The remaining 12 cores are allocated for decayed queries.

DecayIntervalCPUTime is 60,000 (1 minute of CPU time).

The lifecycle of a query may be as follows, as long as it doesn't timeout or complete:

STAGE	STATUS	EXECUTION/SCHEDULING	MCE
0	Fast	The MCE is 20 cores (reserved for fast queries). Query is executed in a FIFO fashion with respect to other <i>fast</i> queries across the 20 reserved cores. Decay interval of 1 minute of CPU time is used up.	20 = MIN(32/2^0, 20)

STAGE	STATUS	EXECUTION/SCHEDULING	MCE
1	Decayed	The MCE is set to 12 cores (12 remaining cores not reserved for fast queries). Jobs are executed based on availability up to MCE. Decay interval of 1 minute of CPU time is used up.	$12 = \text{MIN}(32/2^1, 12)$
2	Decayed	The MCE is set to 8 cores (quarter of 32 total cores). Jobs are executed based on availability up to MCE. Decay interval of 1 minute of CPU time is used up.	$8 = \text{MIN}(32/2^2, 12)$
3	Decayed	The MCE is set to 4 cores. Jobs are executed based on availability up to MCE. Decay interval of 1 minute of CPU time is used up.	$4 = \text{MIN}(32/2^3, 12)$
4	Decayed	The MCE is set to 2 cores. Jobs are executed based on availability up to MCE. Decay interval of 1 minute of CPU time is used up.	$2 = \text{MIN}(32/2^4, 12)$
5	Decayed	The MCE is set to 1 core. Jobs are executed based on availability up to MCE. Decay interval does not apply as the query has bottomed. No further decay since minimum of 1 core is reached.	$1 = \text{MIN}(32/2^5, 12)$

If the system is under CPU pressure, each query will be assigned no more cores than its MCE. If all the cores are currently used by queries within their respective MCEs, then other queries wait until cores become available. As cores become available, the oldest entitled query based on its elapsed calendar time is picked up. The MCE is a cap under pressure; it doesn't guarantee that number of cores at any point in time.

[Server properties in Analysis Services](#)

Server properties in Analysis Services

9/6/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Administrators can modify default server configuration properties of an Azure Analysis Services (Azure AS) or SQL Server Analysis Services (SSAS) instance. To configure server properties, use SQL Server Management Studio.

Properties pages in SQL Server Management Studio show a subset of the properties most likely to be modified. For SSAS, all properties are in the msmdsrv.ini file. In a default installation, msmdsrv.ini can be found in the \Program Files\Microsoft SQL Server\MSAS13.MSSQLSERVER\OLAP\Config folder.

Configure properties by using SQL Server Management Studio

1. In SQL Server Management Studio, connect to an Azure AS or SSAS instance.
2. In Object Explorer, right-click the instance, and then click **Properties**. The General page appears, displaying the more commonly used properties.
3. To view additional properties, click the **Show Advanced (All) Properties** checkbox at the bottom of the page.

Modifying server properties is supported only for tabular mode and multidimensional mode servers. If you installed Power Pivot for SharePoint, always use the default values unless otherwise directed otherwise by Microsoft Support.

Configure properties in msmdsrv.ini

Some properties can only be set in the msmdrsrv.ini file. These properties do not apply to Azure Analysis Services. If the property you want to set is not visible even after you show advanced properties, you might need to edit the msmdsrv.ini file directly.

1. Check the **DataDir** property in the General property page in Management Studio to verify the location of the Analysis Services program files, including the msmdsrv.ini file.

On a server that has multiple instances, checking the program file location ensures you're modifying the correct file.
2. Navigate to the **config** folder of the program files folder location.
3. Create a backup of the file in case you need to revert to the original file.
4. Use a text editor to view or edit the msmdsrv.ini file.
5. Save the file and restart the service.

Configure properties by using XMLA

Properties that cannot be set by using Properties in SSMS or in msmdrsrv.ini file can be set by using the [XMLA Alter Element](#) in an XMLA script in SSMS.

Server property categories

The following topics describe the various Analysis Services configuration properties:

Topic	Description
General Properties	The general properties are both basic and advanced properties, and include properties that define the data directory, backup directory, and other server behaviors.
Data Mining Properties	The data mining properties control which data mining algorithms are enabled and which are disabled. By default, all of the algorithms are enabled.
DAX Properties	Defines properties related to DAX queries.
DSO	DSO is no longer supported. DSO properties are ignored.
Feature Properties	The feature properties pertain to product features, most of them advanced, including properties that control links between server instances.
Filestore Properties	The file store properties are for advanced use only. They include advanced memory management settings.
Lock Manager Properties	The lock manager properties define server behaviors pertaining to locking and timeouts. Most of these properties are for advanced use only.
Log Properties	The log properties controls if, where, and how events are logged on the server. This includes error logging, exception logging, flight recorder, query logging, and traces.
Memory Properties	The memory properties control how the server uses memory. They are primarily for advanced use.
Network Properties	The network properties control server behavior pertaining to networking, including properties that control compression and binary XML. Most of these properties are for advanced use only.
OLAP Properties	The OLAP properties control cube and dimension processing, lazy processing, data caching, and query behavior. These include both basic and advanced properties.
Security Properties	The security section contains both basic and advanced properties that define access permissions. This includes settings pertaining to administrators and users.
Thread Pool Properties	The thread pool properties control how many threads the server creates. These are primarily advanced properties.

Data mining properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services supports the data mining server properties listed in the following tables. For more information about additional server properties and how to set them, see [Server properties in Analysis Services](#).

Applies to: Multidimensional server mode only

Non-specific category

AllowSessionMiningModels

A Boolean property that indicates whether session mining models can be created.

The default value for this property is false, which indicates that session mining models cannot be created.

AllowAdHocOpenRowsetQueries

A Boolean property that indicates whether adhoc open rowset queries are allowed.

The default value for this property is false, which indicates that open rowset queries are not allowed during a session.

AllowedProvidersInOpenRowset

A string property that identifies which providers are allowed in an open rowset, consisting of a comma/semi-colon separated list of provider ProgIDs, or else [All].

MaxConcurrentPredictionQueries

A signed 32-bit integer property that defines the maximum number of concurrent prediction queries.

Algorithms category

Microsoft_Association_Rules\ Enabled

A Boolean property that indicates whether the Microsoft_Association_Rules algorithm is enabled.

Microsoft_Clustering\ Enabled

A Boolean property that indicates whether the Microsoft_Clustering algorithm is enabled.

Microsoft_Decision_Trees\ Enabled

A Boolean property that indicates whether the Microsoft_DecisionTrees algorithm is enabled.

Microsoft_Naive_Bayes\ Enabled

A Boolean property that indicates whether the Microsoft_Naive_Bayes algorithm is enabled.

Microsoft_Neural_Network\ Enabled

A Boolean property that indicates whether the Microsoft_Neural_Network algorithm is enabled.

Microsoft_Sequence_Clustering\ Enabled

A Boolean property that indicates whether the Microsoft_Sequence_Clustering algorithm is enabled.

Microsoft_Time_Series\ Enabled

A Boolean property that indicates whether the Microsoft_Time_Series algorithm is enabled.

Microsoft_Linear_Regression\ Enabled

A Boolean property that indicates whether the Microsoft_Linear_Regression algorithm is enabled.

Microsoft_Logistic_Regression\ Enabled

A Boolean property that indicates whether the Microsoft_Logistic_Regression algorithm is enabled.

NOTE

In addition to properties that define the data mining services available on the server, there are data mining properties that define the behavior of specific algorithms. You configure these properties when you create an individual data mining model, not at the server level. For more information, see [Data Mining Algorithms \(Analysis Services - Data Mining\)](#).

[Physical Architecture \(Analysis Services - Data Mining\)](#)

[Server properties in Analysis Services](#)

[Determine the Server Mode of an Analysis Services Instance](#)

DAX properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

For SQL Server Analysis Services, the DAX section of msmdsrv.ini contains settings used to control certain query behaviors in Analysis Services, such as the upper limit on the number of rows returned in a DAX query result set. For Azure Analysis Services, this property can be specified by using XMLA.

For very large rowsets, such as those returned in DirectQuery models, the default of one million rows could be insufficient. You'll know whether the limit needs adjusting if you get this error: "The result set of a query to external data source has exceeded the maximum allowed size of '1000000' rows."

To increase the upper limit, specify the **MaxIntermediateRowSize** configuration setting. You will need to manually add the entire element to the DAX section of the configuration file. The setting is not present in the file until you add it.

Configuration snippet (msmdsrv.ini)

```
<ConfigurationSettings>
. . .
<DAX>
  <PredicateCheckSpoolCardinalityThreshold>5000
  </PredicateCheckSpoolCardinalityThreshold>
  <DQ>
    <MaxIntermediateRowsetSize>1000000
    </MaxIntermediateRowsetSize>
  </DQ>
</DAX>
. . .
```

Property descriptions

SETTING	VALUE	DESCRIPTION
MaxIntermediateRowsetSize	1000000	Maximum number of rows returned in a DAX query. For SSAS, manually add this entry to the msmdsrv.ini file and increase the value if the default is too low.
PredicateCheckSpoolCardinalityThreshold	5000	An advanced property that you should not change, except under the guidance of Microsoft support.

For more information about additional server properties and how to set them, see [Server properties in Analysis Services](#).

Feature properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Feature properties pertain to product features, most of them advanced, including properties that control links between server instances.

Analysis Services supports the server properties listed in the following table. For more information about additional server properties and how to set them, see [Server properties in Analysis Services](#).

Applies to: Multidimensional server mode only

Properties

PROPERTY	DEFAULT	DESCRIPTION
ManagedCodeEnabled	1	A Boolean property that indicates whether CLR storage procedures are enabled.
LinkInsideInstanceEnabled	1	A Boolean property that indicates whether a linked object can be created inside the same server instance.
LinkToOtherInstanceEnabled	0	A Boolean property that indicates whether objects on remote servers can be linked to.
LinkFromOtherInstanceEnabled	0	A Boolean property that indicates whether objects can be linked to from other server instances.
ConnStringEncryptionEnabled	1	A Boolean property that indicates whether the connection string is encrypted in the server configuration file.
UseCachedPageAllocators	0	A Boolean property that indicates whether cached page allocators are enabled.
ComUdfEnabled	0	A Boolean property that indicates whether user-defined functions defined as COM objects are enabled.
SQMSupportEnabled	1	A Boolean property that indicates whether error and feature usage reports are sent to Microsoft automatically.

PROPERTY	DEFAULT	DESCRIPTION
ResourceMonitoringEnabled	1	<p>A Boolean property that indicates whether internal resource monitoring counters are enabled. This property is on by default. When enabled, this property allows counters to collect usage data about CPU, memory, and I/O activity.</p> <p>Internal resource monitoring counters are used by Dynamic Management Views (DMV) that report on resource utilization. If you disable this property, the DMV queries will still run, but the result set will be invalid. DMVs that depend on this property include the following:</p> <p style="text-align: center;">DISCOVER_OBJECT_ACTIVITY</p> <p style="text-align: center;">DISCOVER_COMMAND_OBJECTS</p> <p style="text-align: center;">DISCOVER_SESSIONS (for SESSION_READS, SESSION_WRITES, SESSION_CPU_TIME_MS)</p> <p>Note: On a multi-core system that uses NUMA architecture, disabling this property can improve query performance, particularly for high multi-user workloads. You will need to run comparison tests to determine whether query performance is improved as the result of changing this property. For best practices on running comparison tests, including clearing the cache and avoiding common mistakes, see the SQL Server 2008 R2 Analysis Services Operations Guide.</p>

[Use Dynamic Management Views \(DMVs\) to monitor Analysis Services](#)

Filestore properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services supports the following filestore properties. These are all advanced properties that you should not change, except under the guidance of Microsoft support.

Applies to: Multidimensional and tabular server mode unless noted otherwise.

Properties

MemoryLimit

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryLimitMin

An advanced property that you should not change, except under the guidance of Microsoft support.

PercentScanPerPrice

An advanced property that you should not change, except under the guidance of Microsoft support.

PerformanceTrace

An advanced property that you should not change, except under the guidance of Microsoft support.

Random FileAccess Mode

A Boolean property that indicates whether database files and cached files are accessed in random file access mode. This property is off by default. By default, the server does not set the random file access flag when opening partition data files for read access.

On high-end systems, particularly those with large memory resources and multiple NUMA nodes, it can be advantageous to use random file access. In random access mode, Windows bypasses page-mapping operations that read data from disk into the system file cache, thereby lowering contention on the cache.

You will need to run comparison tests to determine whether query performance is improved as the result of changing this property. For best practices on running comparison tests, including clearing the cache and avoiding common mistakes, see the [SQL Server 2008 R2 Analysis Services Operations Guide](#). For additional information on the tradeoffs of using this property, see <https://support.microsoft.com/kb/2549369>.

To view or modify this property in Management Studio, enable the advanced properties list in the server properties page. You can also change the property in the msmdsrv.ini file. Restarting the server is recommended after setting this property; otherwise files that are already open will continue to be accessed in the previous mode.

UnbufferedThreshold

An advanced property that you should not change, except under the guidance of Microsoft support.

Memory Model category

MemoryModel\Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryModel\Income

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryModel\MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryModel\MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryModel\InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

[Server properties in Analysis Services](#)

[Determine the Server Mode of an Analysis Services Instance](#)

General properties

9/6/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services supports the following server properties. This article describes those server properties in the msmdsrv.ini file that are not otherwise included in a specific section, such as Security, Network, or ThreadPool.

Applies to: Multidimensional and tabular server mode unless noted otherwise.

Non-specific category

AdminTimeout

A signed 32-bit integer property that defines the administrator timeout in seconds. This is an advanced property that you should not change, except under the guidance of Microsoft support.

The default value for this property is zero (0), which indicates there is no timeout.

AllowedBrowsingFolders

A string property that specifies in a delimited list the folders that can be browsed when saving, opening, and finding files in Analysis Services dialog boxes. The Analysis Services service account must have read and write permissions to any folders that you add to the list.

AutoSetDefaultInitialCatalog

A Boolean property. When set to true, new client connections automatically default to the first catalog (database) the user has permissions to connect to.

When set to false, no initial catalog is specified. Clients must select a default catalog prior to running queries or discover operations against a database on the server. If no default catalog is specified, an error is returned. If Initial Catalog property is specified in the connection string, the default catalog will be applied from this property.

The default value for this property is true.

BackupDir

A string property that identifies the name of the directory where backup files are stored by default, in the event a path is not specified as part of the Backup command.

ClientCacheRefreshPolicy Applies to Azure Analysis Services and SQL Server 2019 and later only. Overrides the **Scheduled cache refresh** setting for all Power BI datasets. All Live Connect reports will observe the server-level setting irrespective of the dataset-level setting, or which workspace they reside on.

The default value for this property is -1, which allows all background cache refreshes as specified in the Scheduled cache refresh setting for the dataset. To discourage all background cache refreshes, specify zero (0).

CollationName

A string property that identifies the server collation. For more information, see [Languages and Collations \(Analysis Services\)](#).

CommitTimeout

An integer property that specifies how long (in milliseconds) the server will wait to acquire a write lock for the purpose of committing a transaction. A waiting period is often required because the server must wait for other locks to be released before it can take a write lock that commits the transaction.

The default value for this property is zero (0), which indicates that the server will wait indefinitely. For more information about lock-related properties, see [SQL Server 2008 R2 Analysis Services Operations Guide](#).

CoordinatorBuildMaxThreads

A signed 32-bit integer property that defines the maximum number of threads allocated to building partition indexes. Increase this value in order to speed-up partition indexing, at the cost of memory usage. For more information about this property, see [SQL Server 2008 R2 Analysis Services Operations Guide](#).

CoordinatorCancelCount

A signed 32-bit integer property that defines how frequently the server should check whether a Cancel event occurred (based on internal iteration count). Decrease this number in order to check for Cancel more frequently, at the expense of general performance. This property is ignored in tabular server mode.

CoordinatorExecutionMode

A signed 32-bit integer property that defines the maximum number of parallel operations the server will attempt, including processing and querying operations. Zero (0) indicates that the server will decide, based on an internal algorithm. A positive number indicates the maximum number of operations in total. A negative number, with the sign reversed, indicates the maximum number of operations per processor.

The default value for this property is -4, which indicates the server is limited to 4 parallel operations per processor. For more information about this property, see [SQL Server 2008 R2 Analysis Services Operations Guide](#).

CoordinatorQueryMaxThreads

A signed 32-bit integer property that defines the maximum number of threads per partition segment during query resolution. The fewer the number of concurrent users, the higher this value can be, at the cost of memory. Conversely, it may need to be lowered if there are a large number of concurrent users.

CoordinatorShutdownMode

A Boolean property that defines coordinator shutdown mode. This is an advanced property that you should not change, except under the guidance of Microsoft support.

DataDir

A string property that identifies the name of the directory where data is stored.

DeploymentMode

Determines the operational context of an Analysis Services server instance. This property is referred to as 'server mode' in dialog boxes, messages, and documentation. This property is configured by SQL Server Setup based on the server mode you selected when installing Analysis Services. This property should be considered internal only, always using the value specified by Setup.

Valid values for this property include the following:

VALUE	DESCRIPTION
0	This is the default value. It specifies multidimensional mode, used to service multidimensional databases that use MOLAP, HOLAP, and ROLAP storage, as well as data mining models.
1	Specifies Analysis Services instances that were installed as part of a Power Pivot for SharePoint deployment. Do not change the deployment mode property of Analysis Services instance that is part of a Power Pivot for SharePoint installation. Power Pivot data will no longer run on the server if you change the mode.
2	Specifies Tabular mode used for hosting tabular model databases that use in-memory storage or DirectQuery storage.

Each mode is exclusive of the other. A server that is configured for tabular mode cannot run Analysis Services databases that contain cubes and dimensions. If the underlying computer hardware can support it, you can install

multiple instances of Analysis Services on the same computer and configure each instance to use a different deployment mode. Remember that Analysis Services is a resource intensive application. Deploying multiple instances on the same system is recommended only for high-end servers.

EnableFast1033Locale

An advanced property that you should not change, except under the guidance of Microsoft support.

ExternalCommandTimeout

An integer property that defines the timeout, in seconds, for commands issued to external servers, including relational data sources and external Analysis Services servers.

The default value for this property is 3600 (seconds).

ExternalConnectionTimeout

An integer property that defines the timeout, in seconds, for creating connections to external servers, including relational data sources and external Analysis Services servers. This property is ignored if a connection timeout is specified on the connection string.

The default value for this property is 60 (seconds).

ForceCommitTimeout

An integer property that specifies how long, in milliseconds, a write commit operation should wait before canceling other commands that preceded the current command, including queries in progress. This allows the commit transaction to proceed by canceling lower priority operations, such as queries.

The default value for this property is 30 seconds (30000 milliseconds), which indicates that other commands will not be forced to timeout until the commit transaction has been waiting for 30 seconds.

NOTE

Queries and processes cancelled by this event will report the following error message:

`Server: The operation has been cancelled`

For more information about this property, see [SQL Server 2008 R2 Analysis Services Operations Guide](#).

IMPORTANT

ForceCommitTimeout applies to cube processing commands and to writeback operations.

IdleConnectionTimeout

An integer property that specifies a timeout, in seconds, for connections that are inactive.

The default value for this property is zero (0), which indicates that idle connections will not be timed out.

IdleOrphanSessionTimeout

An integer property that defines how long, in seconds, orphaned sessions will be retained in server memory. An orphaned session is one that no longer has an associated connection. The default is 120 seconds.

InstanceVisible

A Boolean property that indicates whether the server instance is visible to discover instance requests from SQL Server Browser service. The default is True. If you set it to false, the instance is not visible to SQL Server Browser.

Language

A string property that defines the language, including error messages and number formatting. This property overrides the CollationName property.

The default value for this property is blank, which indicates that the CollationName property defines the language.

LogDir

A string property that identifies the name of the directory that contains server logs. This property only applies when disk files are used for logging, as opposed to database tables (the default behavior).

MaxIdleSessionTimeout

An integer property that defines the maximum idle session timeout, in seconds. The default is zero (0), indicating that sessions are never timed out. However, idle sessions will still be removed if the server is under resource constraints.

MinIdleSessionTimeout

An integer property that defines the minimum time, in seconds, that idle sessions will timeout. The default is 2700 seconds. After this time expires, the server is permitted to end the idle session, but will only do so as memory is needed.

Port

An integer property that defines the port number on which server will listen for client connections. If not set, server dynamically finds first unused port.

The default value for this property is zero (0), which in turn defaults to port 2383. For more information about port configuration, see [Configure the Windows Firewall to Allow Analysis Services Access](#).

ServerTimeout

An integer that defines the timeout, in seconds, for queries. The default is 3600 seconds (or 60 minutes). Zero (0) specifies that no queries will timeout.

TempDir

A string property that specifies the location for storing temporary files used during processing, restoring, and other operations. The default value for this property is determined by setup. If not specified, the default is the Data directory.

RequestPrioritization category

Enabled

An advanced property that you should not change, except under the guidance of Microsoft support.

StatisticsStoreSize

An advanced property that you should not change, except under the guidance of Microsoft support.

[Determine the Server Mode of an Analysis Services Instance](#)

Lock manager properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services supports the following lock manager server properties.

Applies to: Multidimensional and tabular server mode

Properties

DefaultLockTimeoutMS

A signed 32-bit integer property that defines default lock timeout in milliseconds for internal lock requests.

The default value for this property is -1, which indicates there is no timeout for internal lock requests.

LockWaitGranularityMS

An advanced property that you should not change, except under the guidance of Microsoft support.

DeadlockDetectionGranularityMS

An advanced property that you should not change, except under the guidance of Microsoft support.

[Server properties in Analysis Services](#)

[Determine the Server Mode of an Analysis Services Instance](#)

Log Properties

9/6/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services supports the log server properties listed in the following tables. For more information about additional server properties and how to set them, see [Server properties in Analysis Services](#).

NOTE

Not all properties apply to Azure Analysis Services.

General

File

A string property that identifies the name of the server log file. This property only applies when a disk file is used for logging, as opposed to a database table (the default behavior).

The default value for this property is msmdsrv.log.

FileBufferSize

An advanced property that you should not change, except under the guidance of Microsoft support.

MessageLogs

An advanced property that you should not change, except under the guidance of Microsoft support.

Error Log

You can set these properties at the server instance level to modify the default values for Error Configuration that appear in other tools and designers. See [Error Configuration for Cube, Partition, and Dimension Processing \(SSAS - Multidimensional\)](#) and [ErrorConfiguration](#) for more information.

ErrorLog\ErrorLogFileName

A property used as a default during processing operation performed by the server.

ErrorLog\ErrorLogFileSize

A property used as a default during processing operation performed by the server.

ErrorLog\KeyErrorAction

Specifies the action taken by the server when a **KeyNotFound** error occurs. Valid responses to this error include:

- **ConvertToUnknown** tells the server to allocate the error key value to the unknown member.
- **DiscardRecord** tells the server to exclude the record.

ErrorLog\KeyErrorLogFile

This is a user-defined filename that must have a .log file extension, located in a folder on which the service account has read-write permissions. This log file will only contain errors generated during processing. Use the Flight Recorder if you require more detailed information.

ErrorLog\KeyErrorLimit

This is the maximum number of data integrity errors that the server will allow before failing the processing. A value of -1 indicates that there is no limit. The default is 0, which means processing stops after the first error.

occurs. You can also set it to a whole number.

ErrorLog\KeyErrorLimitAction

Specifies the action taken by the server when the number of key errors has reached the upper limit. Valid responses to this action include:

- **StopProcessing** tells the server to stop processing when the error limit is reached.
- **StopLogging** tells the server to stop logging errors when the error limit is reached, but allow processing to continue.

ErrorLog\ LogErrorTypes\KeyNotFound

Specifies the action taken by the server when a **KeyNotFound** error occurs. Valid responses to this error include:

- **IgnoreError** tells the server to continue processing without logging the error or counting it towards the key error limit. By ignoring the error, you simply allow processing to continue without adding to the error count or logging it to the screen or log file. The record in question has a data integrity problem and cannot be added to the database. The record will either be discarded or aggregated to Unknown Member, as determined by the **KeyErrorAction** property.
- **ReportAndContinue** tells the server to log the error, count it towards the key error limit, and continue processing. The record triggering the error is discarded or converted to Unknown Member.
- **ReportAndStop** tells the server to log the error and stop processing immediately, regardless of the key error limit. The record triggering the error is discarded or converted to Unknown Member.

ErrorLog\ LogErrorTypes\KeyDuplicate

Specifies the action taken by the server when a duplicate key is found. Valid values include **IgnoreError** to continue processing as if the error did not occur, **ReportAndContinue** to log the error and continue processing, and **ReportAndStop** to log the error and stop processing immediately, even if the error count is below the error limit.

ErrorLog\ LogErrorTypes\NullKeyConvertedToUnknown

Specifies the action taken by the server when a null key has been converted to Unknown Member. Valid values include **IgnoreError** to continue processing as if the error did not occur, **ReportAndContinue** to log the error and continue processing, and **ReportAndStop** to log the error and stop processing immediately, even if the error count is below the error limit.

ErrorLog\ LogErrorTypes\NullKeyNotAllowed

Specifies the action taken by the server when **NullProcessing** is set to **Error** for a dimension attribute. An error is generated when a null value is not allowed in a given attribute. This error configuration property informs the next step, which is to report the error and continue processing until the error limit is reached. Valid values include **IgnoreError** to continue processing as if the error did not occur, **ReportAndContinue** to log the error and continue processing, and **ReportAndStop** to log the error and stop processing immediately, even if the error count is below the error limit.

ErrorLog\ LogErrorTypes\CalculationError

A property used as a default during processing operation performed by the server.

ErrorLog\IgnoreDataTruncation

A property used as a default during processing operation performed by the server.

Exception

Exception\CreateAndSendCrashReports

An advanced property that you should not change, except under the guidance of Microsoft support.

Exception\CrashReportsFolder

An advanced property that you should not change, except under the guidance of Microsoft support.

Exception\SQLDumperFlagsOn

An advanced property that you should not change, except under the guidance of Microsoft support.

Exception\SQLDumperFlagsOff

An advanced property that you should not change, except under the guidance of Microsoft support.

Exception\MiniDumpFlagsOn

An advanced property that you should not change, except under the guidance of Microsoft support.

Exception\MinidumpErrorList

An advanced property that you should not change, except under the guidance of Microsoft support.

Flight Recorder

FlightRecorder\Enabled

A Boolean property that indicates whether the flight recorder feature is enabled.

FlightRecorder\FileSizeMB

A signed 32-bit integer property that defines the size of the flight recorder disk file, in megabytes.

FlightRecorder\LogDurationSec

A signed 32-bit integer property that defines the frequency that the flight recorder is rolled over, in seconds.

FlightRecorder\SnapshotDefinitionFile

A string property that defines the name of the snapshot definition file, containing discover commands that are issued to the server when a snapshot is taken.

The default value for this property is blank, which in turn defaults to file name FlightRecorderSnapshotDef.xml.

FlightRecorder\SnapshotFrequencySec

A signed 32-bit integer property that defines the snapshot frequency, in seconds.

FlightRecorder\TraceDefinitionFile

A string property that specifies the name of the flight recorder trace definition file.

The default value for this property is blank, which in turn defaults to FlightRecorderTraceDef.xml.

Query Log

Applies to: Multidimensional server mode only

QueryLog\QueryLogFileName

A string property that specifies the name of the query log file. This property only applies when a disk file is used for logging, as opposed to a database table (the default behavior).

QueryLog\QueryLogSampling

A signed 32-bit integer property that specifies the query log sampling rate.

The default value for this property is 10, meaning that 1 out of every 10 server queries is logged.

QueryLog\QueryLogFileSize

An advanced property that you should not change, except under the guidance of Microsoft support.

QueryLog\QueryLogConnectionString

A string property that specifies the connection to the query log database.

QueryLog\QueryLogTableName

A string property that specifies the name of the query log table.

The default value for this property is OlapQueryLog.

QueryLog\CreateQueryLogTable

A Boolean property that specifies whether to create the query log table.

The default value for this property is false, which indicates the server will not automatically create the log table and will not log query events.

Trace

Trace\TraceBackgroundDistributionPeriod

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceBackgroundFlushPeriod

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceFileBufferSize

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceFileWriteTrailerPeriod

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceMaxRowsetSize

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceProtocolTraffic

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceQueryResponseTextChunkSize

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceReportFQDN

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceRequestParameters

An advanced property that you should not change, except under the guidance of Microsoft support.

Trace\TraceRowsetBackgroundFlushPeriod

An advanced property that you should not change, except under the guidance of Microsoft support.

[Determine the Server Mode of an Analysis Services Instance](#)

Memory properties

9/6/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services pre-allocates a modest amount of memory at startup so requests can be handled immediately. Additional memory is allocated as query and processing workloads increase. By specifying configuration settings, you can control the thresholds at which memory is released. For example, the **HardMemoryLimit** setting specifies a self-imposed out-of-memory condition (by default, this threshold is not enabled), where new requests are rejected outright until more resources become available. The following settings apply to both tabular and multidimensional servers unless noted otherwise.

Default memory configuration

Under the default configuration, each instance allocates a small amount of RAM (40 MB to 50 MB) at startup, even if the instance is idle. Configuration settings are per instance. If you are running multiple instances, such as a tabular and multidimensional instance on the same hardware, each instance will allocate its own memory independently of other instances.

SETTING	DESCRIPTION
LowMemoryLimit	For multidimensional instances, a lower threshold at which the server first begins releasing memory allocated to infrequently used objects.
VertiPaqMemoryLimit	For tabular instances, a lower threshold at which the server first begins releasing memory allocated to infrequently used objects.
TotalMemoryLimit	An upper threshold at which Analysis Services begins releasing memory more aggressively to make room for requests that are in execution as well as new high priority requests.
HardMemoryLimit	Another threshold at which Analysis Services begins rejecting requests outright due to memory pressure.

Property reference

The following properties apply to both tabular and multidimensional modes unless specified otherwise.

Values between 1 and 100 represent percentages of **Total Physical Memory** or **Virtual Address Space**, whichever is less. Values over 100 represent memory limits in bytes.

LowMemoryLimit

A signed 64-bit double-precision floating-point number property that defines the first threshold at which Analysis Services begins releasing memory for low-priority objects, such as an infrequently used cache. Once the memory is allocated, the server does not release memory below this limit. The default value is 65; which indicates the low memory limit is 65% of physical memory or the virtual address space, whichever is less.

TotalMemoryLimit

Defines a threshold that when reached, causes the server to deallocate memory to make room for other requests.

When this limit is reached, the instance will start to slowly clear memory out of caches by closing expired sessions and unloading unused calculations. The default value 80% of physical memory or the virtual address space, whichever is less. **TotalMemoryLimit** must always be less than **HardMemoryLimit**

HardMemoryLimit

Specifies a memory threshold after which the instance aggressively terminates active user sessions to reduce memory usage. All terminated sessions will receive an error about being canceled by memory pressure. The default value, zero (0), means the **HardMemoryLimit** will be set to a midway value between **TotalMemoryLimit** and the total physical memory of the system; if the physical memory of the system is larger than the virtual address space of the process, then virtual address space will be used instead to calculate **HardMemoryLimit**.

QueryMemoryLimit

Applies to Azure Analysis Services and SQL Server 2019 and later only. An advanced property to control how much memory can be used by temporary results during a query. Applies only to DAX measures and queries. It does not account for general memory allocations used by the query. Specified in percentage up to 100. Beyond that, it's in bytes. Setting a value of 0 means no limit is specified. For Azure Analysis, the default value is determined by your plan.

PLAN	DEFAULT
D1	80
All other plans	20

VirtualMemoryLimit

An advanced property that you should not change, except under the guidance of Microsoft support.

VertiPaqPagingPolicy

For tabular instances only, specifies the paging behavior in the event the server runs low on memory. Valid values are as follows:

SETTING	DESCRIPTION
0	(default for Azure Analysis Services) Disables paging. If memory is insufficient, processing fails with an out-of-memory error. If you disable paging, you must grant Windows privileges to the service account. See Configure Service Accounts (Analysis Services) for instructions.
1	(default for SQL Server Analysis Services) This property enables paging to disk using the operating system page file (pagefile.sys).

When set to 1, processing is less likely to fail due to memory constraints because the server will try to page to disk using the method that you specified. Setting the **VertiPaqPagingPolicy** property does not guarantee that memory errors will never happen. Out of memory errors can still occur under the following conditions:

- There is not enough memory for all dictionaries. During processing, the server locks the dictionaries for each column in memory, and all of these together cannot be more than the value specified for **VertiPaqMemoryLimit**.
- There is insufficient virtual address space to accommodate the process.

To resolve persistent out of memory errors, you can either try to redesign the model to reduce the amount of data that needs processing, or you can add more physical memory to the computer.

VertiPaqMemoryLimit

For tabular instances only, if paging to disk is allowed, this property specifies the level of memory consumption (as a percentage of total memory) at which paging starts. The default is 60. If memory consumption is less than 60 percent, the server will not page to disk. This property depends on the **VertiPaqPagingPolicyProperty**, which must be set to 1 in order for paging to occur.

HighMemoryPrice

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryHeapType

An advanced property that you should not change, except under the guidance of Microsoft support. Valid values in SQL Server 2016 SP1 and later Analysis Services are as follows:

SETTING	DESCRIPTION
-1	(default) Automatic. The engine will decide which one to use.
1	Analysis Services HEAP.
2	Windows LFH.
5	Hybrid allocator. This allocator will use Windows LFH for <= 16 KB allocations and the AS Heap for >16 KB allocations.
6	Intel TBB allocator. Available in SQL Server 2016 SP1 (and later) Analysis Services.

HeapTypeForObjects

An advanced property that you should not change, except under the guidance of Microsoft support. Valid values are as follows:

SETTING	DESCRIPTION
-1	(default) Automatic. The engine will decide which one to use.
0	Windows LFH heap.
1	Analysis Services slot allocator.
3	Each object has its own Analysis Services Heap.

DefaultPagesCountToReuse

An advanced property that you should not change, except under the guidance of Microsoft support.

HandleIA64AlignmentFaults

An advanced property that you should not change, except under the guidance of Microsoft support.

MidMemoryPrice

An advanced property that you should not change, except under the guidance of Microsoft support.

MinimumAllocatedMemory

An advanced property that you should not change, except under the guidance of Microsoft support.

PreAllocate

An advanced property that you should not change, except under the guidance of Microsoft support.

SessionMemoryLimit

An advanced property that you should not change, except under the guidance of Microsoft support.

WaitCountIfHighMemory

An advanced property that you should not change, except under the guidance of Microsoft support.

[Server properties in Analysis Services](#)

[Determine the Server Mode of an Analysis Services Instance](#)

Network properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: ✓ SQL Server Analysis Services ✓ Azure Analysis Services ✗ Power BI Premium

Analysis Services supports the following server properties. Not all properties apply to Azure Analysis Services.

Applies to: Multidimensional and tabular server mode unless noted otherwise.

General

ListenOnlyOnLocalConnections

A Boolean property that identifies whether to listen only on local connections, for example localhost.

Listener

IPV4Support

A signed 32-bit integer property that defines support for IPv4 protocol. This property has one of the values listed in the following table:

VALUE	DESCRIPTION
0	IPv4 disabled; clients can't connect.
1	(Default) IPv4 is required; server won't start if it cannot listen to IPv4.
2	IPv4 is optional; server tries to listen to IPv4 but starts even if unable to.

IPV6Support

A signed 32-bit integer property that defines support for IPv6 protocol. This property has one of the values listed in the following table:

VALUE	DESCRIPTION
0	IPv6 disabled; clients can't connect.
1	(Default) IPv6 is required; server won't start if it cannot listen to IPv6.
2	IPv6 is optional; server tries to listen to IPv6 but starts even if unable to.

MaxAllowedRequestSize

An advanced property that you should not change, except under the guidance of Microsoft support.

RequestSizeThreshold

An advanced property that you should not change, except under the guidance of Microsoft support.

ServerReceiveTimeout

An advanced property that you should not change, except under the guidance of Microsoft support.

ServerSendTimeout

An advanced property that you should not change, except under the guidance of Microsoft support.

Requests

EnableBinaryXML

A Boolean property that specifies whether the server will recognize requests binary xml format.

EnableCompression

A Boolean property that specifies whether compression is enabled for requests.

Responses

CompressionLevel

An advanced property that you should not change, except under the guidance of Microsoft support.

EnableBinaryXML

A Boolean property that specifies whether the server is enabled for binary xml responses.

EnableCompression

A Boolean property that specifies whether compression is enabled for responses to client requests.

TCP

InitialConnectTimeout

An advanced property that you should not change, except under the guidance of Microsoft support.

MaxCompletedReceiveCount

An advanced property that you should not change, except under the guidance of Microsoft support.

MaxPendingAcceptExCount

An advanced property that you should not change, except under the guidance of Microsoft support.

MaxPendingReceiveCount

An advanced property that you should not change, except under the guidance of Microsoft support.

MaxPendingSendCount

An advanced property that you should not change, except under the guidance of Microsoft support.

MinPendingAcceptExCount

An advanced property that you should not change, except under the guidance of Microsoft support.

MinPendingReceiveCount

An advanced property that you should not change, except under the guidance of Microsoft support.

ScatterReceiveMultiplier

An advanced property that you should not change, except under the guidance of Microsoft support.

SocketOptions\ DisableNonblockingMode

An advanced property that you should not change, except under the guidance of Microsoft support.

SocketOptions\ EnableLingerOnClose

An advanced property that you should not change, except under the guidance of Microsoft support.

SocketOptions\EnableNagleAlgorithm

An advanced property that you should not change, except under the guidance of Microsoft support.

SocketOptions\ LingerTimeout

An advanced property that you should not change, except under the guidance of Microsoft support.

SocketOptions\ ReceiveBufferSize

An advanced property that you should not change, except under the guidance of Microsoft support.

SocketOptions\ SendBufferSize

An advanced property that you should not change, except under the guidance of Microsoft support.

See also

[Server properties in Analysis Services](#)

[Determine the Server Mode of an Analysis Services Instance](#)

OLAP properties

9/6/2019 • 12 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services supports the following OLAP server properties. Not all properties apply to Azure Analysis Services.

Applies to: Multidimensional and tabular server mode unless noted otherwise.

Memory

DefaultPageSizeForData

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultPageSizeForDataHeader

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultPageSizeForIndex

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultPageSizeForIndexHeader

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultPageSizeForString

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultPageSizeForHash

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultPageSizeForProp

An advanced property that you should not change, except under the guidance of Microsoft support.

LazyProcessing

Enabled

A Boolean property that specifies whether lazy aggregation processing is enabled.

SleepIntervalSecs

A signed 32-bit integer property that defines the interval, in seconds, that the server checks whether there are lazy processing jobs pending.

MaxCPUUsage

A signed 64-bit double-precision floating-point number property that defines maximum CPU usage for lazy processing, expressed as a percentage. The server monitors average CPU use based on snapshots. It is normal behavior for the CPU to spike above this threshold.

The default value for this property is 0.5, indicating a maximum of 50% of the CPU will be devoted to lazy processing.

MaxObjectsInParallel

A signed 32-bit integer property that specifies the maximum number of partitions that can be lazily processed in parallel.

MaxRetries

A signed 32-bit integer property that defines the number of retries in the event that lazy processing fails before an error is raised.

ProcessPlan

CacheRowsetRows

An advanced property that you should not change, except under the guidance of Microsoft support.

CacheRowsetToDisk

An advanced property that you should not change, except under the guidance of Microsoft support.

DistinctBuffer

A signed 32-bit integer property that defines the size of an internal buffer used for distinct counts. Increase this value to speed up distinct count processing at the cost of memory use.

EnableRolapDimQueryTableGrouping

A Boolean property that specifies whether table grouping is enabled for ROLAP dimensions. If True, when querying ROLAP dimensions at runtime, entire ROLAP dimension tables are queried at once, as opposed to separate queries for each attribute.

EnableTableGrouping

A Boolean property that specifies whether table grouping is enabled. If True, when processing dimensions, entire dimension tables are queried at once, as opposed to separate queries for each attribute.

ForceMultiPass

An advanced property that you should not change, except under the guidance of Microsoft support.

MaxTableDepth

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryAdjustConst

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryAdjustFactor

An advanced property that you should not change, except under the guidance of Microsoft support.

MemoryLimit

A signed 64-bit double-precision floating-point number property that defines the maximum amount of memory to be devoted to processing, expressed as a percentage of physical memory.

The default value for this property is 65, indicating that 65% of physical memory may be devoted to cube and dimension processing.

MemoryLimitErrorEnabled

An advanced property that you should not change, except under the guidance of Microsoft support.

OptimizeSchema

An advanced property that you should not change, except under the guidance of Microsoft support.

ProactiveCaching

DefaultRefreshInterval

An advanced property that you should not change, except under the guidance of Microsoft support.

DimensionLatencyAccuracy

An advanced property that you should not change, except under the guidance of Microsoft support.

PartitionLatencyAccuracy

An advanced property that you should not change, except under the guidance of Microsoft support.

Process

AggregationMemoryLimitMax

A signed 64-bit double-precision floating-point number property that defines the maximum amount of memory that can be devoted to aggregation processing, expressed as a percentage of physical memory.

The default value for this property is 80, indicating that 80% of physical memory may be devoted to aggregation processing.

AggregationMemoryLimitMin

A signed 64-bit double-precision floating-point number property that defines the minimum amount of memory that can be devoted to aggregation processing, expressed as a percentage of physical memory. A larger value may speed up aggregation processing at the cost of memory usage.

The default value for this property is 10, indicating that minimally 10% of physical memory will be devoted to aggregation processing.

AggregationNewAlgo

An advanced property that you should not change, except under the guidance of Microsoft support.

AggregationPerfLog2

An advanced property that you should not change, except under the guidance of Microsoft support.

AggregationsBuildEnabled

A Boolean property that specifies whether aggregation building is enabled. This is a mechanism to benchmark aggregation building without changing aggregation design.

BufferMemoryLimit

A signed 64-bit double-precision floating-point number property that defines the processing buffer memory limit, expressed as a percent of physical memory.

The default value for this property is 60, which indicates that up to 60% of physical memory can be used for buffer memory.

BufferRecordLimit

A signed 32-bit integer property that defines the number of records that can be buffered during processing.

The default value for this property is 1048576 (records).

CacheRecordLimit

An advanced property that you should not change, except under the guidance of Microsoft support.

CheckDistinctRecordSortOrder

A Boolean property that defines if the sort order for the results of a distinct count query are meaningful when processing partitions. True indicates the sort order is not meaningful and must be "checked" by the server. When processing partitions with distinct count measure, query sent to SQL with order-by. Set to false to speed up processing.

The default value for this property is True, which indicates that the sort order is not meaningful and must be checked.

DatabaseConnectionPoolConnectTimeout

A signed 32-bit integer property that specifies timeout when opening a new connection in seconds.

DatabaseConnectionPoolGeneralTimeout

A signed 32-bit integer property that specifies database connection timeout for use with external OLEDB connections in seconds.

DatabaseConnectionPoolMax

A signed 32-bit integer property that specifies the maximum number of pooled database connections.

The default value for this property is 50 (connections).

DatabaseConnectionPoolTimeout

An advanced property that you should not change, except under the guidance of Microsoft support.

DataFileInitEnabled

An advanced property that you should not change, except under the guidance of Microsoft support.

DataPlacementOptimization

An advanced property that you should not change, except under the guidance of Microsoft support.

DataSliceInitEnabled

An advanced property that you should not change, except under the guidance of Microsoft support.

DeepCompressValue

A Boolean property applying to measures with Double data type that specifies whether numbers can be compressed, causing a loss in numeric precision. A value of False indicates no compression and no precision loss.

The default value for this property is True, which indicates that compression is enabled and precision will be lost.

DimensionPropertyKeyCache

A Boolean property that specifies whether dimension property keys are cached. Must be set to True if keys are non-unique.

IndexBuildEnabled

A Boolean property that specifies whether indexes are built upon processing. This property is for benchmarking and informational purposes.

IndexBuildThreshold

A signed 32-bit integer property that specifies a row count threshold below which indexes will not be built for partitions.

The default value for this property is 4096 (rows).

IndexFileInitEnabled

An advanced property that you should not change, except under the guidance of Microsoft support.

MapFormatMask

An advanced property that you should not change, except under the guidance of Microsoft support.

RecordsReportGranularity

A signed 32-bit integer property that specifies how often the server records Trace events during processing, in rows.

The default value for this property is 1000, which indicates that a Trace event is logged once every 1000 rows.

ROLAPDimensionProcessingEffort

An advanced property that you should not change, except under the guidance of Microsoft support.

Query

AggregationsUseEnabled

A Boolean property that defines whether stored aggregations are used at runtime. This property allows aggregations to be disabled without changing the aggregation design or re-processing, for informational and benchmarking purposes.

The default value for this property is True, indicating that aggregations are enabled.

AllowSEFiltering

An advanced property that you should not change, except under the guidance of Microsoft support.

CalculationCacheRegistryMaxIterations

An advanced property that you should not change, except under the guidance of Microsoft support.

CalculationEvaluationPolicy

An advanced property that you should not change, except under the guidance of Microsoft support.

ConvertDeletedToUnknown

A Boolean property that specifies whether deleted dimension members are converted to Unknown member.

CopyLinkedDataCacheAndRegistry

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCacheRegistryMaxIterations

An advanced property that you should not change, except under the guidance of Microsoft support.

DefaultDrillthroughMaxRows

A signed 32-bit integer property that specifies the maximum number of rows that will return from a drill-through query.

The default value for this property is 10000 (rows).

DimensionPropertyCacheSize

A signed 32-bit integer property that specifies the amount of memory (in bytes) used to cache dimension members used in a query.

The default is 4,000,000 bytes (or 4 MB) per attribute hierarchy, per active query. The default value provides a well-balanced cache size for solutions having typical hierarchies. However, dimensions with a very large number of members (in the millions) or deep hierarchies perform better if you increase this value.

Implications of increasing cache size:

- Memory utilization costs increase when you allow more memory to be used by the dimension cache. Actual usage depends on query execution. Not all queries will use the allowable maximum.

Note that the memory used by these caches is considered nonshrinkable and will be included when accounting against the **TotalMemoryLimit**.

- Affects all databases on the server. **DimensionPropertyCachesize** is a server-wide property. Changing this property affects all databases running on the current instance.

Approach for estimating dimension cache requirements:

1. Start by increasing the size by a large number to determine whether there is a benefit to increasing the dimension cache size. For example, you might want to double the default value as an initial step.
2. If a performance improvement is evident, incrementally reduce the value until you reach a balance between performance and memory utilization.

ExpressNonEmptyUseEnabled

An advanced property that you should not change, except under the guidance of Microsoft support.

IgnoreNullRolapRows

An advanced property that you should not change, except under the guidance of Microsoft support.

IndexUseEnabled

A Boolean property that defines whether indexes are used at runtime. This property is for informational and benchmarking purposes.

MapHandleAlgorithm

An advanced property that you should not change, except under the guidance of Microsoft support.

MaxRolapOrConditions

An advanced property that you should not change, except under the guidance of Microsoft support.

RowsetSerializationLimit

Applies to Azure Analysis Services and SQL Server 2019 and later only. Limits the number of rows returned in a rowset to clients. Default value is -1, meaning no limit is applied. Applies to both DAX and MDX queries. It can be used to protect server resources from extensive data export. Queries submitted to the server that exceed the limit are cancelled and an error is returned.

UseCalculationCacheRegistry

An advanced property that you should not change, except under the guidance of Microsoft support.

UseDataCacheFreeLastPageMemory

An advanced property that you should not change, except under the guidance of Microsoft support.

UseDataCacheRegistry

A Boolean property that specifies whether to enable the data cache registry, where query results are cached (though not calculated results).

UseDataCacheRegistryHashTable

An advanced property that you should not change, except under the guidance of Microsoft support.

UseDataCacheRegistryMultiplyKey

An advanced property that you should not change, except under the guidance of Microsoft support.

UseDataSlice

A Boolean property that defines whether to use partition data slices at runtime for query optimization. This property is for benchmarking and informational purposes.

UseMaterializedIterators

An advanced property that you should not change, except under the guidance of Microsoft support.

UseSinglePassForDimSecurityAutoExist

An advanced property that you should not change, except under the guidance of Microsoft support.

UseVBANet

A Boolean property that defines whether to use the VBA .net assembly for user-defined functions.

CalculationPrefetchLocality\ ApplyIntersect

An advanced property that you should not change, except under the guidance of Microsoft support.

CalculationPrefetchLocality\ ApplySubtract

An advanced property that you should not change, except under the guidance of Microsoft support.

CalculationPrefetchLocality\ PrefetchLowerGranularities

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ CachedPageAlloc\ Income

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ CachedPageAlloc\ InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ CachedPageAlloc\ MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ CachedPageAlloc\ MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ CachedPageAlloc\ Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\CellStore\ Income

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\CellStore\ InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\CellStore\ MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\CellStore\ MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\CellStore\ Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ MemoryModel \ Income

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ MemoryModel \ InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ MemoryModel \ MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ MemoryModel \ MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

DataCache\ MemoryModel\ Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

Jobs

ProcessAggregation\ MemoryModel\ Income

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ MemoryModel\ InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ MemoryModel\ MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ MemoryModel\ MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ MemoryModel\ Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessPartition\ Income

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessPartition \ InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessPartition \ MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessPartition \ MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessPartition \ Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessProperty\ Income

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessProperty\ InitialBonus

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessProperty\ MaximumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessProperty\ MinimumBalance

An advanced property that you should not change, except under the guidance of Microsoft support.

ProcessAggregation\ ProcessProperty\ Tax

An advanced property that you should not change, except under the guidance of Microsoft support.

Security properties

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

An Analysis Services supports the following security properties. Not all properties apply to Azure Analysis Services.

Applies to: Multidimensional and tabular server mode unless noted otherwise.

Properties

RequireClientAuthentication

A Boolean property that indicates whether client authentication is required.

The default value for this property is True, which indicates that client authentication is required.

SecurityPackageList

A string property that contains a comma-separated list of SSPI packages used by the server for client authentication.

DisableClientImpersonation

A Boolean property that indicates whether client impersonation (for example, from stored procedures) is disabled.

The default value for this property is False, which indicates that client impersonation is enabled.

BuiltinAdminsAreServerAdmins

A Boolean property that indicates whether members of the local machine administrators group are administrators.

ServiceAccountIsServerAdmin

A Boolean property that indicates whether the service account is a server administrator.

The default value for this property is True, which indicates that the service account is a server administrator.

ErrorMessageMode

An advanced property that you should not change, except under the guidance of Microsoft support.

DataProtection\ RequiredProtectionLevel

A signed 32-bit integer property that defines the required protection level for all client requests. This property has one of the values listed in the following table.

VALUE	DESCRIPTION
0	None, clear text allowed.
1	(Default) Encryption required, no clear-text logging.
2	Clear-text requests allowed but only with signatures (weaker protection than encryption).

AdministrativeDataProtection\ RequiredProtectionLevel

An advanced property that you should not change, except under the guidance of Microsoft support.

[Determine the Server Mode of an Analysis Services Instance](#)

Thread pool properties

9/6/2019 • 29 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services uses multi-threading for many operations, improving overall server performance by running multiple jobs in parallel. To manage threads more efficiently, the engine uses thread pools to pre-allocate threads and facilitate thread availability for the next job.

Each instance maintains its own set of thread pools. There are differences in how tabular and multidimensional instances use thread pools. For example, only multidimensional instances use the **IOProcess** thread pool. As such, the **PerNumaNode** property, described in this article, is not meaningful for Tabular instances. In the [Property reference](#) section below, mode requirements are called out for each property.

NOTE

Tabular deployment on NUMA systems is out of scope for this topic. Although tabular solutions can be successfully deployed on NUMA systems, the performance characteristics of the in-memory database technology used by tabular models may show limited benefits on a highly scaled up architectures. For more information, see [Analysis Services Case Study: Using Tabular Models in Large-scale Commercial Solutions](#) and [Hardware Sizing a Tabular Solution](#).

Thread management

Analysis Services uses multi-threading to take advantage of the available CPU resources by increasing the number of tasks executing in parallel. The storage engine is multi-threaded. Examples of multi-threaded jobs that execute within the storage engine include processing objects in parallel or handling discrete queries that have been pushed to the storage engine, or returning data values requested by a query. The formula engine, due to the serial nature of the calculations it evaluates, is single threaded. Each query executes primarily on a single thread, requesting and often waiting for data returned by the storage engine. Query threads have longer executions, and are released only after the entire query is completed.

By default, Analysis Services will use all available logical processors. Upon start up, the msmdsrv.exe process will be assigned to a specific processor group, but over time threads can be scheduled on any logical processor, in any processor group.

One side-effect of using a large number of processors is that you can sometimes experience performance degradation as query and processing loads are spread out across a large number of processors and contention for shared data structures increase. This can occur particularly on high-end systems that use NUMA architecture, but also on non-NUMA systems running multiple data intensive applications on the same hardware.

You can set affinity between types of operations and a specific set of logical processors. The **GroupAffinity** property lets you create custom affinity masks that specify which system resource to use for each of the thread pool types managed by Analysis Services.

GroupAffinity is a property that can be set on any of the thread pools used for various workloads:

- **ThreadPool \ Parsing \ Short** is a parsing pool for short requests. Requests that fit within a single network message are considered short.
- **ThreadPool \ Parsing \ Long** is a parsing pool for all other requests that do not fit within a single network message.

NOTE

A thread from either parsing pool can be used to execute a query. Queries that execute quickly, such as a fast Discover or Cancel request, are sometimes executed immediately rather than queued to the Query thread pool.

- **ThreadPool \ Query** is the thread pool that executes all requests that are not handled by the parsing thread pool. Threads in this thread pool will execute all types of operations, such as Discover, MDX, DAX, DMX, and DDL commands. A
- **ThreadPool \ IOProcess** is used for IO jobs associated with storage engine queries in the multidimensional engine. The work done by these threads is expected to not have dependencies on other threads. These threads will typically be scanning a single segment of a partition and performing filtering and aggregation on the segment data. **IOProcess** threads are particularly sensitive to NUMA hardware configurations. As such, this thread pool has the **PerNumaNode** configuration property which can be used to tune the performance if needed.
- **ThreadPool \ Process** is for longer duration storage engine jobs, including aggregations, indexing, and commit operations. ROLAP storage mode also uses threads from the Processing thread pool.
- **VertiPaq \ ThreadPool** is the thread pool for executing table scans in a tabular model.

To service requests, Analysis Services may exceed the maximum thread pool limit, requesting additional threads if they are necessary to perform the work. However, when a thread finishes executing its task, if the current count of threads is greater than the maximum limit, the thread is simply ended, rather than returned to the thread pool.

NOTE

Exceeding the maximum thread pool count is a protection invoked only when certain deadlock conditions arise. To prevent runaway thread creation beyond the maximum, threads are created gradually (after a short delay) after the maximum limit has been reached. Exceeding maximum thread count can lead to a slowdown in task execution. If the performance counters show the thread counts are regularly beyond the thread pool maximum size, you might consider that as an indicator that thread pool sizes are too small for the degree of concurrency being requested from the system.

By default, thread pool size is determined by Analysis Services, and is based on the number of cores. For SSAS, you can observe the selected default values by examining the msmdsrv.log file after server startup. As a performance tuning exercise, you might choose to increase the size of the thread pool, as well as other properties, to improve query or processing performance.

Thread pool property reference

This section describes the thread pool properties found in the msmdsrv.ini file of each Analysis Services instance. A subset of these properties also appears in SQL Server Management Studio.

Properties are listed in alphabetical order.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
------	------	-------------	---------	----------

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
IOProcess \ Concurrency	double	A double-precision floating point value that determines the algorithm for setting a target on the number of threads that can be queued at one time.	2.0	<p>An advanced property that you should not change, except under the guidance of Microsoft support.</p> <p>Concurrency is used to initialize thread pools, which are implemented using IO Completion Ports in Windows. See I/O Completion Ports for details.</p> <p>Applies to multidimensional models only.</p>
IOProcess \ GroupAffinity	string	An array of hexadecimal values that correspond to processor groups on the system, used to set affinity of threads in the IOProcess thread pool to logical processors in each processor group.	none	<p>You can use this property to create custom affinities. The property is empty by default.</p> <p>See Set GroupAffinity to affinitize threads to processors in a processor group for details.</p> <p>Applies to multidimensional models only.</p>

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
IOProcess \ MaxThreads	int	A signed 32-bit integer that specifies the maximum number of threads to include in the thread pool.	0	<p>0 indicates the server determines the defaults. By default, the server either sets this value to 64, or to 10 times the number of logical processors, whichever is higher. For example, on a 4-core system with hyperthreading, the thread pool maximum is 80 threads.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors. For example, when set to -10 on a server having 32 logical processors, the maximum is 320 threads.</p> <p>The maximum value is subject to available processors per any custom affinity masks that you previously defined. For example, if you already set thread pool affinity to use 8 out of 32 processors, and you now set MaxThreads to -10, then the upper bound on the thread pool would 10 times 8, or 80 threads.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p> <p>More information about tuning the thread pool settings can be found in the Analysis Services Operations Guide.</p> <p>Applies to multidimensional models only.</p>

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
IOProcess \ MinThreads	int	A signed 32-bit integer that specifies the minimum number of threads to preallocate for the thread pool.	0	<p>0 indicates the server determines the defaults. By default, the minimum is 1.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p> <p>More information about tuning the thread pool settings can be found in the Analysis Services Operations Guide.</p> <p>Applies to multidimensional models only.</p>

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
IOProcess \ PerNumaNode	int	A signed 32-bit integer that determines the number of thread pools created for the msmdsrv process.	-1	<p>Valid values are -1, 0, 1, 2</p> <p>-1 = The server selects a different IO Thread Pool strategy based on the number of NUMA nodes. On systems having fewer than 4 NUMA nodes, the server behavior is the same as 0 (one IOProcess thread pool is created for the system). On systems having 4 or more nodes, the behavior is the same as 1 (IOProcess thread pools are created for each node).</p> <p>0 = Disables per NUMA node thread pools so that there is only one IOProcess thread pool used by the msmdsrv.exe process.</p> <p>1 = Enables one IOProcess thread pool per NUMA node.</p> <p>2 = One IOProcess thread pool per logical processor. Threads in each thread pool are affinitized to the NUMA node of the logical processor, with the ideal processor set to the logical processor.</p> <p>See Set PerNumaNode to affinize IO threads to processors in a NUMA node for details.</p> <p>Applies to multidimensional models only.</p>

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
IOProcess \ PriorityRatio	int	A signed 32-bit integer that can be used to ensure that lower priority threads are sometimes executed even when a higher priority queue is not empty.	2	An advanced property that you should not change, except under the guidance of Microsoft support. Applies to multidimensional models only.
IOProcess \ StackSizeKB	int	A signed 32-bit integer that can be used to adjust memory allocation during thread execution.	0	An advanced property that you should not change, except under the guidance of Microsoft support. Applies to multidimensional models only.
Parsing \ Long \ Concurrency	double	A double-precision floating point value that determines the algorithm for setting a target on the number of threads that can be queued at one time.	2.0	An advanced property that you should not change, except under the guidance of Microsoft support. Concurrency is used to initialize thread pools, which are implemented using IO Completion Ports in Windows. See I/O Completion Ports for details.
Parsing \ Long \ GroupAffinity	string	An array of hexadecimal values that correspond to processor groups on the system, used to set affinity of parsing threads to logical processors in each processor group.	none	You can use this property to create custom affinities. The property is empty by default. See Set GroupAffinity to affinitize threads to processors in a processor group for details.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
Parsing \ Long \ NumThreads	int	A signed 32-bit integer property that defines the number of threads that can be created for long commands.	0	<p>0 indicates that the server determines the defaults. The default behavior is to set NumThreads to an absolute value of 4, or 2 times the number of logical processors, whichever is higher.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors. For example, when set to -10 on a server having 32 logical processors, the maximum is 320 threads.</p> <p>The maximum value is subject to available processors per any custom affinity masks that you previously defined. For example, if you already set thread pool affinity to use 8 out of 32 processors, and you now set NumThreads to -10, then the upper bound on the thread pool would 10 times 8, or 80 threads.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p>
Parsing \ Long \ PriorityRatio	int	A signed 32-bit integer that can be used to ensure that lower priority threads are sometimes executed even when a higher priority queue is not empty.	0	An advanced property that you should not change, except under the guidance of Microsoft support.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
Parsing \ Long \ StackSizeKB	int	A signed 32-bit integer that can be used to adjust memory allocation during thread execution.	0	An advanced property that you should not change, except under the guidance of Microsoft support.
Parsing \ Short \ Concurrency	double	A double-precision floating point value that determines the algorithm for setting a target on the number of threads that can be queued at one time.	2.0	An advanced property that you should not change, except under the guidance of Microsoft support. Concurrency is used to initialize thread pools, which are implemented using IO Completion Ports in Windows. See I/O Completion Ports for details.
Parsing \ Short \ GroupAffinity	string	An array of hexadecimal values that correspond to processor groups on the system, used to set affinity of parsing threads to logical processors in each processor group.	none	You can use this property to create custom affinities. The property is empty by default. See Set GroupAffinity to affinitize threads to processors in a processor group for details.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
Parsing \ Short \ NumThreads	int	A signed 32-bit integer property that defines the number of threads that can be created for short commands.	0	<p>0 indicates that the server determines the defaults. The default behavior is to set NumThreads to an absolute value of 4, or 2 times the number of logical processors, whichever is higher.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors. For example, when set to -10 on a server having 32 logical processors, the maximum is 320 threads.</p> <p>The maximum value is subject to available processors per any custom affinity masks that you previously defined. For example, if you already set thread pool affinity to use 8 out of 32 processors, and you now set NumThreads to -10, then the upper bound on the thread pool would 10 times 8, or 80 threads.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p>
Parsing \ Short \ PriorityRatio	int	A signed 32-bit integer that can be used to ensure that lower priority threads are sometimes executed even when a higher priority queue is not empty.	0	An advanced property that you should not change, except under the guidance of Microsoft support.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
Parsing \ Short \ StackSizeKB	int	A signed 32-bit integer that can be used to adjust memory allocation during thread execution.	64 * logical processors	An advanced property that you should not change, except under the guidance of Microsoft support.
Process \ Concurrency	double	A double-precision floating point value that determines the algorithm for setting a target on the number of threads that can be queued at one time.	2.0	An advanced property that you should not change, except under the guidance of Microsoft support. Concurrency is used to initialize thread pools, which are implemented using IO Completion Ports in Windows. See I/O Completion Ports for details.
Process \ GroupAffinity	string	An array of hexadecimal values that correspond to processor groups on the system, used to set affinity of processing threads to logical processors in each processor group.	none	You can use this property to create custom affinities. The property is empty by default. See Set GroupAffinity to affinitize threads to processors in a processor group for details.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
Process \ MaxThreads	int	A signed 32-bit integer that specifies the maximum number of threads to include in the thread pool.	0	<p>0 indicates the server determines the defaults. By default, the server either sets this value to an absolute value of 64, or the number of logical processors, whichever is higher. For example, on a 64-core system with hyperthreading enabled (resulting in 128 logical processors), the thread pool maximum is 128 threads.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors. For example, when set to -10 on a server having 32 logical processors, the maximum is 320 threads.</p> <p>The maximum value is subject to available processors per any custom affinity masks that you previously defined. For example, if you already set thread pool affinity to use 8 out of 32 processors, and you now set MaxThreads to -10, then the upper bound on the thread pool would 10 times 8, or 80 threads.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p> <p>More information about tuning the thread pool settings can be found in the Analysis Services Operations Guide.</p>

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
Process \ MinThreads	int	A signed 32-bit integer that specifies the minimum number of threads to preallocate for the thread pool.	0	<p>0 indicates the server determines the defaults. By default, the minimum is 1.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p> <p>More information about tuning the thread pool settings can be found in the Analysis Services Operations Guide.</p>
Process \ PriorityRatio	int	A signed 32-bit integer that can be used to ensure that lower priority threads are sometimes executed even when a higher priority queue is not empty.	2	An advanced property that you should not change, except under the guidance of Microsoft support.
Process \ StackSizeKB	int	A signed 32-bit integer that can be used to adjust memory allocation during thread execution.	0	An advanced property that you should not change, except under the guidance of Microsoft support.
Query \ Concurrency	double	A double-precision floating point value that determines the algorithm for setting a target on the number of threads that can be queued at one time.	2.0	<p>An advanced property that you should not change, except under the guidance of Microsoft support.</p> <p>Concurrency is used to initialize thread pools, which are implemented using IO Completion Ports in Windows. Query \ StackSizeKB	int	A signed 32-bit integer that can be used to adjust memory allocation during thread execution.	0	An advanced property that you should not change, except under the guidance of Microsoft support.

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
VertiPaq \ CPUs	int	A signed 32-bit integer that specifies the maximum number of processors to use for tabular queries.	0	<p>0 indicates the server determines the defaults. By default, the server either sets this value to an absolute value of 10, or 2 times the number of logical processors, whichever is higher. For example, on a 4-core system with hyperthreading, the maximum thread count is 16.</p> <p>If you set this value to a negative value, the server multiples that value by the number of logical processors. For example, when set to -10 on a server having 32 logical processors, the maximum is 320 threads.</p> <p>The maximum value is subject to available processors per any custom affinity masks that you previously defined. For example, if you already set thread pool affinity to use 8 out of 32 processors, and you now set MaxThreads to -10, then the upper bound on the thread pool would 10 times 8, or 80 threads.</p> <p>The actual values used for this thread pool property are written to the msmdsrv log file upon service start up.</p>

NAME	TYPE	DESCRIPTION	DEFAULT	GUIDANCE
VertiPaq \ GroupAffinity	string	An array of hexadecimal values that correspond to processor groups on the system, used to set affinity of processing threads to logical processors in each processor group.	none	You can use this property to create custom affinities. The property is empty by default. See Set GroupAffinity to affinize threads to processors in a processor group for details. Applies to Tabular only.

Set GroupAffinity to affinize threads to processors in a processor group

GroupAffinity is provided for advanced tuning purposes. You can use the **GroupAffinity** property to set affinity between Analysis Services thread pools and specific processors; however, for most installations, Analysis Services performs best when it can use all available logical processors. Accordingly, group affinity is unspecified by default.

Should performance testing indicate a need for CPU optimization, you might consider a higher level approach, such as using Windows Server Resource Manager to set affinity between logical processors and a server process. Such an approach can be simpler to implement and manage than defining custom affinities for individual thread pools.

If that approach is insufficient, you can achieve greater precision by defining custom affinities for thread pools. Customizing affinity settings is more likely to be recommended on large multi-core systems (either NUMA or non-NUMA) experiencing performance degradation due to thread pools spread out over too-wide a range of processors. Although you can set **GroupAffinity** on systems having fewer than 64 logical processors, the benefit is negligible and might even degrade performance.

NOTE

GroupAffinity is constrained by editions that limit the number of cores used by Analysis Services. At startup, Analysis Services uses edition information and the **GroupAffinity** properties to compute affinity masks for each thread pool managed by Analysis Services. Standard edition can use a maximum of 24 cores. If you install Analysis Services standard edition on a large multi-core system that has more than 24 cores, Analysis Services will only use 24 of them. For more information about processor maximums, see the cross-box scale limits in [Features by editions in SQL Server](#).

Syntax

The value is hexadecimal for each processor group, with the hexadecimal representing the logical processors that Analysis Services attempts to use first when allocating threads for a given thread pool.

Bitmask for Logical Processors

You can have up to 64 logical processors within a single processor group. The bitmask is 1 (or 0) for each logical processor in the group that is used (or not used) by a thread pool. Once you compute the bitmask, you then calculate the hexadecimal value as the value for **GroupAffinity**.

Multiple processor groups

Processor groups are determined on system startup. **GroupAffinity** accepts hexadecimal values for each processor group in a comma delimited list. Given multiple processor groups (up to 10 on higher end systems), you can bypass individual groups by specifying 0x0. For example, on a system with four processor groups (0, 1, 2,

3), you could exclude groups 0 and 2 by entering 0x0 for the first and third values.

```
<GroupAffinity>0x0, 0xFF, 0x0, 0xFF</GroupAffinity>
```

Steps for computing the processor affinity mask

You can set **GroupAffinity** in msmdsrv.ini or in server property pages in SQL Server Management Studio.

1. Determine the number of processors and processor groups

You can download [Coreinfo utility from winsysinternals](#).

Run **coreinfo** to get this information from the Logical Processor to Group Map section. A separate line is generated for each logical processor.

2. Sequence the processors, from right to left:

```
7654 3210
```

The example shows only 8 processors (0 through 7), but a processor group can have a maximum of 64 logical processors, and there can be up to 10 processor groups in an enterprise-class Windows server.

3. Compute the bitmask for the processor groups you want to use

```
7654 3210
```

Replace the number with a 0 or 1, depending on whether you want to exclude or include the logical processor. On a system having eight processors, your calculation might look like this if you wanted to use processors 7, 6, 5, 4, and 1 for Analysis Services:

```
1111 0010
```

4. Convert the binary number to a Hex value

Using a calculator or conversion tool, convert the binary number to its hexadecimal equivalent. In our example,

```
1111 0010
```

 converts to

```
0xF2
```

.

5. Enter the hex value in the **GroupAffinity** property

In msmdsrv.ini or in the server property page in Management Studio, set **GroupAffinity** to the value calculated in step 4.

IMPORTANT

Setting **GroupAffinity** is a manual task encompassing multiple steps. When computing **GroupAffinity**, check your calculations carefully. Although Analysis Services will return an error if the entire mask is invalid, a combination of valid and invalid settings results in Analysis Services ignoring the property. For example, if the bitmask includes extra values, Analysis Services ignores the setting, using all processors on the system. There is no error or warning to alert you when this action occurs, but you can check the msmdsrv.log file to learn how the affinities are actually set.

Set PerNumaNode to affinitize IO threads to processors in a NUMA node

For multidimensional Analysis Services instances, you can set **PerNumaNode** on the **IOProcess** thread pool to further optimize thread scheduling and execution. Whereas **GroupAffinity** identifies which set of logical processors to use for a given thread pool, **PerNumaNode** goes one step further by specifying whether to create multiple thread pools, further affinitized to some subset of the allowed logical processors.

Valid values for **PerNumaNode** are -1, 0, 1, 2, as described in the [Thread Pool Property Reference](#) section in this topic.

Default (Recommended)

On systems having NUMA nodes, we recommend using the default setting of **PerNumaNode=-1**, allowing Analysis Services to adjust the number of thread pools and their thread affinity based on node count. If the system has fewer than 4 nodes, Analysis Services implements the behaviors described by **PerNumaNode=0**, whereas **PerNumaNode=1** is used on systems having 4 or more nodes.

Choosing a value

You can also override the default to use another valid value.

Setting PerNumaNode=0

NUMA nodes are ignored. There will be just one IOProcess thread pool, and all threads in that thread pool will be affinitized to all logical processors. By default (where PerNumaNode=-1), this is the operative setting if the computer has fewer than 4 NUMA nodes.

NUMA Nodes	0								1								2								3							
Logical Processors	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
IO Thread Pools	0																															
	0																															

Setting PerNumaNode=1

IOProcess thread pools are created for each NUMA node. Having separate thread pools improves coordinated access to local resources, such as local cache on a NUMA node.

NUMA Nodes	0								1								2								3							
Logical Processors	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
IO Thread Pools	0								1								2								3							
	0																															

Setting PerNumaNode=2

This setting is for very high-end systems running intensive workloads. This property sets IOProcess thread pool affinity at its most granular level, creating and affinizing separate thread pools at the logical processor level.

In the following example, on a system having 4 NUMA nodes and 32 logical processors, setting **PerNumaNode** to 2 would result in 32 IOProcess thread pools. The threads in the first 8 thread pools would be affinized to all the logical processors in the NUMA node 0, but with the ideal processor set to 0, 1, 2, up to 7. The next 8 thread pools would be affinized to all the logical processors in NUMA node 1, with the ideal processor set to 8, 9, 10, up to 15, and so on.

NUMA Nodes	0								1								2								3							
Logical Processors	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
IO Thread Pools	0																															
	0																															

At this level of affinity, the scheduler always attempts to use the ideal logical processor first, within the preferred NUMA node. If the logical processor is unavailable, the scheduler chooses another processor within the same node, or within the same processor group if no other threads are available. For more information and examples, see [Analysis Services 2012 Configuration settings \(Wordpress Blog\)](#).

Work distribution among IOProcess threads

As you consider whether to set the **PerNumaNode** property, knowing how **IOProcess** threads are used can help you make a more informed decision.

Recall that **IOProcess** is used for IO jobs associated with storage engine queries in the multidimensional engine.

When a segment is scanned, the engine identifies the partition to which the segment belongs, and attempts to queue the segment job to the thread pool used by the partition. In general, all segments belonging to a partition will queue their tasks to the same thread pool. On NUMA systems, this behavior is particularly advantageous because all scans for a partition will use memory in the file system cache that is allocated locally to that NUMA node.

The following scenarios suggest adjustments that can sometimes improve query performance on NUMA systems:

- For measure groups that are under-partitioned (for example, having a single partition), increase the number of partitions. Using just one partition will cause the engine to always queue tasks to one thread pool (thread pool 0). Adding more partitions allows the engine to use additional thread pools.

Alternatively, if you cannot create additional partitions, try setting **PerNumaNodE=0** as a way to increase the number of threads available to thread pool 0.

- For databases in which segment scans are evenly distributed across multiple partitions, setting **PerNumaNodE** to 1 or 2 can improve query performance because it increases the overall number of **IOProcess** thread pools used by the system.
- For solutions that have multiple partitions, but only one is heavily scanned, try setting **PerNumaNodE=0** to see if it improves performance.

Although both partition and dimension scans use the **IOProcess** thread pool, dimension scans only use thread pool 0. This can result in a slightly uneven load on that thread pool, but the imbalance should be temporary, as dimension scans tend to be very fast and infrequent.

NOTE

When changing a server property, remember that the configuration option applies to all databases running on the instance. Choose settings that benefit the most important databases, or the greatest number of databases. You cannot set processor affinity at the database level, nor can you set affinity between individual partitions and specific processors.

For more information about job architecture, see section 2.2 in [SQL Server Analysis Services Performance Guide](#).

Dependent or related properties

As explained in section 2.4 of the [Analysis Services Operations Guide](#), if you increase the processing thread pool, you should make sure that the **CoordinatorExecutionMode** settings, as well as the **CoordinatorQueryMaxThreads** settings, have values that enable you to make full use of the increased thread pool size.

Analysis Services uses a coordinator thread for gathering the data needed to complete a processing or query request. The coordinator first queues up one job for each partition that must be touched. Each of those jobs then continues to queue up more jobs, depending on the total number of segments that must be scanned in the partition.

The default value for **CoordinatorExecutionMode** is -4, meaning a limit of 4 jobs in parallel per core, which constrains the total number of coordinator jobs that can be executed in parallel by a subcube request in the storage engine.

The default value for **CoordinatorQueryMaxThreads** is 16, which limits the number of segment jobs that can be executed in parallel for each partition.

Determine current thread pool settings

At each service startup, Analysis Services outputs the current thread pool settings into the msmdsrv.log file, including minimum and maximum threads, processor affinity mask, and concurrency.

The following example is an excerpt from the log file, showing the default settings for the Query thread pool (MinThread=0, MaxThread=0, Concurrency=2), on a 4-core system with hyper-threading enabled. The affinity mask is 0xFF, indicating 8 logical processors. Notice that leading zeros are prepended to the mask. You can ignore the leading zeros.

```
"10/28/2013 9:20:52 AM) Message: The Query thread pool now has 1 minimum threads, 16 maximum threads, and a concurrency of 16. Its thread pool affinity mask is 0x00000000000000ff. (Source: \\?\C:\Program Files\Microsoft SQL Server\MSAS11.MSSQLSERVER\OLAP\Log\msmdsrv.log, Type: 1, Category: 289, Event ID: 0x4121000A)"
```

Recall that the algorithm for setting **MinThread** and **MaxThread** incorporates system configuration, particularly the number of processors. The following blog post offers insights into how the values are calculated: [Analysis Services 2012 Configuration settings \(Wordpress Blog\)](#). Note that these settings and behaviors are subject to adjustment in subsequent releases.

The following list shows examples of other affinity mask settings, for different combinations of processors:

- Affinity for processors 3-2-1-0 on an 8 core system results in this bitmask: 00001111, and a hexadecimal value: 0xF
- Affinity for processors 7-6-5-4 on an 8 core system results in this bitmask: 11110000, and a hexadecimal value: 0xF0
- Affinity for processors 5-4-3-2 on an 8 core system results in this bitmask: 00111100, and a hexadecimal value: 0x3C
- Affinity for processors 7-6-1-0 on an 8 core system results in this bitmask: 11000011, and a hexadecimal value: 0xC3

Recall that on systems having multiple processor groups, a separate affinity mask is generated for each group, in a comma separated list.

About msmdsrv.ini

The msmdsrv.ini file in SQL Server Analysis Services contains configuration settings for an instance, affecting all databases running on that instance. You cannot use server configuration properties to optimize performance of just one database to the exclusion of all others. However, you can install multiple instances of Analysis Services and configure each instance to use properties that benefit databases sharing similar characteristics or workloads.

All server configuration properties are included in the msmdsrv.ini file. Subsets of the properties more likely to be modified also appear in administration tools, such as SSMS. The contents of msmdsrv.ini are identical for both tabular and multidimensional instances, however, some settings apply to one mode only. Differences in behavior based on server mode are noted in property reference documentation.

Monitoring overview

9/5/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services has several different tools to help you monitor and tune the performance of your servers. The choice of tool depends on the type of monitoring or tuning to be done and the particular events to be monitored.

Monitoring tools

TOOL	DESCRIPTION
SQL Server Profiler	Tracks engine process events. It also captures data about those events, enabling you to monitor server and database activity.
Extended Events	A light-weight tracing and performance monitoring system that uses very few system resources, making it an ideal tool for diagnosing problems on both production and test servers.
Trace Events	Follow the activity of an instance by capturing and then analyzing the trace events generated by the instance. Trace events are grouped so that you can more easily find related trace events.
Dynamic Management Views (DMVs)*	Queries that return information about model objects, server operations, and server health. The query, based on SQL, is an interface to schema rowsets.
Performance counters*	Using Performance Monitor, you can monitor the performance of an Analysis Services instance by using performance counters.
Log operations*	An Analysis Services instance will log server notifications, errors, and warnings to the msmdsrv.log file - one for each instance you install.

* Applies to SQL Server Analysis Services only.

For more detailed information about monitoring SQL Server Analysis Services, see the [SQL Server 2008 R2 Operations Guide](#).

Use SQL Server Profiler to Monitor Analysis Services

9/5/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

SQL Server Profiler tracks engine process events, such as the start of a batch or a transaction, and it captures data about those events, thus enabling you to monitor server and database activity (for example, user queries or login activity). You can capture SQL Server Profiler data to a SQL Server table or a file for later analysis, and you can also replay the events captured on the same or another Analysis Services instance to see exactly what happened. You can replay events in real time or on a step-by-step basis. It is also very useful to run the trace events along with the Performance counters on the same machine. The profiler can correlate these two based on time and display them together along a single timeline. Trace events will give you more details while Performance counters give you an aggregate view. For information about how to create and run traces, see [Create Profiler Traces for Replay \(Analysis Services\)](#).

The following table describes the topics in this section.

In This Section

TOPIC	DESCRIPTION
Introduction to Monitoring Analysis Services with SQL Server Profiler	Describes how to use SQL Server Profiler to monitor an Analysis Services instance.
Create Profiler Traces for Replay (Analysis Services)	Describes the requirements for creating a trace for replay by using SQL Server Profiler.
Analysis Services Trace Events	Describes Analysis Services event classes. These event classes map to actions generated by Analysis Services and are used for trace replays.

Monitoring Analysis Services with SQL Server Profiler

9/5/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can use SQL Server Profiler to monitor events generated by an instance of Analysis Service to do the following:

- Monitor the performance of an instance of the Analysis Services engine.
- Debug query statements.
- Identify queries that run slowly.
- Test query statements in the development phase of a project by stepping through statements to confirm that the code works as expected.
- Troubleshoot problems by capturing events on a production system and replaying them on a test system. This approach is useful for testing or debugging purposes and lets users continue to use the production system without interference.
- Audit and review activity that occurred on an instance. A security administrator can review any one of the audited events. This includes the success or failure of a login try and the success or failure of permissions in accessing statements and objects.
- Display data about the captured events to the screen, or capture and save data about each event to a file or SQL Server table for future analysis or playback. When you replay data, you can rerun the saved events as they originally occurred, either in real time or step by step.

Using SQL Server Profiler

To use SQL Server Profiler to create or replay traces, you must be a member of the Analysis Services server role. If you are a member of the Analysis Services server role, you can start SQL Server Profiler from the Microsoft SQL Server program group on the **Start** menu.

When you use SQL Server Profiler, note the following:

- Trace definitions are stored with the Analysis Services database by using the CREATE statement.
- Multiple traces can be running at the same time.
- Multiple connections can receive events from the same trace.
- A trace can continue when Analysis Services stops and restarts.

NOTE

Passwords are not revealed in trace events, but are replaced by ***** in the event.

For optimal performance, use SQL Server Profiler to monitor only those events in which you are most interested. Monitoring too many events adds overhead and can cause the trace file or table to grow very large, especially when you monitor over a long period of time. In addition, use filtering to limit the amount of data that is collected and to prevent traces from becoming too large.

[Analysis Services Trace Events](#)

[Create Profiler Traces for Replay \(Analysis Services\)](#)

Create Profiler Traces for Replay (Analysis Services)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

To replay queries, discovers, and commands that are submitted by users to Microsoft SQL Server Analysis Services, SQL Server Profiler must gather the required events. In order to initiate collection of these events, appropriate event classes must be selected in the **Event Selection** tab of the **Trace Properties** dialog box. For example if the Query Begin event class is selected, events that contain queries are collected and used for replay. Also, the trace file contains sufficient information to support replaying server transactions in a distributed environment in the original sequence of transactions.

Replay for Queries

To replay queries, SQL Server Profiler must capture the following events:

- Audit Login event class with all its data columns. This event class provides information about which user logged in and about the session settings. The server process ID (SPID) provides the reference to the user session. For more information, see [Security Audit Data Columns](#).
- Query Begin event class with all its data columns. This event class provides information about the query that was submitted to Analysis Services. The Event Subclass column provides information about the type of query. The TextData column provides the actual text of the query. The RequestParameters column provides the parameters for parameterized queries, and the RequestProperties column provides the properties of an XML for Analysis (XMLA) request. For more information, see [Queries Events Data Columns](#).
- Query End event class with all its data columns. This event class verifies the status of the query execution. For more information, see [Queries Events Data Columns](#).

Replay for Discovers

To replay discovers, SQL Server Profiler must capture the following events:

- Audit Login event class with all its data columns. This event class provides information about which user logged in and about the session settings. The SPID provides the reference to the user session. For more information, see [Security Audit Data Columns](#).
- Discover Begin event class with all its data columns. The TextData column provides the <RequestType> portion of the discover request, and the RequestProperties column provides the <Properties> portion of the discover request. The EventSubclass column provides the discover type. For more information, see [Discover Events Data Columns](#).
- Discover End event class with all its data columns. This event class verifies the status of the discover request. For more information, see [Discover Events Data Columns](#).

Replay for Commands

To replay commands, SQL Server Profiler must capture the following events:

- Command Begin event class with all its data columns. The TextData column provides the command details, such as the process type, database ID, and cube ID. The RequestParameters column provides the parameters for parameterized command, and the RequestProperties column provides the properties of an

XMLA request. For more information, see [Command Events Data Columns](#).

- Command End event class with all its data columns. This event class verifies the status of the command.
For more information, see [Command Events Data Columns](#).

[Analysis Services Trace Events](#)

[Introduction to Monitoring Analysis Services with SQL Server Profiler](#)

Monitor Analysis Services with SQL Server Extended Events

9/5/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: ✓ SQL Server Analysis Services ✓ Azure Analysis Services ✓ Power BI Premium

Extended Events (*xEvents*) is a light-weight tracing and performance monitoring system that uses very few system resources, making it an ideal tool for diagnosing problems on both production and test servers. It's also highly scalable, configurable, and in SQL Server 2016 , easier to use through new built-in tool support. In SQL Server Management Studio, on connections to Analysis Services instances, you can configure, run, and monitor a live trace, similar to using SQL Server Profiler. The addition of better tooling should make xEvents a more reasonable replacement for SQL Server Profiler and creates more symmetry in how you diagnose issues in your database engine and Analysis Services workloads.

Besides SQL Server Management Studio, you can also configure Analysis Services Extended Event sessions the old way, through XMLA scripting, as was supported in previous releases.

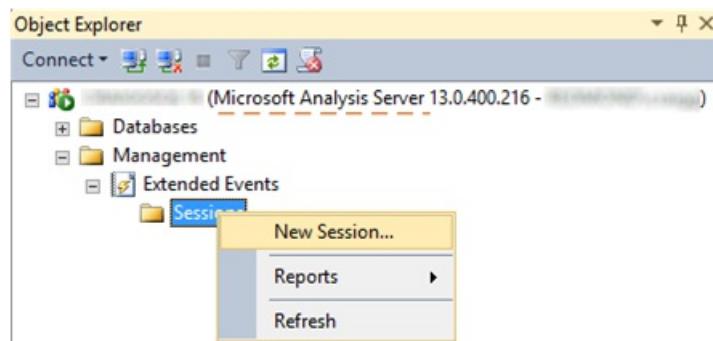

All Analysis Services events can be captured and targeted to specific consumers, as defined in [Extended Events](#).

NOTE

Watch this [quick video introduction](#) or read the [supporting blog post](#) to learn more about xEvents for Analysis Services in SQL Server 2016.

Use Management Studio to Configure Analysis Services

For both tabular and multidimensional instances, Management Studio provides a new Management folder that contains user-initiated xEvent sessions. You can run multiple sessions at once. However, in the current implementation, the Analysis Services Extended Events user interface does not support updating or replaying an existing session.

Choose Events

If you already know which events you want to capture, searching for them is the easiest way to add them to the trace. Otherwise, the following events are commonly used for monitoring operations:

- **CommandBegin** and **CommandEnd**.
- **QueryBegin**, **QueryEnd**, and **QuerySubcubeVerbose** (shows the entire MDX or DAX query sent to the server), plus **ResourceUsage** for stats on resources consumed by the query and how many rows are returned.

- **ProgressReportBegin** and **ProgressReportEnd** (for processing operations).
- **AuditLogin** and **AuditLogout** (captures the user identity under which a client application connects to Analysis Services).

Choose Data Storage

A session can be streamed live to a window in Management Studio or persisted to a file for subsequent analysis using Power Query or Excel.

- **event_file** stores session data in an .xel file.
- **event_stream** enables the **Watch Live Data** option in Management Studio.
- **ring_buffer** stores session data in memory for as long as the server is running. On a server restart, the session data is thrown out

Add Event Fields

Be sure to configure the session to include event fields so that you can easily see information of interest.

Configure is an option on the far side of the dialog box.

In configuration, on the Event Fields tab, select **TextData** so that this field appears adjacent to the event, showing return values, including queries that are executing on the server.

After you configure a session for the desired events and data storage, you can click the script button to send your configuration to one of supported destinations including a file, a new query in SQL Server Management Studio, and the clipboard.

Refresh Sessions

Once you create the session, be sure to refresh the Sessions folder in Management Studio to see the session you just created. If you configured an **event_stream**, you can right-click the session name and choose **Watch Live Data** to monitor server activity in real time.

XMLA Script to Start Extended Events in Analysis Services

Extended Event tracing is enabled using a similar XMLA create object script command as shown below:

```

<Execute ...>
  <Command>
    <Batch ...>
      <Create ...>
        <ObjectDefinition>
          <Trace>
            <ID>trace_id</ID>
            <Name>trace_name</Name>
            <ddl300_300:XEvent>
              <event_session ...>
                <event package="AS" name="AS_event">
                  <action package="PACKAGE0" .../>
                </event>
                <target package="PACKAGE0" name="asynchronous_file_target">
                  <parameter name="filename" value="data_filename.xel"/>
                  <parameter name="metadatafile" value="metadata_filename.xem"/>
                </target>
              </event_session>
            </ddl300_300:XEvent>
          </Trace>
        </ObjectDefinition>
      </Create>
    </Batch>
  </Command>
  <Properties></Properties>
</Execute>

```

Where the following elements are to be defined by the user, depending on the tracing needs:

trace_id

Defines the unique identifier for this trace.

trace_name

The name given to this trace; usually a human readable definition of the trace. It is a common practice to use the *trace_id* value as the name.

AS_event

The Analysis Services event to be exposed. See [Analysis Services Trace Events](#) for names of the events.

data_filename

The name of the file that contains the events data. This name is suffixed with a time stamp to avoid data overwriting if the trace is sent over and over.

metadata_filename

The name of the file that contains the events metadata. This name is suffixed with a time stamp to avoid data overwriting if the trace is sent over and over.

XMLA Script to Stop Extended Events in Analysis Services

To stop the Extended Events tracing object you need to delete that object using a similar XMLA delete object script command as shown below:

```
<Execute xmlns="urn:schemas-microsoft-com:xml-analysis">
  <Command>
    <Batch ...>
      <Delete ...>
        <Object>
          <TraceID>trace_id</TraceID>
        </Object>
      </Delete>
    </Batch>
  </Command>
  <Properties></Properties>
</Execute>
```

Where the following elements are to be defined by the user, depending on the tracing needs:

trace_id

Defines the unique identifier for the trace to be deleted.

[Extended Events](#)

Dynamic Management Views (DMVs)

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services Dynamic Management Views (DMV) are queries that return information about model objects, server operations, and server health. The query, based on SQL, is an interface to *schema rowsets*. Schema rowsets are predetermined tables that contain information about Analysis Services objects and server state, including database schema, active sessions, connections, commands, and jobs that are executing on the server.

DMV queries are an alternative to running XML/A Discover commands. For most administrators, writing a DMV query is simpler because the syntax is based on SQL. In addition, the result is returned in a table format that is easier to read and copy.

Most DMV queries use a **SELECT** statement and the **\$System** schema with an XML/A schema rowset, for example:

```
SELECT * FROM $System.<schemaRowset>
```

DMV queries return information about server and object state at the time the query is run. To monitor operations in real-time, use tracing instead. To learn more about real-time monitoring using traces, see [Use SQL Server Profiler to Monitor Analysis Services](#).

Query syntax

The query engine for DMVs is the Data Mining parser. The DMV query syntax is based on the SELECT (DMX) statement. Although DMV query syntax is based on a SQL SELECT statement, it does not support the full syntax of a SELECT statement. Notably, JOIN, GROUP BY, LIKE, CAST, and CONVERT are not supported.

```
SELECT [DISTINCT] [TOP <n>] <select list>
FROM $System.<schemaRowset>
[WHERE <condition expression>]
[ORDER BY <expression>[DESC|ASC]]
```

The following example for DISCOVER_CALC_DEPENDENCY illustrates the use of the WHERE clause for supplying a parameter to the query:

```
SELECT * FROM $System.DISCOVER_CALC_DEPENDENCY
WHERE OBJECT_TYPE = 'ACTIVE_RELATIONSHIP'
```

For schema rowsets that have restrictions, the query must include the SYSTEMRESTRICTSCHEMA function. The following example returns CSDL metadata about 1103 compatibility level tabular models. Note that CATALOG_NAME is case-sensitive:

```
Select * from SYSTEMRESTRICTSCHEMA ($System.Discover_cSDL_Metadata, [CATALOG_NAME] = 'Adventure Works DW')
```

Examples and scenarios

A DMV query can help you answer questions about active sessions and connections, and which objects are

consuming the most CPU or memory at a specific point in time. For example:

```
Select * from $System.discover_object_activity
```

This query reports on object activity since the service last started.

```
Select * from $System.discover_object_memory_usage
```

This query reports on memory consumption by object.

```
Select * from $System.discover_sessions
```

This query reports on active sessions, including session user and duration.

```
Select * from $System.discover_locks
```

This query returns a snapshot of the locks used at a specific point in time.

Tools and permissions

You can use any client application that supports MDX or DMX queries. In most cases, it's best to use SQL Server Management Studio. You must have server administrator permissions on the instance to query a DMV.

To run a DMV query from SQL Server Management Studio

1. Connect to the server and model object you want to query.
2. Right-click the server or database object > **New Query** > **MDX**.
3. Type your query, and then click **Execute**, or press F5.

Schema rowsets

Not all schema rowsets have a DMV interface. To return a list of all the schema rowsets that can be queried using DMV, run the following query.

```
SELECT * FROM $System.DBSchema_Tables  
WHERE TABLE_TYPE = 'SCHEMA'  
ORDER BY TABLE_NAME ASC
```

If a DMV is not available for a given rowset, the server returns error:

The <scmearowset> request type was not recognized by the server. All other errors indicate problems with the syntax.

Schema rowsets are described in two SQL Server Analysis Services protocols:

[\[MS-SSAS-T\]: SQL Server Analysis Services Tabular Protocol](#) - Describes schema rowsets for tabular models at the 1200 and higher compatibility levels.

[\[MS-SSAS\]: SQL Server Analysis Services Protocol](#) - Describes schema rowsets for multidimensional models and tabular models at the 1100 and 1103 compatibility levels.

Rowsets described in the [MS-SSAS-T]: SQL Server Analysis Services Tabular Protocol

ROWSET	DESCRIPTION
TMSCHEMA_ANNOTATIONS	Provides information about the Annotation objects in the model.
TMSCHEMA_ATTRIBUTE_HIERARCHIES	Provides information about the AttributeHierarchy objects for a column.
TMSCHEMA_COLUMNS	Provides information about the Column objects in each table.

ROWSET	DESCRIPTION
TMSchema_Column_Permissions	Provides information about the ColumnPermission objects in each table-permission.
TMSchema_Cultures	Provides information about the Culture objects in the model.
TMSchema_Data_Sources	Provides information about the DataSource objects in the model.
TMSchema_Detail_Rows_Definitions	Provides information about the DetailRowsDefinition objects in the model.
TMSchema_Expressions	Provides information about the Expression objects in the model.
TMSchema_Extended_Properties	Provides information about the ExtendedProperty objects in the model.
TMSchema_Hierarchies	Provides information about the Hierarchy objects in each table.
TMSchema_KPIs	Provides information about the KPI objects in the model.
TMSchema_Levels	Provides information about the Level objects in each hierarchy.
TMSchema_Linguistic_Metadata	Provides information about the synonyms for objects in the model for a particular culture
TMSchema_Measures	Provides information about the Measure objects in each table.
TMSchema_Model	Specifies a Model object in the database.
TMSchema_Object_Translations	Provides information about the translations of different objects for a culture.
TMSchema_Partitions	Provides information about the Partition objects in each table.
TMSchema_Perspective_Columns	Provides information about the PerspectiveColumn objects in each PerspectiveTable object.
TMSchema_Perspective_Hierarchies	Provides information about the PerspectiveHierarchy objects in each PerspectiveTable object.
TMSchema_Perspective_Measures	Provides information about the PerspectiveMeasure objects in each PerspectiveTable object.
TMSchema_Perspective_Tables	Provides information about the Table objects in a perspective.
TMSchema_Perspectives	Provides information about the Perspective objects in the model.
TMSchema_Relationships	Provides information about the Relationship objects in the model.

ROWSET	DESCRIPTION
TMSchema_Role_Memberships	Provides information about the RoleMembership objects in each role.
TMSchema_Roles	Provides information about the Role objects in the model.
TMSchema_Table_Permissions	Provides information about the TablePermission objects in each role.
TMSchema_Tables	Provides information about the Table objects in the model.
TMSchema_Variations	Provides information about the Variation objects in each column.

Rowsets described in the [MS-SSAS]: SQL Server Analysis Services Protocol

ROWSET	DESCRIPTION
DBSchema_Catalogs	Describes the catalogs that are accessible on the server.
DBSchema_Columns	Returns a row for each measure, each cube dimension attribute, and each schema rowset column, exposed as a column.
DBSchema_Provider_Types	Identifies the (base) data types supported by the server.
DBSchema_Tables	Returns dimensions, measure groups, or schema rowsets exposed as tables.
Discover_Calc_Dependency	Returns information about the calculation dependency for an object that is specified in a Tabular database or in a DAX query that is executed against a Tabular database.
Discover_Command_Objects	Provides resource usage and activity information about the objects in use by the referenced command.
Discover_Commands	Provides resource usage and activity information about the currently executing or last executed commands in the opened connections on the server.
Discover_Connections	Provides resource usage and activity information about the currently opened connections on the server.
Discover_CSDL_Metadata	Returns information about database metadata for in-memory databases.
Discover_Datasources	Returns a list of the data sources that are available on the server.
Discover_Db_Connections	Provides resource usage and activity information about the currently opened connections from the server to a database.
Discover_Dimension_Stat	returns statistics on the specified dimension.

ROWSET	DESCRIPTION
DISCOVER_ENUMERATORS	Returns a list of names, data types, and enumeration values of enumerators supported by the XMLA Provider for a specific data source.
DISCOVER_INSTANCES	Describes the instances on the server.
DISCOVER_JOBS	Provides information about the active jobs executing on the server. A job is a part of a command that executes a specific task on behalf of the command.
DISCOVER_KEYWORDS (XMLA)	Returns information about keywords that are reserved by the XMLA server.
DISCOVER_LITERALS	Returns information about literals supported by the server.
DISCOVER_LOCATIONS	Returns information about the contents of a backup file.
DISCOVER_LOCKS	Provides information about the current standing locks on the server.
DISCOVER_MASTER_KEY	Returns the server's master encryption key.
DISCOVER_MEMORYGRANT	Returns a list of internal memory quota grants that are taken by jobs that are currently running on the server.
DISCOVER_MEMORYUSAGE	Returns the DISCOVER_MEMORYUSAGE statistics for various objects allocated by the server.
DISCOVER_OBJECT_ACTIVITY	Provides resource usage per object since the start of the service.
DISCOVER_OBJECT_MEMORY_USAGE	Returns the DISCOVER_MEMORYUSAGE statistics for various objects allocated by the server.
DISCOVER_PARTITION_DIMENSION_STAT	Returns statistics on the dimension that is associated with a partition.
DISCOVER_PARTITION_STAT	Returns statistics on aggregations in a particular partition.
DISCOVER_PERFORMANCE_COUNTERS	Returns the value of one or more specified performance counters.
DISCOVER_PROPERTIES	Returns a list of information and values about the properties that are supported by the server for the specified data source.
DISCOVER_RING_BUFFERS	Returns information about the current XEvent ring buffers on the server.
DISCOVER_SCHEMA_ROWSETS	Returns the names, restrictions, description, and other information for all Discover requests.

ROWSET	DESCRIPTION
DISCOVER_SESSIONS	Provides resource usage and activity information about the currently opened sessions on the server.
DISCOVER_STORAGE_TABLE_COLUMN_SEGMENTS	Returns information about the column segments used for storing data for in-memory tables.
DISCOVER_STORAGE_TABLE_COLUMNS	Contains information about the columns used for representing the columns of an in-memory table.
DISCOVER_STORAGE_TABLES	Returns statistics about in-memory tables available to the server.
DISCOVER_TRACE_COLUMNS	
DISCOVER_TRACE_DEFINITION_PROVIDERINFO	Contains the DISCOVER_TRACE_COLUMNS schema rowset.
DISCOVER_TRACE_EVENT_CATEGORIES	Contains the DISCOVER_TRACE_EVENT_CATEGORIES schema rowset.
DISCOVER_TRACES	Contains the DISCOVER_TRACES schema rowset.
DISCOVER_TRANSACTIONS	Returns the current set of pending transactions on the system.
DISCOVER_XEVENT_TRACE_DEFINITION	Provides information about the XEvent traces that are currently active on the server.
DISCOVER_XEVENT_PACKAGES	Provides information about the XEvent packages that are described on the server.
DISCOVER_XEVENT_OBJECTS	Provides information about the XEvent objects that are described on the server.
DISCOVER_XEVENT_OBJECT_COLUMNS	Provides information about the schema of XEvent objects that are described on the server.
DISCOVER_XEVENT_SESSIONS	Provides information about the current XEvent sessions on the server.
DISCOVER_XEVENT_SESSION_TARGETS	Provides information about the current XEvent session targets on the server.
DISCOVER_XML_METADATA	Returns a rowset with one row and one column.
DMSCHEMA_MINING_COLUMNS	Describes the individual columns of all described data mining models that are deployed on the server.
DMSCHEMA_MINING_FUNCTIONS	Describes the data mining functions that are supported by the data mining algorithms that are available on a server that is running Analysis Services.
DMSCHEMA_MINING_MODEL_CONTENT	Enables the client application to browse the content of a trained data mining model.

ROWSET	DESCRIPTION
DMSchema_Mining_Model_Content_PMML	Returns the XML structure of the mining model. The format of the XML string follows the PMML 2.1 standard.
DMSchema_Mining_Model_XML	Returns the XML structure of the mining model. The format of the XML string follows the PMML 2.1 standard.
DMSchema_Mining_Models	Enumerates the data mining models that are deployed on the server.
DMSchema_Mining_Service_Parameters	Provides a list of parameters that can be used to configure the behavior of each data mining algorithm that is installed on the server.
DMSchema_Mining_Services	Provides information about each data mining algorithm that the server supports.
DMSchema_Mining_Structure_Columns	Describes the individual columns of all mining structures that are deployed on the server.
DMSchema_Mining_Structures	Enumerates information about the mining structures in the current catalog.
MDSchema_Actions	Describes the actions that can be available to the client application.
MDSchema_Cubes	Describes the structure of cubes within a database. Perspectives are also returned in this schema.
MDSchema_Dimensions	Describes the dimensions within a database.
MDSchema_Functions	Returns information about the functions that are currently available for use in the DAX and MDX languages.
MDSchema_Hierarchies	Describes each hierarchy within a particular dimension.
MDSchema_Input_Datasources	Describes the data source objects described within the database.
MDSchema_KPIs	Describes the KPIs within a database.
MDSchema_Levels	Describes each level within a particular hierarchy.
MDSchema_Measuregroup_Dimensions	Enumerates the dimensions of measure groups.
MDSchema_Measuregroups	Describes the measure groups within a database.
MDSchema_Measures	Describes each measure.
MDSchema_Members	Describes the members within a database.
MDSchema_Properties	Describes the properties of members and cell properties.

ROWSET	DESCRIPTION
MDSHEMA_SETS	Describes any sets that are currently described in a database, including session-scoped sets.

NOTE

STORAGES DMVs do not have a schema rowset described in the protocol.

Performance counters

10/22/2019 • 17 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

By using Performance Monitor, you can monitor the performance of an Analysis Services instance with performance counters.

Azure Analysis Services uses Azure Metrics Explorer in the portal. To learn more, see [Monitor Azure Analysis Services server metrics](#).

Performance Monitor is a Microsoft Management Control (MMC) snap-in that tracks resource usage. You can start the MMC snap-in by typing in **PerfMon** at the command prompt or from Control Panel by clicking **Administrative Tools**, then **Performance Monitor**. Performance Monitor lets you track server and process performance and activity by using predefined objects and counters, and monitor events by using user-defined counters. Performance Monitor collects counts instead of data about the events, for example, memory usage, number of active transactions, or CPU activity. You can also set thresholds on specific counters to generate alerts that notify operators.

Performance Monitor can monitor remote and local instances of Analysis Services or SQL Server. For more information, see [Using Performance Monitor](#).

To see the description of any counter that can be used with SQL Server Analysis Services, in Performance Monitor, open the **Add Counters** dialog box, select a performance object, and then click **Show Description**. The most important counters are CPU usage, memory usage, disk IO rate. It is recommended you start with these important counters, and move to more detailed counters when you have a better idea of what else could be improved through monitoring. For more information about which counters to include, see the [SQL Server 2008 R2 Operations Guide](#).

Counters are grouped so you can more easily find related counters.

Counters by Groups

GROUP	DESCRIPTION
Cache	Statistics related to the Analysis Services aggregation cache.
Connection	Statistics related to Microsoft Analysis Services connections.
Data Mining Prediction	Statistics related to processing data mining models processing.
Data Mining Model Processing	Statistics related to creating predictions from data mining models.
Locks	Statistics related to Microsoft Analysis Services internal server locks.
MDX	Statistics related to Microsoft Analysis Services MDX calculations.

GROUP	DESCRIPTION
Memory	Statistics related to Microsoft Analysis Services internal server memory.
Proactive Caching	Statistics related to Microsoft Analysis Services Proactive Caching.
Processing Aggregations	Statistics related to processing of aggregations in MOLAP data files.
Processing Indexes	Statistics related to processing of indexes for MOLAP data files.
Processing	Statistics related to processing of data.
Storage Engine Query	Statistics related to Microsoft Analysis Services storage engine queries.
Threads	Statistics related to Microsoft Analysis Services threads.

Cache

Statistics related to the Microsoft Analysis Services aggregation cache.

COUNTER	DESCRIPTION
Current KB	Current memory used by the aggregation cache, in KB.
KB added/sec	Rate of memory added to the cache, KB/sec.
Current entries	Current number of cache entries.
Inserts/sec	Rate of insertions into the cache. The rate is tracked per partition per cube per database.
Evictions/sec	Rate of evictions from the cache. This is per partition per cube per database. Evictions are typically due to background cleaner.
Total inserts	Insertions into the cache. The rate is tracked per partition per cube per database.
Total evictions	Evictions from the cache. Evictions are tracked per partition per cube per database. Evictions are typically due to background cleaner.
Direct hits/sec	Rate of cache direct hits. A cache hit indicates that queries were answered from an existing cache entry.
Misses/sec	Rate of cache misses.
Lookups/sec	Rate of cache lookups.

COUNTER	DESCRIPTION
Total direct hits	Total count of direct cache hits. A direct cache hit indicates that queries were answered from existing cache entries.
Total misses	Total count of cache misses.
Total lookups	Total number of lookups into the cache.
Direct hit ratio	Ratio of cache direct hits to cache lookups, for the period between counter values.
Total filtered iterator cache hits	Total number of cache hits that returned an indexed iterator over the filtered results.
Total filtered iterator cache misses	Total number of cache hits that were unable to build an indexed iterator over the filtered results and had to build a new cache with the filtered results.

Connection

Statistics related to Microsoft Analysis Services connections.

COUNTER	DESCRIPTION
Current connections	Current number of client connections established.
Requests/sec	Rate of connection requests. These are arrivals.
Total requests	Total connection requests. These are arrivals.
Successes/sec	Rate of successful connection completions.
Total successes	Total successful connections.
Failures/sec	Rate of connection failures.
Total failures	Total failed connection attempts.
Current user sessions	Current number of user sessions established.

Data Mining Model Processing

Statistics related to Microsoft Analysis Services Data Mining model processing.

COUNTER	DESCRIPTION
Cases/sec	Rate at which cases are processed.
Current models processing	Current number of models being processed.

Data Mining Prediction

Statistics related to Microsoft Analysis Services Data Mining prediction.

COUNTER	DESCRIPTION
Concurrent DM queries	Current number of data mining queries being actively worked on.
Predictions/sec	Number of predictions generated in data mining queries
Rows/sec	Number of rows handled during a data mining prediction query.
Queries/sec	Number of data mining queries that were handled.
Total Queries	Total data mining queries received by the server.
Total Rows	Total rows returned by data mining queries.
Total Predictions	Total data mining prediction queries received by the server.

Locks

Statistics related to Microsoft Analysis Services internal server locks.

COUNTER	DESCRIPTION
Current latch waits	Current number of threads waiting for a latch. These are latch requests that could not be given immediate grants and are in a wait state.
Latch waits/sec	Rate of latch requests that could not be granted immediately and had to wait before being granted.
Current locks	Current number of locked objects.
Current lock waits	Current number of clients waiting for a lock.
Lock requests/sec	Number of lock requests per second.
Lock grants/sec	Number of lock grants per second.
Lock waits/sec	Number of lock waits per second. These are lock requests that could not be given immediate lock grants and were put in a wait state.
Lock denials/sec	Rate of lock denials.
Unlock requests/sec	Number of unlock requests per second.
Total deadlocks detected	Total number of deadlocks detected.

MDX

Statistics related to Microsoft Analysis Services MDX Calculations.

COUNTER	DESCRIPTION
Number of calculation covers	Total number of evaluation nodes built by MDX execution plans, including active and cached.
Current number of evaluation nodes	Current (approximate) number of evaluation nodes built by MDX execution plans, including active and cached.
Number of Storage Engine evaluation nodes	Total number of Storage Engine evaluation nodes built by MDX execution plans.
Number of cell-by-cell evaluation nodes	Total number of cell-by-cell evaluation nodes built by MDX execution plans.
Number of bulk-mode evaluation nodes	Total number of bulk-mode evaluation nodes built by MDX execution plans.
Number of evaluation nodes that covered a single cell	Total number of evaluation nodes built by MDX execution plans that covered only one cell.
Number of evaluation nodes with calculations at the same granularity	Total number of evaluation nodes built by MDX execution plans for which the calculations were at the same granularity as the evaluation node.
Current number of cached evaluation nodes	Current (approximate) number of cached evaluation nodes built by MDX execution plans.
Number of cached Storage Engine evaluation nodes	Total number of cached Storage Engine evaluation nodes built by MDX execution plans
Number of cached bulk-mode evaluation nodes	Total number of cached bulk-mode evaluation nodes built by MDX execution plans.
Number of cached 'other' evaluation nodes	Total number of cached evaluation nodes built by MDX execution plans that are neither Storage Engine nor Bulk-mode.
Number of evictions of evaluation nodes	Total number of cache evictions of evaluation nodes due to collisions.
Number of hash index hits in the cache of evaluation nodes	Total number of hits in the cache of evaluation nodes that were satisfied by the hash index.
Number of cell-by-cell hits in the cache of evaluation nodes	Total number of cell-by-cell hits in the cache of evaluation nodes.
Number of cell-by-cell misses in the cache of evaluation nodes	Total number of cell-by-cell misses in the cache of evaluation nodes.
Number of subcube hits in the cache of evaluation nodes	Total number of subcube hits in the cache of evaluation nodes.
Number of subcube misses in the cache of evaluation nodes	Total number of subcube misses in the cache of evaluation nodes.
Total Sonar subcubes	Total number of subcubes that the query optimizer generated.

COUNTER	DESCRIPTION
Total cells calculated	Total number of cell properties calculated.
Total recomputes	Total number of cells recomputed due to error.
Total flat cache inserts	Total number of cell values inserted into flat calculation cache.
Total calculation cache registered	Total number of calculation caches registered.
Total NON EMPTY	Total number of times a NON EMPTY algorithm was used.
Total NON EMPTY unoptimized	Total number of times an unoptimized NON EMPTY algorithm was used.
Total NON EMPTY for calculated members	Total number of times a NON EMPTY algorithm looped over calculated members.
Total Autoexist	Total number of times Autoexist was performed.
Total EXISTING	Total number of times an EXISTING set operation was performed.

Memory

Statistics related to Microsoft Analysis Services internal server memory.

COUNTER	DESCRIPTION
Page Pool 64 Alloc KB	Memory borrowed from system, in KB. This memory is given away to other parts of the server.
Page Pool 64 Lookaside KB	Current memory in 64KB lookaside list, in KB. (Memory pages ready to be used.)
Page Pool 8 Alloc KB	Memory borrowed from 64KB page pool, in KB. This memory is given away to other parts of the server.
Page Pool 8 Lookaside KB	Current memory in 8KB lookaside list, in KB. (Memory pages ready to be used.)
Page Pool 1 Alloc KB	Memory borrowed from 64KB page pool, in KB. This memory is given away to other parts of the server.
Page Pool 1 Lookaside KB	Current memory in 8KB lookaside list, in KB. (Memory pages ready to be used.)
Cleaner Current Price	Current price of memory, \$/byte/time, normalized to 1000.
Cleaner Balance/sec	Rate of balance+shrink operations.
Cleaner Memory shrunk KB/sec	Rate of shrinking, in KB/sec.
Cleaner Memory shrinkable KB	Amount of memory, in KB, subject to purging by the background cleaner.

COUNTER	DESCRIPTION
Cleaner Memory nonshrinkable KB	Amount of memory, in KB, not subject to purging by the background cleaner.
Cleaner Memory KB	Amount of memory, in KB, known to the background cleaner. (Cleaner memory shrinkable + Cleaner memory nonshrinkable.)
Memory Usage KB	Memory usage of the server process as used in calculating cleaner memory price. Equal to counter Process\PrivateBytes plus the size of memory-mapped data, ignoring any memory which was mapped or allocated by the VertiPaq in-memory analytics engine (VertiPaq) in excess of the VertiPaq engine Memory Limit.
Memory Limit Low KB	Low memory limit, from configuration file.
Memory Limit High KB	High memory limit, from configuration file.
AggCacheKB	Current memory allocated to aggregation cache, in KB.
Quota KB	Current memory quota, in KB. Memory quota is also known as a memory grant or memory reservation.
Quota Blocked	Current number of quota requests that are blocked until other memory quotas are freed.
Filestore KB	Current memory allocated to filestore (file cache), in KB.
Filestore Page Faults/sec	Filestore page fault rate.
Filestore Reads/sec	Filestore pages read/sec.
Filestore KB Reads/sec	Filestore KB read/sec.
Filestore Writes/sec	Filestore pages written/sec. The writes are asynchronous.
Filestore KB Write/sec	Filestore KB written/sec. The writes are asynchronous.
Filestore IO Errors/sec	Filestore IO Error rate.
Filestore IO Errors	Filestore IO Errors total.
Filestore Clock Pages Examined/sec	Rate of background cleaner examining pages for eviction consideration.
Filestore Clock Pages HaveRef/sec	Rate of background cleaner examining pages that have a current reference count (are currently in use).
Filestore Clock Pages Valid/sec	Rate of background cleaner examining pages that are valid candidates for eviction.
Filestore Memory Pinned KB	Current filestore memory pinned, in KB.

COUNTER	DESCRIPTION
In-memory Dimension Property File KB	Current size of in-memory dimension property file, in KB.
In-memory Dimension Property File KB/sec	Rate of writes to in-memory dimension property file, in KB.
Potential In-memory Dimension Property File KB	Potential size of in-memory dimension property file, in KB.
Dimension Property Files	Number of dimension property files.
In-memory Dimension Index (Hash) File KB	Size of current in-memory dimension index (hash) file, in KB.
In-memory Dimension Index (Hash) File KB/sec	Rate of writes to in-memory dimension index (hash) file, in KB.
Potential In-memory Dimension Index (Hash) File KB	Potential size of in-memory dimension index (hash) file, in KB.
Dimension Index (Hash) Files	Number of dimension index (hash) files.
In-memory Dimension String File KB	Current size of in-memory dimension string file, in KB.
In-memory Dimension String File KB/sec	Rate of writes to in-memory dimension string file, in KB.
Potential In-memory Dimension String File KB	Potential size of in-memory dimension string file, in KB.
Dimension String Files	Number of dimension string files.
In-memory Map File KB	Current size of in-memory map file, in KB.
In-memory Map File KB/sec	Rate of writes to in-memory map file, in KB.
Potential In-memory Map File KB	Potential size of in-memory map file, in KB.
Map Files	Number of map files.
In-memory Aggregation Map File KB	Current size of in-memory aggregation map file, in KB.
In-memory Aggregation Map File KB/sec	Rate of writes to in-memory aggregation map file, in KB.
Potential In-memory Aggregation Map File KB	Size of potential in-memory aggregation map file, in KB.
Aggregation Map Files	Number of aggregation map files.
In-memory Fact Data File KB	Size of current in-memory fact data file, in KB.
In-memory Fact Data File KB/sec	Rates of writes to in-memory fact data file KB rate.
Potential In-memory Fact Data File KB	Size of potential in-memory fact data file, in KB.
Fact Data Files	Number of fact data files.
In-memory Fact String File KB	Size of current in-memory fact string file, in KB.

COUNTER	DESCRIPTION
In-memory Fact String File KB/sec	Rate of writes to in-memory fact string file, in KB.
Potential In-memory Fact String File KB	Size of potential in-memory fact string file, in KB.
Fact String Files	Number of fact string files.
In-memory Fact Aggregation File KB	Current size of in-memory fact aggregation file, in KB.
In-memory Fact Aggregation File KB/sec	Rate of writes to in-memory fact aggregation file, in KB.
Potential In-memory Fact Aggregation File KB	Size of potential in-memory fact aggregation file, in KB.
Fact Aggregation Files	Number of fact aggregation files.
In-memory Other File KB	Size of current in-memory other file, in KB.
In-memory Other File KB/sec	Rate of writes to in-memory other file, in KB.
Potential In-memory Other File KB	Size of potential in-memory other file, in KB.
Other Files	Number of other files.
VertiPaq Paged KB	Kilobytes of paged memory in use for in-memory data.
VertiPaq Nonpaged KB	Kilobytes of memory locked in the working set for use by the in-memory engine.
VertiPaq Memory-Mapped KB	Kilobytes of pageable memory in use for in-memory data.
Memory Limit Hard KB	Hard memory limit, from configuration file.
Memory Limit VertiPaq KB	In-memory limit, from configuration file.

Proactive Caching

Statistics related to Microsoft Analysis Services Proactive Caching.

COUNTER	DESCRIPTION
Notifications/sec	Rate of notifications from relational database.
Processing Cancellations/sec	Rate of processing cancellations caused by notifications.
Proactive Caching Begin/sec	Rate of proactive caching begin.
Proactive Caching Completion/sec	Rate of proactive caching completion.

Processing Aggregations

Statistics related to Microsoft Analysis Services processing of aggregations in MOLAP data files.

COUNTER	DESCRIPTION
Current partitions	Current number of partitions being processed.
Total partitions	Total number of partitions processed (successfully or otherwise).
Memory size rows	Size of current aggregations in memory. This count is an estimate.
Memory size bytes	Size of current aggregations in memory. This count is an estimate.
Rows merged/sec	Rate of rows merged or inserted into an aggregation.
Rows created/sec	Rate of aggregation rows created.
Temp file rows written/sec	Rate of writing rows to a temporary file. Temporary files are written when aggregations exceed memory limits.
Temp file bytes written/sec	Rate of writing bytes to a temporary file. Temporary files are written when aggregations exceed memory limits.

Processing Indexes

Statistics related to Microsoft Analysis Services processing of indexes for MOLAP data files.

COUNTER	DESCRIPTION
Current partitions	Current number of partitions being processed.
Total partitions	Total number of partitions processed (successfully or otherwise).
Rows/sec	Rate of rows from MOLAP files used to create indexes.
Total rows	Total rows from MOLAP files used to create indexes.

Processing

Statistics related to Microsoft Analysis Services processing of data.

COUNTER	DESCRIPTION
Rows read/sec	Rate of rows read from all relational databases.
Total rows read	Count of rows read from all relational databases.
Rows converted/sec	Rate of rows converted during processing.
Total rows converted	Count of rows converted during processing.
Rows written/sec	Rate of rows written during processing.
Total rows written	Count of rows written during processing.

Storage Engine Query

Statistics related to Microsoft Analysis Services storage engine queries.

COUNTER	DESCRIPTION
Current measure group queries	Current number of measure group queries being actively worked on.
Measure group queries/sec	Rate of measure group queries
Total measure group queries	Total number of queries to measure group.
Current dimension queries	Current number of dimension queries being actively worked on.
Dimension queries/sec	Rate of dimension queries
Total dimension queries.	Total number of dimension queries.
Queries answered/sec	Rate of queries answered.
Total queries answered	Total number of queries answered.
Bytes sent/sec	Rate of bytes sent by server to clients, in response to queries.
Total bytes sent	Total bytes sent by server to clients, in response to queries.
Rows sent/sec	Rate of rows sent by server to clients.
Total rows sent	Total rows sent by server to clients.
Queries from cache direct/sec	Rate of queries answered from cache directly.
Queries from cache filtered/sec	Rate of queries answered by filtering existing cache entry.
Queries from file/sec	Rate of queries answered from files.
Total queries from cache direct	Total number of queries derived directly from cache. Note that this is per partition.
Total queries from cache filtered	Total queries answered by filtering existing cache entries.
Total queries from file	Total number of queries answered from files.
Map reads/sec	Number of logical read operations using the Map file.
Map bytes/sec	Bytes read from the Map file.
Data reads/sec	Number of logical read operations using the Data file.
Data bytes/sec	Bytes read from the Data file.

COUNTER	DESCRIPTION
Avg time/query	Average time per query, in milliseconds. Response time based on queries answered since the last counter measurement.
Network round trips/sec	Rate of network round trips. This includes all client/server communication.
Total network round trips	Total network round trips. This includes all client/server communication.
Flat cache lookups/sec	Rate of flat cache lookups. This includes global, session, and query scope flat caches.
Flat cache hits/sec	Rate of flat cache hits. This includes global, session, and query scope flat caches.
Calculation cache lookups/sec	Rate of calculation cache lookups. This includes global, session, and query scope calculation caches.
Calculation cache hits/sec	Rate of calculation cache hits. This includes global, session, and query scope calculation caches.
Persisted cache lookups/sec	Rate of persisted cache lookups. Persisted caches are created by the MDX script CACHE statement.
Persisted cache hits/sec	Rate of persisted cache hits. Persisted caches are created by the MDX script CACHE statement.
Dimension cache lookups/sec	Rate of dimension cache lookups.
Dimension cache hits/sec	Rate of dimension cache hits.
Measure group cache lookups/sec	Rate of measure group cache lookups.
Measure group cache hits/sec	Rate of measure group cache hits.
Aggregation lookups/sec	Rate of aggregation lookups.
Aggregation hits/sec	Rate of aggregation hits.

Threads

Statistics related to Microsoft Analysis Services threads.

COUNTER	DESCRIPTION
Short parsing idle threads	Number of idle threads in the short parsing thread pool.
Short parsing busy threads	Number of busy threads in the short parsing thread pool.
Short parsing job queue length	Number of jobs in the queue of the short parsing thread pool.
Short parsing job rate	Rate of jobs through the short parsing thread pool.

COUNTER	DESCRIPTION
Long parsing idle threads	Number of idle threads in the long parsing thread pool.
Long parsing busy threads	Number of busy threads in the long parsing thread pool.
Long parsing job queue length	Number of jobs in the queue of the long parsing thread pool.
Long parsing job rate	Rate of jobs through the long parsing thread pool.
Query pool idle threads	Number of idle threads in the query thread pool.
Query pool busy threads	Number of busy threads in the query thread pool.
Query pool job queue length	Number of jobs in the queue of the query thread pool.
Query pool job rate	Rate of jobs through the query thread pool.
Processing pool idle non-I/O threads	Number of idle threads in the processing thread pool dedicated to non-I/O jobs.
Processing pool busy non-I/O threads	Number of threads running non-I/O jobs in the processing thread pool.
Processing pool job queue length	Number of non-I/O jobs in the queue of the processing thread pool.
Processing pool job rate	Rate of non-I/O jobs through the processing thread pool.
Processing pool idle I/O job threads	Number of idle threads for I/O jobs in the processing thread pool.
Processing pool busy I/O job threads	Number of threads running I/O jobs in the processing thread pool.
Processing pool I/O job queue length	Number of I/O jobs in the queue of the processing thread pool.
Processing pool I/O job completion rate	Rate of I/O jobs through the processing thread pool.

Log operations in Analysis Services

9/6/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

An Analysis Services instance will log server notifications, errors, and warnings to the msmdsrv.log file - one for each instance you install. Administrators refer to this log for insights into routine and extraordinary events alike. In recent releases, logging has been enhanced to include more information. Log records now include product version and edition information, as well as processor, memory, connectivity, and blocking events. You can review the entire change list at [Logging improvements](#).

Besides the built-in logging feature, many administrators and developers also use tools provided by the Analysis Services community to collect data about server operations, such as **ASTrace**. See [Microsoft SQL Server Community Samples: Analysis Services](#) for the download links.

This topic contains the following sections:

- [Location and types of logs](#)
- [General information on log file configuration settings](#)
- [MSMDSRV service log file](#)
- [Query logs](#)
- [Mini dump \(.mdmp\) files](#)
- [Tips and best practices](#)

Location and types of logs

Analysis Services provides the logs described below.

FILE NAME OR LOCATION	TYPE	USED FOR	ON BY DEFAULT
Msmdsrv.log	Error log	Routine monitoring and basic troubleshooting	Yes
OlapQueryLog table in a relational database	Query log	Collect inputs for the Usage Optimization Wizard	No
SQLDmp<guid>.mdmp files	Crashes and exceptions	Deep troubleshooting	No

We highly recommend the following link for additional information resources not covered in this topic: [Initial data collection tips from Microsoft Support](#).

General information on log file configuration settings

You can find sections for each log in the msmdsrv.ini server configuration file, located in the \Program Files\Microsoft SQL Server\MSAS13.MSSQLSERVER\OLAP\Config folder. See [Server properties in Analysis Services](#) for instructions on editing the file.

Where possible, we suggest that you set logging properties in the server properties page of Management Studio. Although in some cases, you must edit the msmdsrv.ini file directly to configure settings that are not visible in the

administrative tools.

```
- <Log>
  <File>msmdsrv.log</File>
  <FileBufferSize>0</FileBufferSize>
  <MessageLogs>File;Console;System</MessageLogs>
+ <ErrorLog>
+ <QueryLog>
+ <Exception>
+ <Trace>
+ <FlightRecorder>
</Log>
```

MSMDSRV service log file

Analysis Services logs server operations to the msmdsrv.log file, one per instance, located at \program files\Microsoft SQL Server\<instance>\Olap\Log.

This log file is emptied at each service restart. In previous releases, administrators would sometimes restart the service for the sole purpose of flushing the log file before it could grow so large as to become unusable. This is no longer necessary. Configuration settings, introduced in SQL Server 2012 SP2 and later, give you control over the size of the log file and its history:

- **MaxFileSizeMB** specifies a maximum log file size in megabytes. The default is 256. A valid replacement value must be a positive integer. When **MaxFileSizeMB** is reached, Analysis Services renames the current file as msmdsrv{current timestamp}.log file, and starts a new msmdsrv.log file.
- **MaxNumberFiles** specifies retention of older log files. The default is 0 (disabled). You can change it to a positive integer to keep versions of the log file. When **MaxNumberFiles** is reached, Analysis Services deletes the file with the oldest timestamp in its name.

To use these settings, do the following:

1. Open msmdsrv.ini in NotePad.
2. Copy the following two lines:

```
<MaxFileSizeMB>256</MaxFileSizeMB>
<MaxNumberOfLogFile>5</MaxNumberOfLogFile>
```

3. Paste the two lines into the Log section of msmdsrv.ini, below the filename for msmdsrv.log. Both settings must be added manually. There are no placeholders for them in the msmdsrv.ini file.

The changed configuration file should look like the following:

```
<Log>
<File>msmdsrv.log</File>
<MaxFileSizeMB>256</MaxFileSizeMB>
<MaxNumberOfLogFile>5</MaxNumberOfLogFile>
<FileBufferSize>0</FileBufferSize>
```

4. Edit the values if those provided differ from what you want.
5. Save the file.
6. Restart the service.

Query logs

The query log is a bit of a misnomer in that it does not log the MDX or DAX query activity of your users. Instead, it collects data about queries generated by Analysis Services, which is subsequently used as data input in the Usage Based Optimization Wizard. The data collected in the query log is not intended for direct analysis. Specifically, the datasets are described in bit arrays, with a zero or a one indicating the parts of dataset is included in the query. Again, this data is meant for the wizard.

For query monitoring and troubleshooting, many developers and administrators use a community tool, **ASTrace**, to monitor queries. You can also use SQL Server Profiler, xEvents, or an Analysis Services trace.

When should you use the query log? We recommend enabling the query log as part of a query performance tuning exercise that includes the Usage Based Optimization Wizard. The query log does not exist until you enable the feature, create the data structures to support it, and set properties used by Analysis Services to locate and populate the log.

To enable the query log, follow these steps:

1. Create a SQL Server relational database to store the query log.
2. Grant the Analysis Services service account sufficient permissions on the database. The account needs permission to create a table, write to the table, and read from the table.
3. In SQL Server Management Studio, right-click **Analysis Services | Properties | General**, set **CreateQueryLogTable** to true.
4. Optionally, change **QueryLogSampling** or **QueryLogTableName** if you want to sample queries at a different rate, or use a different name for the table.

The query log table will not be created until you have run enough MDX queries to meet the sampling requirements. For example, if you keep the default value of 10, you must run at least 10 queries before the table will be created.

Query log settings are server wide. The settings you specify will be used by all databases running on this server.

Name	Value	Current Value	Default Value	Restart
DataMining \ MaxConcurrentPredictionQueries	0	0	0	
Feature \ ComUdfEnabled	false	false	false	
Feature \ LinkFromOtherInstanceEnabled	false	false	false	
Feature \ LinkInsideInstanceEnabled	true	true	true	
Feature \ LinkToOtherInstanceEnabled	false	false	false	
ForceCommit Timeout	30000	30000	30000	
Log \ FlightRecorder \ Enabled	true	true	true	
Log \ QueryLog \ CreateQueryLogTable	true	true	false	
Log \ QueryLog \ QueryLogConnectionString	Provider=SQLNCLI11.1;Data	Provider=SQLN...		
Log \ QueryLog \ QueryLogSampling	10	10	10	
Log \ QueryLog \ QueryLogTableName	OlapQueryLog	OlapQueryLog	OlapQueryLog	
LogDir	C:\Program Files\Microsoft...	C:\Program File...		yes

After the configuration settings are specified, run an MDX query multiple times. If sampling is set to 10, run the query 11 times. Verify the table is created. In Management Studio, connect to the relational database engine, open the database folder, open the **Tables** folder, and verify that **OlapQueryLog** exists. If you do not immediately see the table, refresh the folder to pick up any changes to its contents.

Allow the query log to accumulate sufficient data for the Usage Based Optimization Wizard. If query volumes are cyclical, capture enough traffic to have a representative set of data. See [Usage Based Optimization Wizard](#) for instructions on how to run the wizard.

See [Configuring the Analysis Services Query Log](#) to learn more about query log configuration. Although the paper is quite old, query log configuration has not changed in recent releases and the information it contains still applies.

Mini dump (.mdmp) files

Dump files capture data used for analyzing extraordinary events. Analysis Services automatically generates mini dumps (.mdmp) in response to a server crash, exception, and some configuration errors. The feature is enabled, but does not send crash reports automatically.

Crash reports are configured through the Exception section in the Msmdsrv.ini file. These settings control memory dump file generation. The following snippet shows the default values:

```
<Exception>
<CreateAndSendCrashReports>1</CreateAndSendCrashReports>
<CrashReportsFolder/>
<SQLDumperFlagsOn>0x0</SQLDumperFlagsOn>
<SQLDumperFlagsOff>0x0</SQLDumperFlagsOff>
<MiniDumpFlagsOn>0x0</MiniDumpFlagsOn>
<MiniDumpFlagsOff>0x0</MiniDumpFlagsOff>
<MinidumpErrorList>0xC1000000, 0xC1000001, 0xC102003F, 0xC1360054, 0xC1360055</MinidumpErrorList>
<ExceptionHandlingMode>0</ExceptionHandlingMode>
<CriticalErrorHandling>1</CriticalErrorHandling>
<MaxExceptions>500</MaxExceptions>
<MaxDuplicateDumps>1</MaxDuplicateDumps>
</Exception>
```

Configure Crash Reports

Unless otherwise directed by Microsoft Support, most administrators use the default settings. This older KB article is still used to provide instruction on how to configure dump files: [How to configure Analysis Services to generate memory dump files](#).

The configuration setting most likely to be modified is the **CreateAndSendCrashReports** setting used to determine whether a memory dump file will be generated.

VALUE	DESCRIPTION
0	Turns off the memory dump file. All other settings under the Exception section are ignored.
1	(Default) Enables, but does not send, the memory dump file.
2	Enables and automatically sends an error report to Microsoft.

CrashReportsFolder is the location of the dump files. By default, an .mdmp file and associated log records can be found in the \Olap\Log folder.

SQLDumperFlagsOn is used to generate a full dump. By default, full dumps are not enabled. You can set this property to **0x34**.

The following links provide more background:

- [Looking Deeper into SQL Server using Minidumps](#)
- [How to create a user mode dump file](#)
- [How to use the Sqldumper.exe utility to generate a dump file in SQL Server](#)

Tips and best practices

This section is a recap of the tips mentioned throughout this article.

- Configure the msmdsrv.log file to control the size and number of msmdsrv log file. The settings are not enabled by default, so be sure to add them as post-installation step. See [MSMDSRV service log file](#) in this

topic.

- Review this blog post from Microsoft Customer Support to learn what resources they use to get information about server operations: [Initial Data Collection](#)
- Use AS Trace2012, rather than a query log, to find out who is querying cubes. The query log is typically used to provide input into the Usage Based Optimization Wizard, and the data it captures is not easy to read or interpret. AS Trace2012 is a community tool, widely used, that captures query operations. See [Microsoft SQL Server Community Samples: Analysis Services](#).

[Server properties in Analysis Services](#)

Clear the Analysis Services Caches

10/22/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services caches data to boost query performance. This topic provides recommendations for using the XMLA ClearCache command to clear caches that were created in response to an MDX query. The effects of running ClearCache vary depending on whether you are using a tabular or multidimensional model.

When to clear the cache for multidimensional models

For multidimensional databases, Analysis Services builds caches in the formula engine when evaluating a calculation, and in the storage engine for the results of dimension queries and measure group queries. Measure group queries occur when the formula engine needs measure data for a cell coordinate or subcube. Dimension queries occur when querying unnatural hierarchies and when applying autoexists.

Clearing the cache is recommended when conducting performance testing. By clearing the cache between test runs, you ensure that caching does not skew any test results that measure the impact of a query design change.

When to clear the cache for tabular models

Tabular models are generally stored in memory, where aggregations and other calculations are performed at the time a query is executed. As such, the ClearCache command has a limited effect on tabular models. For a tabular model, data may be added to the Analysis Services caches if MDX queries are run against it. In particular, DAX measures referenced by MDX and autoexists operations can cache results in the formula cache and dimension cache respectively. Note however, that unnatural hierarchies and measure group queries do not cache results in the storage engine. Additionally, it is important to recognize that DAX queries do not cache results in the formula and storage engine. To the extent that caches exist as a result of MDX queries, running ClearCache against a tabular model will invalidate any cached data from the system.

Running ClearCache will also clear in-memory caches in the VertiPaq in-memory analytics engine. The VertiPaq engine maintains a small set of cached results. Running ClearCache will invalidate these caches in the engine.

Finally, running ClearCache will also remove residual data that is left in memory when a tabular model is reconfigured for **DirectQuery** mode. This is particularly important if the model contains sensitive data that is subject to tight controls. In this case, running ClearCache is a precautionary action that you can take to ensure that sensitive data exists only where you expect it to be. Clearing the cache manually is necessary if you are using Management Studio to deploy the model and change the query mode. In contrast, using Visual Studio with Analysis Services projects to specify **DirectQuery** on the model and partitions will automatically clear the cache when you switch the model to use that query mode.

Compared with recommendations for clearing multidimensional model caches during performance testing, there is no broad recommendation for clearing tabular model caches. If you are not managing the deployment of a tabular model that contains sensitive data, there is no specific administrative task that calls for clearing the cache.

Clear the cache for Analysis Services models

To clear the cache, use XMLA and SQL Server Management Studio. You can clear the cache at the database, cube, dimension or table, or measure group level. The following steps for clearing the cache at the database level apply to both multidimensional models and tabular models.

NOTE

Rigorous performance testing might require a more comprehensive approach to clearing the cache. For instructions on how to flush Analysis Services and file system caches, see the section on clearing caches in the [SQL Server 2008 R2 Analysis Services Operations Guide](#).

For both multidimensional and tabular models, clearing some of these caches can be a two-step process that consists of invalidating the cache when ClearCache executes, followed by emptying the cache when the next query is received. A reduction in memory consumption will be evident only after the cache is actually emptied.

Clearing the cache requires that you provide an object identifier to the **ClearCache** statement in an XMLA query. The first step in this topic explains how to get an object identifier.

Step 1: Get the object identifier

1. In Management Studio, right-click an object, select **Properties**, and copy the value from the ID property in the **Properties** pane. This approach works for the database, cube, dimension, or table.
2. To get the measure group ID, right-click the measure group and select **Script Measure Group As**. Choose either **Create** or **Alter**, and send the query to a window. The ID of the measure group will be visible in the object definition. Copy the ID of the object definition.

Step 2: Run the query

1. In Management Studio, right-click a database, point to **New Query**, and select **XMLA**.
2. Copy the following code example into the XMLA query window. Change **DatabaseID** to the ID of the database on the current connection.

```
<ClearCache xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object>
    <DatabaseID> Adventure Works DW Multidimensional</DatabaseID>
  </Object>
</ClearCache>
```

Alternatively, you can specify a path of a child object, such as a measure group, to clear the cache for just that object.

```
<ClearCache xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object>
    <DatabaseID>Adventure Works DW Multidimensional</DatabaseID>
      <CubeID>Adventure Works</CubeID>
        <MeasureGroupID>Fact Currency Rate</MeasureGroupID>
    </Object>
</ClearCache>
```

3. Press F5 to execute the query. You should see the following result:

```
<return xmlns="urn:schemas-microsoft-com:xml-analysis">
  <root xmlns="urn:schemas-microsoft-com:xml-analysis:empty" />
</return>
```

Database Consistency Checker (DBCC) for Analysis Services

9/6/2019 • 19 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

DBCC provides on-demand database validation for Multidimensional and Tabular databases on an Analysis Services instance. You can execute DBCC in an MDX or XMLA query window in SQL Server Management Studio (SSMS) and trace the DBCC output in either SQL Server Profiler or xEvent sessions in SSMS.

The command takes an object definition and returns either an empty result set or detailed error information if the object is corrupted. In this article, you'll learn how to run the command, interpret results, and address any problems that arise.

For Tabular databases, consistency checks performed by DBCC are equivalent to the built-in validation that occurs automatically every time you reload, synchronize, or restore a database. In contrast, consistency checks for Multidimensional databases happen only when you run DBCC on demand.

The range of validation checks will vary by mode, with Tabular databases subject to a broader range of checks. Characteristics of a DBCC workload also varies by server mode. Check operations on Multidimensional databases involve reading data from disk, constructing temporary indexes for comparison against actual indexes -- all of which takes significantly longer to complete.

Command syntax for DBCC uses the object metadata specific to the type of database you are checking:

- Multidimensional + pre-SQL Server 2016 Tabular 1100 or 1103 compatibility level databases are described in Multidimensional modeling constructs like **cubeID**, **measuregroupID**, and **partitionID**.
- Metadata for new Tabular model databases at compatibility level 1200 and higher consist of descriptors like **TableName** and **PartitionName**.

DBCC for Analysis Services will execute on any Analysis Services database at any compatibility level, as long as the database is running on a SQL Server 2016 instance. Just make sure you're using the right command syntax for each database type.

NOTE

If you're familiar with [DBCC \(Transact-SQL\)](#), you'll quickly notice that the DBCC in Analysis Services has a much narrower scope. DBCC in Analysis Services is a single command that reports exclusively on data corruption across the database or on individual objects. If you have other tasks in mind, such as collecting information, try using AMO PowerShell or XMLA scripts instead.

Permission requirements

You must be an Analysis Services database or server administrator (a member of the server role) to run the command. See [Grant database permissions \(Analysis Services\)](#) or [Grant server admin rights to an Analysis Services instance](#) for instructions.

Command syntax

Tabular databases at the 1200 and higher compatibility levels use tabular metadata for object definitions. The complete DBCC syntax for a tabular database created at a SQL Server 2016 functional level is illustrated in the

following example.

Key differences between the two syntaxes include a newer XMLA namespace, no <Object> element, and no <Model> element (there is still only one model per database).

```
<DBCC xmlns="http://schemas.microsoft.com/analysisservices/2014/engine">
  <DatabaseID>MyTabular1200DB_7811b5d8-c407-4203-8793-12e16c3d1b9b</DatabaseID>
  <TableName>FactSales</TableName>
  <PartitionName>FactSales 4</PartitionName>
</DBCC>
```

You can omit lower-level objects, such as table or partition names, to check the entire schema.

You can get object names and DatabaseID from Management Studio, through the property page of each object.

Command syntax for Multidimensional and Tabular 110x databases

DBCC uses identical syntax for multidimensional as well as tabular 1100 and 1103 databases. You can run DBCC against specific database objects, including the entire database. See [Object Element \(XMLA\)](#) for more information about the object definition.

```
<DBCC xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object>
    <DatabaseID>AdventureWorksDW2014Multidimensional-EE</DatabaseID>
    <CubeID>Adventure Works</CubeID>
    <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
    <PartitionID>Internet_Sales_2006</PartitionID>
  </Object>
</DBCC>
```

To run DBCC on objects higher up the object chain, delete any lower-level object ID elements you don't need:

```
<DBCC xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object>
    <DatabaseID>AdventureWorksDW2014Multidimensional-EE</DatabaseID>
    <CubeID>Adventure Works</CubeID>
  </Object>
</DBCC>
```

For tabular 110x databases, the object definition syntax is modeled after the syntax of Process command (specifically, in how tables are mapped to dimensions and measure groups).

- **CubeID** maps to the model ID, which is **Model**.
- **MeasureGroupID** maps to a table ID.
- **PartitionID** maps to a partition ID.

Usage

In SQL Server Management Studio, you can invoke DBCC using either an MDX or XMLA query window. Additionally, you can use either SQL Server 2017 Profiler or Analysis Services xEvents to view DBCC output. Note that SSAS DBCC messages are not reported to the Windows application event log or the msmdsrv.log file.

DBCC checks for physical data corruption, as well as logical data corruption that occur when orphaned members exist in a segment. A database must be processed before you can run DBCC. It skips remote, empty, or

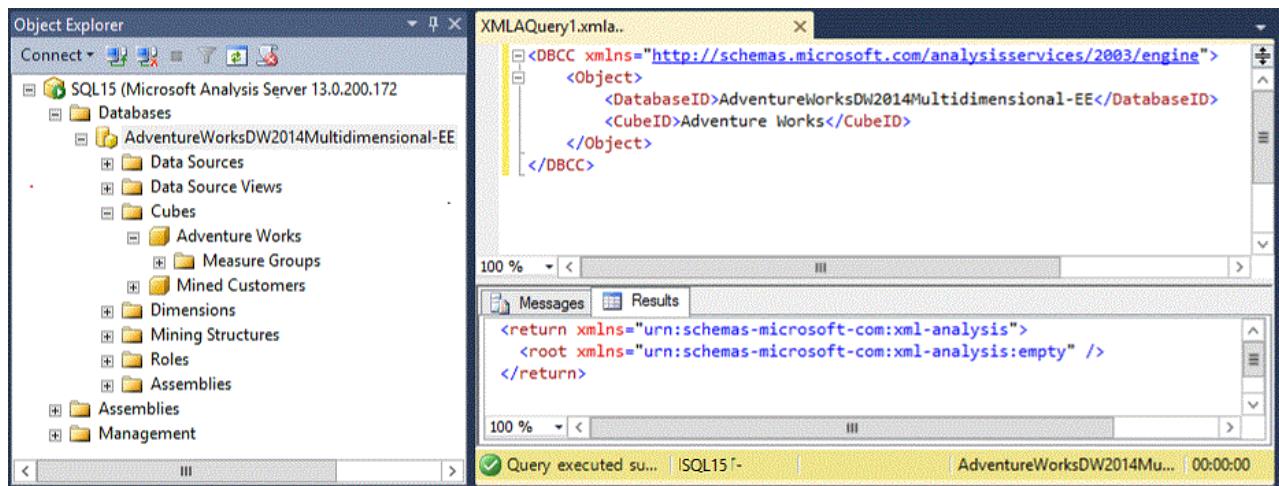

unprocessed partitions.

The command runs in a read transaction, and can thus be kicked out by force commit timeout. Partition checks are run in parallel.

A service restart might be required to pick up any corruption errors that have occurred since the last service restart. Reconnecting to the server is not enough to pick up the changes.

Run DBCC commands in Management Studio

For ad hoc queries, open an MDX or XMLA query window in SQL Server Management Studio. To do this, right-click the database | **New Query | XMLA**) to run the command and read the output.

The Results tab will indicate an empty result set (as shown in the screenshot) if no problems were detected.

The Messages tab provides detail information but is not always reliable for smaller databases. Status messages are sometimes trimmed, indicating the command completed, but without the status check messages on each object. A typical message report might look similar to the one shown below.

Messages reported from DBCC for the cube validation check

```

Executing the query ...
READS, 0
READ_KB, 0
WRITES, 0
WRITE_KB, 0
CPU_TIME_MS, 0
ROWS_SCANNED, 0
ROWS_RETURNED, 0

<DBCC xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
<Object>

Run complete

```

Output when running DBCC against an earlier version of Analysis Services

DBCC is only supported on databases running on a SQL Server 2017 instance. Running the command on older systems will return this error.

```

Executing the query ...
The DBCC element at line 7, column 87 (namespace http://schemas.microsoft.com/analysisservices/2003/engine)
cannot appear under Envelope/Body/Execute/Command.
Execution complete

```

Trace DBCC output in SQL Server Profiler 2016

You can view DBCC output in a Profiler trace that includes Progress Reports events (Progress Report Begin, Progress Report Current, Progress Report End, and Progress Report Error).

1. Start a trace. See [Use SQL Server Profiler to Monitor Analysis Services](#) for help on how to use SQL Server Profiler with Analysis Services.
2. Choose **Command Begin** and **Command End** plus any or all of the **Progress Report** Events.
3. Run the DBCC command in Management Studio in either an XMLA or MDX query window, using the syntax provided in a previous section.
4. In SQL Server Profiler, DBCC activity is indicated through **Command** events having an event subclass of DBCC:

EventClass	EventSubclass	ActivityID	ApplicationName
Command Begin	12 - Batch		
Command Begin	32 - DBCC	374D0361...	Microsoft SQL Server Management Studio - Query
Command End	32 - DBCC	374D0361...	Microsoft SQL Server Management studio - Query

Event code 32 is DBCC execution.

Event code 64 is a DBCC progress report on individual objects.

Event code 63 is a segment check for multidimensional objects.

For both event subclases, review **TextData** values for messages returned by DBCC.

Status messages start with "Checking consistency of <object>" , "Started checking <object>" , or "Finished checking <object>" .

NOTE

In CTP 3.0, objects are identified by internal names. For example, a Categories hierarchy is articulated as H\$Categories-<objectID>. Internal names should be replaced by user friendly names in an upcoming CTP.

Error messages are listed below.

Trace DBCC output in an xEvent session in SSMS

Extended events sessions can use both profiler events or xEvents. Refer to the previous section for guidance on adding **Command** and **Progress Report** events.

1. Start a session by right-clicking a database > **Management** > **Extended Events** > **Sessions** > **New Session**. See [Monitor Analysis Services with SQL Server Extended Events](#) for more information.
2. Choose any or all of the **Progress Report** Events for the Profiler event category or **RequestProgress** events for the PureXevent category.
3. Run the DBCC command in Management Studio in either an XMLA or MDX query window, using the syntax provided in a previous section.
4. In SSMS, refresh the Sessions folder. Right-click the session name > **Watch Live Data**.
5. Review TextData values for messages returned by DBCC. TextData is a property of an event field and shows status and error messages returned by the event.

Status messages start with "Checking consistency of <object>" , "Started checking <object>" , or "Finished checking <object>" .

Error messages are listed below.

Reference: Consistency checks and errors for Multidimensional databases

For multidimensional databases, only partition indexes are validated. During execution, DBCC builds a temporary index for each partition and compares it with the persisted index on disk. Building a temporary index requires reading all data from the partition data on disk and then holding the temporary index in memory for comparison. Given the additional workload, your server might experience significant disk IO and memory consumption while running a DBCC execution.

Detection of Multidimensional index corruption includes the following checks. Errors in this table appear in xEvent or Profiler traces for failures at the object level.

Object	DBCC check description	Error on failure

Partition Index	<p>Check segment statistics and indexes.</p> <p>Compares the ID of each member in the temporary partition index against the partition statistics stored on disk. If a member is found in the temporary index with a data ID value outside the range stored for the partition index statistics on disk, then the statistics for the index are considered corrupt.</p>	The partition segment statistics are corrupted.
Partition Index	<p>Validates metadata.</p> <p>Verifies that each member in the temporary index can be found in the index header file for the segment on disk.</p>	The partition segment is corrupted.
Partition Index	<p>Scan segments to look for physical corruptions.</p> <p>Reads the index file on disk for each member in the temporary index and verifies that the size of the index records match, and that the same data pages are flagged as having records for the current member.</p>	The partition segment is corrupted.

Reference: Consistency checks and errors for Tabular databases

The following table is list of all consistency checks performed on tabular objects, alongside errors that are raised if the check indicates corruption. Errors in this table appear in xEvent or Profiler traces for failures at the object level.

Object	DBCC check description	Error on failure
Database	Checks count of tables in the database. A value less than zero indicates corruption.	There is corruption in the storage layer. The collection of tables in the '% {parent/}' database is corrupt.
Database	Checks internal structure used to track Referential Integrity and throw an error if the size is incorrect.	Database files failed to pass consistency checks.
Table	Checks internal value used to determine if table is a Dimension or Fact table. A value that falls outside the known range indicates corruption.	Database consistency checks (DBCC) failed while checking the table statistics.
Table	Checks that the number of partitions in the segment map for the table matches the number of partitions defined for the table.	There is corruption in the storage layer. The collection of partitions in the '% {parent/}' table is corrupt.

Table	If a tabular database was created or imported from PowerPivot for Excel 2010 and has a partition count greater than one, an error will be raised, as partition support was added in later versions and this would indicate corruption.	Database consistency checks (DBCC) failed while checking the segment map.
Partition	Verifies for each partition that the number segments of data and the record count for each segment of data in the segment matches the values stored in the index for the segment.	Database consistency checks (DBCC) failed while checking the segment map.
Partition	Raise an error if the number of total records, segments, or records per segment is not valid (less than zero), or the number of segments doesn't match the calculated number of segments needed based on total record count.	Database consistency checks (DBCC) failed while checking the segment map.
Relationship	Raise an error if the structure used to store data about the relationship contains no records or if the name of the table used in the relationship is empty.	Database consistency checks (DBCC) failed while checking relationships.
Relationship	<p>Verify that the name of the primary table, primary column, foreign table, and foreign column are set and that the columns and tables involved in the relationship can be accessed.</p> <p>Verify that the column types involved are valid and that the index of Primary Key-Foreign Key values results in a valid lookup structure.</p>	Database consistency checks (DBCC) failed while checking relationships.
Hierarchy	Raise an error if the sort order for the hierarchy isn't a recognized value.	Database consistency checks (DBCC) failed while checking the '%{hier/}' hierarchy.
Hierarchy	<p>The checks performed on the hierarchy depend on the internal type of hierarchy mapping scheme used.</p> <p>All hierarchies are checked for correct processed state, that the hierarchy store exists, and that where applicable, data structures used for a data-ID-to-hierarchy-position conversion exists.</p> <p>Assuming all these checks pass, the hierarchy structure is walked to verify that each position in the hierarchy points to the correct member.</p> <p>If any of these tests fail, an error is raised.</p>	Database consistency checks (DBCC) failed while checking the '%{hier/}' hierarchy.

User defined Hierarchy	<p>Checks that the hierarchy level names are set.</p> <p>If the hierarchy has been processed, check that the internal hierarchy data store has the correct format. Verify that the internal hierarchy store doesn't contain any invalid data values.</p> <p>If the hierarchy is marked as unprocessed, confirm that this state applies to old data structures and that all levels of the hierarchy are marked as empty.</p>	Database consistency checks (DBCC) failed while checking the '%{hier/}' hierarchy.
Column	Raise an error if the encoding used for the column is not set to a known value.	Database consistency checks (DBCC) failed while checking the column statistics.
Column	Check whether the column was compressed by the in-memory engine or not.	Database consistency checks (DBCC) failed while checking the column statistics.
Column	Check the compression type on the column for known values.	Database consistency checks (DBCC) failed while checking the column statistics.
Column	When the column "tokenization" is not set to a known value, raise an error.	Database consistency checks (DBCC) failed while checking the column statistics.
Column	If the id range stored for a columns data dictionary does not match the number of values in the data dictionary or is outside the allowed range, raise an error.	Database consistency checks (DBCC) failed while checking the data dictionary.
Column	Check that the number of data segments for a column matches the number of data segments for the table to which it belongs.	There is corruption in the storage layer. The collection of segments in the '%{parent/}' column is corrupt.
Column	Check that the number of Partitions for a data column matches the number of partitions for the data segment map for the column.	Database consistency checks (DBCC) failed while checking the segment map.
Column	Verify that the number of records in a column segment matches the record count stored in the index for that column segment.	There is corruption in the storage layer. The collection of segments in the '%{parent/}' column is corrupt.
Column	If a column has no segment statistics, raise an error.	Database consistency checks (DBCC) failed while checking the segment statistics.

Column	If a column has no compression information or segment storage, raise an error.	Database files failed to pass consistency checks.
Column	Report an error if segment statistics for a column don't match the actual column values for Minimum Data ID, Maximum Data ID, number of Distinct values, number of rows, or presence of NULL values.	Database consistency checks (DBCC) failed while checking the segment statistics.
ColumnSegment	If the minimum data ID or maximum data ID is less than the system reserved value for NULL, mark the column segment information as corrupt.	Database consistency checks (DBCC) failed while checking the segment statistics.
ColumnSegment	If there are no rows for this segment, the minimum and maximum data values for the column should be set to the system reserved value for NULL. If the value is not null, raise an error.	Database consistency checks (DBCC) failed while checking the segment statistics.
ColumnSegment	If the column has rows and at least one non-null value, check that the minimum and maximum data id for the column is greater than the system reserved value for NULL.	Database consistency checks (DBCC) failed while checking the segment statistics.
Internal	Verify that the store tokenization hint is set and that if the store is processed, there are valid pointers for internal tables. If the store is not processed, verify all the pointers are null. If not, return a generic DBCC error.	Database files failed to pass consistency checks.
DBCC Database	Raise an error if the database schema has no tables or one or more tables cannot be accessed.	There is corruption in the storage layer. The collection of tables in the '%{parent/}' database is corrupt.
DBCC Database	Raise an error if a table is marked as temporary or has an unknown type.	A bad table type was encountered.
DBCC Database	Raise an error if the number of relationships for a table has a negative value, or if any table has a relationship defined and a corresponding relationship structure cannot be found.	There is corruption in the storage layer. The collection of relationships in the '%{parent/}' table is corrupt.
DBCC Database	If the compatibility level for the database is 1050 (SQL Server 2008 R2/PowerPivot v1.0) and the number of relationships exceeds the number of tables in the model, mark the database as corrupted.	Database files failed to pass consistency checks.

DBCC Table	For the table under validation, check if the number of columns is less than zero and raise an error if true. An error also occurs if the column store for a column in the table is NULL.	There is corruption in the storage layer. The collection of columns in the '% {parent/}' table is corrupt.
DBCC Partition	Checks the table that the partition being validated belongs to, and if the number of columns for the table is less than zero, it indicates the Columns collection is corrupt for the table. An error will also occur if the column store for a column in the table is NULL.	There is corruption in the storage layer. The collection of columns in the '% {parent/}' table is corrupt.
DBCC Partition	Loops through each column for the selected partition and checks that each segment for the partition has a valid link to a column segment structure. If any segment has a NULL link, the partition is considered corrupt.	There is corruption in the storage layer. The collection of segments in the '% {parent/}' column is corrupt.
Column	Returns an error if the column type is not valid.	A bad segment type was encountered.
Column	Returns an error if any column has a negative count for the number of segments in a column, or if the pointer to the column segment structure for a segment has a NULL link.	There is corruption in the storage layer. The collection of segments in the '% {parent/}' column is corrupt.
DBCC Command	The DBCC Command will report multiple status messages as it proceeds through the DBCC operation. It will report a status message before starting that includes the database, table, or column name of the object, and again after finishing each object check.	<p>Checking consistency of the <objectname> <objecttype>. Phase: pre-check.</p> <p>Checking consistency of the <objectname> <objecttype>. Phase: post-check.</p>

Common resolutions for error conditions

The following errors appear in SQL Server Management Studio or in msmdsrv.log files. These errors appear when one or more checks fail to pass. Depending on the error, the recommended resolution is to either reprocess an object, delete and redeploy a solution, or restore the database.

ERROR	ISSUE	RESOLUTION
Errors in the metadata manager The object reference '<objectID>' is not valid. It does not match the structure of the metadata class hierarchy.	malformed command	Check the command syntax. Most likely, you included a lower level object without specifying one or more of its parent objects.

ERROR	ISSUE	RESOLUTION
Errors in the metadata manager Either the <object> with the ID of '<objectId>' does not exist in the <parentobject> with the ID of '<parentobjectID>', or the user does not have permissions to access the object.	Index corruption (multidimensional)	Reprocess the object and any dependent objects.
Error occurred during consistency check of the partition An error occurred while checking consistency of the <partition-name> partition of the <measure-group-name> measure group for the <cube-name> cube from the <database-name> database. Please re-process the partition or indexes in order to fix the corruption.	Index corruption (multidimensional)	Reprocess the object and any dependent objects.
Partition segment statistics corrupted	Index corruption (multidimensional)	Reprocess the object and any dependent objects.
Partition segment is corrupted	Metadata corruption (multidimensional or tabular)	Delete and redeploy the project, or restore from a backup and reprocess. See How to handle corruption in Analysis Services databases (blog) for instructions.
Table metadata corruption Table <table-name> metadata file is corrupt. The main table is not found under DataFileList node.	Metadata corruption (tabular only)	Delete and redeploy the project, or restore from a backup and reprocess. See How to handle corruption in Analysis Services databases (blog) for instructions.
Corruption in storage layer Corruption in storage layer: collection of <type-name> in <parent-name> <parent-type> is corrupt.	Metadata corruption (tabular only)	Delete and redeploy the project, or restore from a backup and reprocess. See How to handle corruption in Analysis Services databases (blog) for instructions.
System table is missing System table <table-name> is missing.	Object corruption (tabular only)	Reprocess the object and any dependent objects
Table statistics are corrupt Statistics of table System table <table-name> is missing.	Metadata corruption (tabular only)	Delete and redeploy the project, or restore from a backup and reprocess. See How to handle corruption in Analysis Services databases (blog) for instructions.

Disable automatic consistency checks on database load operations

through the msmdsrv.ini configuration file

Although its not recommended, you can disable the built-in database consistency checks that occur automatically on database load events (on tabular databases only). To do this, you will need to modify a configuration setting in the msmdsrv.ini file:

```
<ConfigurationSettings>
  <Vertipaq />
    <DisableConsistencyChecks />
```

This setting is not present in the configuration file and must be added manually.

Valid values are as follows:

- **-2** (default) DBCC is enabled. If the server can logically resolve the error with a high degree of certainty, a fix will be applied automatically. Otherwise, an error will be logged.
- **-1** DBCC is partially enabled. It is enabled for RESTORE and on pre-commit validations that check database state at the end of a transaction.
- **0** DBCC is partially enabled. Database consistency checks are performed during RESTORE, IMAGELOAD, LOCALCUBELOAD, and ATTACH operations.
- **1** DBCC is disabled. Data integrity checks are disabled, however deserialization checks will still occur.

NOTE

This setting has no impact on DBCC when running the command on demand.

Analysis Services Scripts Project in SQL Server Management Studio

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Analysis Services, you can create an Analysis Server Scripts project in SQL Server Management Studio to group related scripts together for development, management, and source control purposes. If no solution is currently loaded in SQL Server Management Studio, creating a new Analysis Server Scripts project automatically creates a new solution. Otherwise, the new Analysis Server Scripts project can be added to the existing solution or created in a new solution.

You use the following basic steps to create an Analysis Server Scripts project in SQL Server Management Studio:

1. On the File menu, point to **New**, and then click **Project**.

Select **Analysis Server Scripts** project template and then specify a name and location for the new project.

2. Right-click **Connections** to create a new connection in the Connections folder of the Analysis Server Scripts project in Solution Explorer.

This folder contains connection strings to Analysis Services instances, against which the scripts contained by the Analysis Server Scripts project can be executed. You can have multiple connections in an Analysis Server Scripts project, and you can choose a connection against which to run a script contained by the project at the time of execution.

3. Right-click **Queries** to create Multidimensional Expressions (MDX), Data Mining Extensions (DMX), and XML for Analysis (XMLA) scripts in the Scripts folder of the Analysis Server Scripts project in Solution Explorer.
4. Right-click on the project, point to **Add**, and then select **Existing Item** to add miscellaneous files, such as text files that contain notes on the project, in the **Miscellaneous** folder of the Analysis Server Scripts project in Solution Explorer. These files are ignored by SQL Server Management Studio.

File Types

A SQL Server Management Studio solution can contain several file types, depending on what projects you included in the solution and what items you included in each project for that solution. For more information about file types for solutions in SQL Server Management Studio, see [Files That Manage Solutions and Projects](#).

Typically, the files for each project in a SQL Server Management Studio solution are stored in the solution folder, in a separate folder for each project.

The project folder for an Analysis Server Scripts project can contain the file types listed in the following table.

FILE TYPE	DESCRIPTION
-----------	-------------

FILE TYPE	DESCRIPTION
Analysis Server Scripts project definition file (.ssmsasproj)	<p>Contains metadata about the folders shown in Solution Explorer, as well as information that indicates which folders should display files included in the project.</p> <p>The project definition file also contains the metadata for Analysis Services connections contained in the project, as well as metadata that associates connections with script files included in the project.</p>
DMX script file (.dmx)	Contains a DMX script included in the project.
MDX script file (.mdx)	Contains an MDX script included in the project.
XMLA script file (.xmla)	Contains an XMLA script included in the project.

Analysis Services Templates

When adding new MDX, DMX, or XMLA scripts to an Analysis Server Scripts project, you have the option of using Template Explorer to locate Analysis Services templates, which are a collection of predefined scripts or statements that demonstrate how to perform a specified action. Template Explorer is available on the **View** menu and includes templates for SQL Server, Analysis Services, and SQL Server Compact. For more information, see [Use Analysis Services Templates in SQL Server Management Studio](#).

Create Analysis Services Scripts in Management Studio

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

SQL Server Management Studio includes script generation features, templates, and editors that you can use to script Analysis Services objects and tasks.

Script Analysis Services Tasks in Management Studio

Scripting tasks in SQL Server Management Studio is accomplished by clicking one of the Script options in a task-oriented dialog box. All of the dialog boxes that you use to perform tasks such as backup or restore database, process an object, or design an aggregation, include a Script option at the top of the dialog box. Selecting one of these options generates an XMLA script based on the information and settings in the dialog box.

By default, the script is generated and placed in an XMLA query editor, but you can also expand the Script option list to direct the script to the Windows Clipboard or a file.

To script an Analysis Services task

1. In SQL Server Management Studio, connect to an instance of Analysis Services.
2. Right-click a database and click **Backup**. This opens the Backup Database dialog box. Specify a backup file name and choose the options you want for this backup.
3. Click **Script** at the top of the dialog box. The Script feature is part of all task-based dialog boxes in Management Studio. It has the following options: **Script Action to New Query Window** to open the query editor window, **Script Action to File** to save the XMLA script to a file, or **Script Action to Clipboard** to save the XMLA script to the Clipboard.

Note that the **Script Action to Job** option that is listed as a script option in Management Studio is not supported for Analysis Services scripts.

4. If you select the default option, **Script Action to New Query Window**, a generated script is placed in an XMLA query window.

You can now close the Backup Database dialog box and edit or run the XMLA script directly.

Script Analysis Services Objects in Management Studio

Scripting objects in SQL Server Management Studio is accomplished by right-clicking an Analysis Services object in SQL Server Management Studio and selecting either **Create to**, **Alter to**, or **Delete to**. Each of these options can be directed to a window or a file, but regardless of where the script is directed to, it will come in the form of a DDL script in an XMLA wrapper. One great advantage to such scripts is that they can be run against any server you point them at. Also, names in the scripts can be changed and run on an iterative basis for mass construction, alteration, or deletion of objects.

Objects that you can script include the elements of an Analysis Services database, including data sources, data source views, cubes, dimensions, mining structures, and roles.

Prerequisites include an understanding of XML for Analysis (XMLA). Fortunately, SQL Server Management Studio has a feature that automatically creates the XMLA script required to create objects, such as cubes. This automation

feature helps reduce the learning curve for XMLA. For more information about how to use XMLA, see [Developing with XMLA in Analysis Services](#). For more information about how to use XMLA, see [Developing with XMLA in Analysis Services](#).

IMPORTANT

When scripting the Role Object, be aware that security permissions are contained by the objects they secure rather than with the security role with which they are associated.

To script Analysis Services objects

1. In SQL Server Management Studio, connect to an instance of Analysis Services.
2. Locate the object for which you want to create a script that either creates, alters, or deletes objects.
3. Right-click the object, point to **Script Cube as**, point to **CREATE To**, **ALTER To**, or **Delete To**, and then click one of the following options: **New Query Editor Window** to open the query editor window, **File** to save the XMLA script to a file, or **Clipboard** to save the XMLA script to the Clipboard.

NOTE

Typically, you would select **File** if you want to create multiple different versions of the file.

Schedule SSAS Administrative Tasks with SQL Server Agent

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Using the SQL Server Agent service, you can schedule Analysis Services administrative tasks to run in the order and times that you need. Scheduled tasks help you automate processes that run on regular or predictable cycles. You can schedule administrative tasks, such as cube processing, to run during times of slow business activity. You can also determine the order in which tasks run by creating job steps within a SQL Server Agent job. For example, you can process a cube and then perform a backup of the cube.

Job steps give you control over flow of execution. If one job fails, you can configure SQL Server Agent to continue to run the remaining tasks or to stop execution. You can also configure SQL Server Agent to send notifications about the success or failure of job execution.

This topic is a walkthrough that shows two ways of using SQL Server Agent to run XMLA script. The first example demonstrates how to schedule processing of a single dimension. Example two shows how to combine processing tasks into a single script that runs on a schedule. To complete this walkthrough, you will need to meet the following prerequisites.

Prerequisites

SQL Server Agent service must be installed.

By default, jobs run under the service account. The default account for SQL Server Agent is NT Service\SQLAgent\$<instancename>. To perform a backup or processing task, this account must be a system administrator on the Analysis Services instance. For more information, see [Grant server admin rights to an Analysis Services instance](#).

You should also have a test database to work with. You can deploy the AdventureWorks multidimensional sample database or a project from the Analysis Services multidimensional tutorial to use in this walkthrough. For more information, see [Install Sample Data and Projects for the Analysis Services Multidimensional Modeling Tutorial](#).

Example 1: Processing a dimension in a scheduled task

This example demonstrates how to create and schedule a job that processes a dimension.

An Analysis Services scheduled task is an XMLA script that is embedded into a SQL Server Agent job. This job is scheduled to run at desired times and frequency. Because the SQL Server Agent is part of SQL Server, you work with both the Database Engine and Analysis Services to create and schedule an administrative task.

Create a script for processing a dimension in a SQL Server Agent job

1. In SQL Server Management Studio, connect to Analysis Services. Open a database folder and find a dimension. Right-click the dimension and select **Process**.
2. In the **Process Dimension** dialog box, in the **Process Options** column under **Object list**, verify that the option for this column is **Process Full**. If it is not, under **Process Options**, click the option, and then select **Process Full** from the drop-down list.
3. Click **Script**.

This step opens an **XML Query** window that contains the XMLA script that processes the dimension.

4. In the **Process Dimension** dialog box, click **Cancel** to close the dialog box.
5. In the **XMLA Query** window, highlight the XMLA script, right-click the highlighted script, and select **Copy**.

This step copies the XMLA script to the Windows Clipboard. You can leave the XMLA script in the Clipboard or paste it into Notepad or another text editor. The following is an example of the XMLA script.

```
<Batch xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Parallel>
    <Process xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
      <Object>
        <DatabaseID>Adventure Works DW Multidimensional</DatabaseID>
        <DimensionID>Dim Account</DimensionID>
      </Object>
      <Type>ProcessFull</Type>
      <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
    </Process>
  </Parallel>
</Batch>
```

Create and schedule the dimension processing job

1. Connect to an instance of the Database Engine and then open Object Explorer.
2. Expand **SQL Server Agent**.
3. Right-click **Jobs** and select **New Job**.
4. In the **New Job** dialog box, enter a job name in **Name**.
5. Under **Select a page**, select **Steps**, and then click **New**.
6. In the **New Job Step** dialog box, enter a step name in **Step Name**.
7. In **Server**, type **localhost** for a default instance of Analysis Services and **localhost\<instance name>** for a named instance.
If you will be running the job from a remote computer, use the server name and instance name where the job will run. Use the format **<server name>** for a default instance, and **<server name>\<instance name>** for a named instance.
8. In **Type**, select **SQL Server Analysis Services Command**.
9. In **Command**, right-click and select **Paste**. The XMLA script that you generated in the previous step should appear in the command window.
10. Click **OK**.
11. Under **Select a page**, click **Schedules**, and then click **New**.
12. In the **New Job Schedule** dialog box, enter a schedule name in **Name**, and then click **OK**.

This step creates a schedule for Sunday at 12:00 AM. The next step shows you how to manually execute the job. You can also specify a schedule that executes the job when you are monitoring it.

13. In the **New Job** dialog box, click **OK**.
14. In **Object Explorer**, expand **Jobs**, right-click the job you created, and then select **Start Job at Step**.

Because the job has only one step, the job executes immediately. If the job contains more than one step, you

can select the step at which the job should start.

- When the job finishes, click **Close**.

Example 2: Batch processing a dimension and a partition in a scheduled task

The procedures in this example demonstrate how to create and schedule a job that batch processes an Analysis Services database dimension, and at the same time to process a cube partition that depends on the dimension for aggregation. For more information about batch processing of Analysis Services objects, see [Batch Processing \(Analysis Services\)](#).

Create a script for batch processing a dimension and partition in a SQL Server Agent job

- Using the same database, expand **Dimensions**, right-click the **Customer** dimension, and select **Process**.
- In the **Process Dimension** dialog box, in **Process Options** column under **Object list**, verify that the option for this column is **Process Full**.
- Click **Script**.

This step opens an **XML Query** window that contains the XMLA script that processes the dimension.

- In the **Process Dimension** dialog box, click **Cancel** to close the dialog box.
- Expand **Cubes**, expand **Adventure Works**, expand **Measure Groups**, expand **Internet Sales**, expand **Partitions**, right-click the last partition in the list, and then select **Process**.
- In the **Process Partition** dialog box, in the **Process Options** column under **Object list**, verify that the option for this column is **Process Full**.
- Click **Script**.

This step opens a second **XML Query** window that contains the XMLA script that processes the partition.

- In the **Process Partition** dialog box, click **Cancel** to close the editor.

At this point you must merge the two scripts, and ensure that the dimension is processed first.

WARNING

If the partition is processed first, the subsequent dimension processing causes the partition to become unprocessed. The partition would then require a second processing to reach a processed state.

- In the **XMLA Query** window that contains the XMLA script that processes the partition, highlight the code inside the **Batch** and **Parallel** tags, right-click the highlighted script, and select **Copy**.

```
<Process xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
    <Object>
        <DatabaseID> Adventure Works DW Multidimensional</DatabaseID>
        <CubeID>Adventure Works</CubeID>
        <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
        <PartitionID> Internet_Sales_2004</PartitionID>
    </Object>
    <Type>ProcessFull</Type>
    <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
</Process>
```

- Open the **XMLA Query** window that contains the XMLA script that processes the dimension. Right-click

within the script to the left of the `</Process>` tag and select **Paste**.

The following example shows the revised XMLA script.

```
<Batch xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Parallel>
    <Process xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
      <Object>
        <DatabaseID>Adventure Works DW Multidimensional</DatabaseID>
        <DimensionID>Dim Customer</DimensionID>
      </Object>
      <Type>ProcessFull</Type>
      <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
    </Process>
    <Process xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
      <Object>
        <DatabaseID>Adventure Works DW Multidimensional</DatabaseID>
        <CubeID>Adventure Works</CubeID>
        <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
        <PartitionID>Internet_Sales_2004</PartitionID>
      </Object>
      <Type>ProcessFull</Type>
      <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
    </Process>
  </Parallel>
</Batch>
```

11. Highlight the revised XMLA script, right-click the highlighted script, and select **Copy**.
 12. This step copies the XMLA script to the Windows Clipboard. You can leave the XMLA script in the Clipboard, save it to a file, or paste it into Notepad or another text editor.
- Create and schedule the batch processing job**
1. Connect to an instance of SQL Server, and then open Object Explorer.
 2. Expand **SQL Server Agent**. Start the service if is not running.
 3. Right-click **Jobs** and select **New Job**.
 4. In the **New Job** dialog box, enter a job name in **Name**.
 5. In **Steps**, click **New**.
 6. In the **New Job Step** dialog box, enter a step name in **Step Name**.
 7. In **Type**, select **SQL Server Analysis Services Command**.
 8. In **Run as**, select the **SQL Server Agent Service Account**. Recall from the Prerequisites section that this account must have administrative permissions on Analysis Services.
 9. In **Server**, specify the server name of the Analysis Services instance.
 10. In **Command**, right-click and select **Paste**.
 11. Click **OK**.
 12. In the **Schedules** page, click **New**.
 13. In the **New Job Schedule** dialog box, enter a schedule name in **Name**, and then click **OK**.

This step creates a schedule for Sunday at 12:00 AM. The next step shows you how to manually execute the job. You can also select a schedule which will execute the job when you are monitoring it.

14. Click **OK** to close the dialog box.

15. In **Object Explorer**, expand **Jobs**, right-click the job you created, and select **Start Job at Step**.

Because the job has only one step, the job executes immediately. If the job contains more than one step, you can select the step at which the job should start.

16. When the job finishes, click **Close**.

[Processing Options and Settings \(Analysis Services\)](#)

Use Analysis Services Templates in SQL Server Management Studio

10/22/2019 • 13 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

SQL Server Management Studio provides a set of templates to help you quickly create XMLA scripts, DMX or MDX queries, create KPIs in a cube or tabular model, script backup and restore operations, and perform many other tasks. Templates are located in the **Template Explorer** in Management Studio.

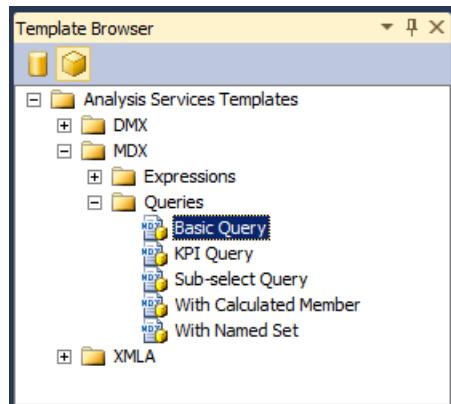

This topic includes a list of the templates for multidimensional models and tabular models, and provides examples of how to build an MDX query and XMLA statement by using the Metadata Explorer and the Template Explorer.

This topic does not cover DMX templates. For examples of how to create data mining queries using the templates, see [Create a DMX Query in SQL Server Management Studio](#) or [Create a Singleton Prediction Query from a Template](#).

Open an Analysis Services Template

All templates for database engine queries and Analysis Services queries and commands are available in Template Explorer.

To open **Template Explorer**, select it from the **View** menu. Next, click the cube icon to see a list of the templates that are available for Analysis Services.

To open a template, right-click the template name and select **Open**, or drag the template into a query window that you already opened. After the query window is open, you can use commands on the toolbar or Query menu to help you build statements:

- To check the syntax of a query, click **Parse**.
- To run a query, click **Execute**.

To stop a query that is running, click **Cancel Executing Query**.

- View the results of a query in the **Results** tab at the bottom of the screen.

Switch to the **Messages** tab to see the number of records returned, errors, query statements, and any other messages that are associated with the execution of the query. For example, if you execute a DAX statement against a model running in Direct Query mode, you can see the Transact-SQL statement that is generated by the VertiPaq in-memory analytics engine.

Build and Run an MDX Query on a Tabular Model using a Template

This example shows you how to create an MDX query in SQL Server Management Studio, using a tabular model database as the data source. To repeat this example on your computer, you can [download the Adventureworks tabular model sample project](#).

WARNING

You cannot use MDX queries against tabular models that have been deployed in Direct Query mode. You can, however, send equivalent queries by using the DAX table queries with the EVALUATE command. For more information, see [DAX query parameters](#).

Create an MDX query from a template

1. In SQL Server Management Studio, open the instance that contains the tabular model you want to query. Right-click the database icon, select **New Query**, and then select **MDX**.
2. In Template Browser, in Analysis Services Templates, open **MDX**, and then open **Queries**. Drag **Basic Query** to the query window.
3. Using **Metadata Explorer**, drag the following fields and measures into the query template:
 - a. Replace <row_axis, mdx_set> with **[Product Category].[Product Category Name]**.
 - b. Replace <column_axis, mdx_set> with **[Date].[Calendar Year].[Calendar Year]**.
 - c. Replace <from_clause, mdx_name> with **[Internet Sales]**.
 - d. Replace <where_clause, mdx_set> with **[Measures].[Internet Total Sales]**.
4. You can execute the query as is, but you will probably want to make some changes, such as adding a function to return specific members. For example, type **.members** after **[Product Category].[Product Category Name]**. For more information, see [Using Member Expressions](#).

Create XMLA Script from a Template

The XMLA command templates that are provided in Template Explorer can be used to create scripts for monitoring and updating Analysis Services objects, regardless of whether the instance is in multidimensional and data mining mode, or tabular mode. The **XMLA** templates include samples for the following types of scripts:

- Backup, restore, and synchronize operations
- Cancel specified process or command
- Process an object
- Discover schema rowsets
- Monitor server status, including jobs, connections, transactions, memory, and performance counters

Create a backup command script from a template

1. In SQL Server Management Studio, open the instance that contains the database you want to query. Right-click the database icon, select **New Query**, and then select **XMLA**.

WARNING

You cannot set the context of an XMLA query by changing the restriction list, or by specifying a database in the connection dialog. You must open the XMLA query window from the database that you want to query.

2. Drag the **Backup** template into the empty query window.
3. Double-click the text within the <DatabaseID> element.
4. In Object Explorer, select the database you want to backup, and drag and drop the database between the brackets of the DatabaseID element.
5. Double-click the text within the <File> element. Type the name of the backup file, including the .abf file extension. Specify the full file path if you are not using the default backup location. For more information, see [Backing Up, Restoring, and Synchronizing Databases \(XMLA\)](#).

Generate a Schema Rowset Query using an XMLA Template

The **Template Explorer** contains only one template for schema rowset queries. To use this template, you must be familiar with the requirements of the individual schema rowset that you want to use, including any required elements, and the columns that can be used as restrictions. For more information, see [Analysis Services Schema Rowsets](#).

Note that many of the schema rowsets have also been exposed as Dynamic Management Views (DMV) for simplicity. By using the corresponding DMV, you can query the schema rowset using syntax like that of Transact-SQL. For example, the following queries return the same results, but one is in XML format, and one is in a tabular format. For more information about DMVs, see [Use Dynamic Management Views \(DMVs\) to Monitor Analysis Services](#).

DMV that returns a list of all schema rowsets available as DMVs:

```
SELECT * FROM $system.DISCOVER_SCHEMA_ROWSETS
```

XMLA command that returns list of available schema rowsets:

```
<Discover xmlns="urn:schemas-microsoft-com:xml-analysis">
<RequestType>DISCOVER_SCHEMA_ROWSETS</RequestType>
<Restrictions>
<RestrictionList>
</RestrictionList>
</Restrictions>
<Properties>
<PropertyList>
</PropertyList>
</Properties>
</Discover>
```

Get a list of data sources for a tabular model using a schema rowset query

1. In SQL Server Management Studio, open the instance that contains the database you want to query. Right-click the database icon, select **New Query**, and then select **XMLA**.

WARNING

You cannot set the context of an XMLA query by changing the restriction list, or by specifying a database in the connection dialog. You must open the XMLA query window from the database that you want to query.

2. Open **Template Explorer**, and drag the template, **Discover Schema Rowsets**, into the blank query window.
3. In the template, replace the **RequestType Element (XMLA)** element with the following text:

```
<RequestType>MDSHEMA_INPUT_DATASOURCES</RequestType>
```

4. Click **Execute**.

Expected results:

```
<CATALOG_NAME>AW Internet Sales Tabular Model_ 24715b71-ea74-4828-aefc-d4c12c15db64</CATALOG_NAME>
<DATASOURCE_NAME>SqlServer localhost AdventureWorksDW2012</DATASOURCE_NAME>
<DATASOURCE_TYPE>Relational</DATASOURCE_TYPE>
<CREATED_ON>2011-10-12T20:27:05.196667</CREATED_ON>
<LAST_SCHEMA_UPDATE>2011-10-12T20:27:05.196667</LAST_SCHEMA_UPDATE>
<DESCRIPTION />
<TIMEOUT>0</TIMEOUT>
<DBMS_NAME>Microsoft SQL Server</DBMS_NAME>
<DBMS_VERSION>11.00.1724</DBMS_VERSION>
```

Analysis Services Template Reference

The following templates are provided for working with Analysis Services databases and the objects within the database, including mining strictures and mining models, cubes, and tabular models:

CATEGORY	ITEM TEMPLATE	DESCRIPTION
DMX\Model Content	Content Query	Demonstrates how to use the DMX SELECT FROM < <i>model</i> >.CONTENT statement to retrieve the mining model schema rowset content for a specified mining model.
	Continuous Column Values	Demonstrates how to use the DMX SELECT DISTINCT FROM < <i>model</i> > statement with the DMX RangeMin and RangeMax functions to retrieve a set of values in a specified range from continuous columns in a specified mining model.
	Discrete Column Values	Demonstrates how to use the DMX SELECT DISTINCT FROM < <i>model</i> > statement retrieve a complete set of values from discrete columns in a specified mining model.
	Drillthrough Query	Demonstrates how to use the DMX SELECT * FROM Model.CASES statement with the DMX IsInNode function to perform a drillthrough query
	Model Attributes	Demonstrates how to use the DMX System.GetModelAttributes function to return a list of attributes used by a model.

CATEGORY	ITEM TEMPLATE	DESCRIPTION
	PMML Content	Demonstrates how to use the DMX SELECT * FROM <model>.PMML statement to retrieve the Predictive Model Markup Language (PMML) representation of the mining model, for algorithms that support this functionality.
DMX\Model Management	Add Model	Demonstrates how to use the DMX ALTER MINING MODEL STRUCTURE statement to add a mining model
	Clear Model	Demonstrates how to use the DMX DELETE * FROM MINING MODEL statement to delete the content of a specified mining model.
	Clear Structure Cases	Demonstrates how to use the DMX DELETE FROM MINING STRUCTURE statement to clear mining model structure cases
	Clear Structure	Demonstrates how to use the DMX DELETE FROM MINING STRUCTURE statement to clear a mining model structure
	Create from PMML	Demonstrates how to use the DMX CREATE MINING MODEL statement with the FROM PMML clause to create a mining model from a PMML representation.
	Create Structure Nested	Demonstrates how to use the DMX CREATE MINING STRUCTURE statement with a nested column definition list to create a mining model with nested columns.
	Create Structure	Demonstrates how to use the DMX CREATE MINING STRUCTURE statement to create a mining model.
	Drop Model	Demonstrates how to use the DMX DROP MINING MODEL statement to delete an existing mining model.
	Drop Structure	Demonstrates how to use the DMX DROP MINING STRUCTURE statement to delete an existing mining structure.

CATEGORY	ITEM TEMPLATE	DESCRIPTION
	Export Model	Demonstrates how to use the DMX EXPORT MINING MODEL statement using the WITH DEPENDENCIES and PASSWORD clauses to export a mining model, including the data source and data source view on which the mining model depends, to a file.
	Export Structure	Demonstrates how to use the DMX EXPORT MINING STRUCTURE statement using the WITH DEPENDENCIES clause to export a mining structure, including all of the mining models contained by the mining structure and the data source and data source view on which the mining structure depends, to a file.
	Import	Demonstrates how to use the DMX IMPORT FROM statement using the WITH PASSWORD clause to perform an import .
	Rename Model	Demonstrates how to use the DMX RENAME MINING MODEL statement to rename an existing mining model.
	Rename Structure	Demonstrates how to use the DMX RENAME MINING STRUCTRE statement to rename an existing mining structure.
	Train Model	Demonstrates how to use the DMX INSERT INTO MINING MODEL statement to train a mining model inside a previously trained structure.
	Train Nested Structure	Demonstrates how to combine the DMX INSERT INTO MINING STRUCTURE statement with the SHAPE source data query to train a mining model that contains nested columns with data that contains nested tables, retrieved using a query, from an existing data source.
	Train Structure	Demonstrates how to combine the DMX INSERT INTO MINING STRUCTURE statement with the OPENQUERY source data query to train a mining structure.
DMX\Prediction Queries	Base Prediction	Demonstrates how to combine a DMX SELECT FROM <model> PREDICTION JOIN statement with the OPENQUERY source data query to execute a prediction query against a mining model using data, retrieved using a query, from an existing data source.

CATEGORY	ITEM TEMPLATE	DESCRIPTION
	Nested Prediction	Demonstrates how to combine a DMX SELECT FROM <model> PREDICTION JOIN statement with the SHAPE and OPENQUERY source data queries to execute a prediction query against a mining model using data that contains nested tables, retrieved using a query, from an existing data source.
	Nested Singleton Prediction	Demonstrates how to use a DMX SELECT FROM <model> NATURAL PREDICTION JOIN clause to execute a prediction query against a mining model using a single value, explicitly specified in the prediction query, in a column whose name matches a column in the mining model and which contains a set of values in a nested table created using a UNION statement whose names also match to nested columns in the mining model.
	Singleton Prediction	Demonstrates how to use a DMX SELECT FROM <model> NATURAL PREDICTION JOIN statement to execute a prediction query against a mining model using a single value, explicitly specified in the prediction query, in a column whose name matches a column in the mining model.
	Stored Procedure Call	Demonstrates how to use the DMX CALL statement to call a stored procedure
MDX Expressions	Moving Average-Fixed	Demonstrates how to use the MDX ParallelPeriod and CurrentMember functions with a naturally ordered set to create a calculated measure that provides a moving average of a measure over a fixed number of time periods contained by a hierarchy in a time dimension.
	Moving Average-Variable	Demonstrates how to use the MDX CASE statement within the Avg function to create a calculated measure that provides a moving average of a measure over a variable number of time periods contained by hierarchy in a time dimension.
	Periods to Date	Demonstrates how to use the MDX PeriodsToDate function in a calculated member.

CATEGORY	ITEM TEMPLATE	DESCRIPTION
	Ratio to Parent	Demonstrates how to use the MDX Parent function to create a calculated measure that represents a ratio percentage of a measure for each child of a parent member in a specified hierarchy.
	Ratio to Total	Demonstrates how to use the All member to create a calculated measure that represents a ratio percentage of a measure for each member in a specified hierarchy.
MDX\Queries	Basic Query	Demonstrates a basic MDX SELECT statement from which you can construct an MDX query.
	KPI Query	Demonstrates how to use the MDX KPIValue and KPIGoal functions to retrieve key performance indicator (KPI) information in an MDX query.
	Sub-select Query	Demonstrates how to create a MDX SELECT statement that retrieves information from a subcube defined by another SELECT statement.
	With Calculated Member	Demonstrates how to use the MDX WITH clause in a SELECT statement to define a calculated member for an MDX query.
	With Named Set	Demonstrates how to use the MDX WITH clause in a SELECT statement to define a named set for an MDX query.
XMLA\Management	Backup	Demonstrates how to use the XMLA Backup command to back up an Analysis Services database to a file.
	Cancel	Demonstrates how to use the XMLA Cancel command to cancel all running operations on the current session (for users other than administrators or server administrators), database (for administrators), or instance (for server administrators.)
	Create Remote Partition Database	Demonstrates how to use the XMLA Create command with the Analysis Services Scripting Language (ASSL) Database element to create an Analysis Services database and a data source for storing remote partitions.

CATEGORY	ITEM TEMPLATE	DESCRIPTION
	Delete	Demonstrates how to use the XMLA Delete command to delete an existing Analysis Services database.
	Process Dimension	Demonstrates how to use the XMLA Batch command, combined with the Parallel element and the Process command, to update the attributes of a dimension by using a parallel batch operation.
	Process Partition	Demonstrates how to use the XMLA Batch command, combined with the Parallel element and the Process command, to fully process a partition by using a parallel batch operation.
	Restore	Demonstrates how to use the XMLA Restore command to restore an Analysis Services database from an existing backup file.
	Synchronize	Demonstrates how to use the XMLA Synchronize command to synchronize another Analysis Services database with the current Analysis Services database using the SkipMembership option for the SynchronizeSecurity tag.
XMLA\Schema Rowsets	Discover Schema Rowsets	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_SCHEMA_ROWSETS schema rowset.
XMLA\Server Status	Connections	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_CONNECTIONS schema rowset.
	Jobs	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_JOBS schema rowset.
	Locations	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_LOCATIONS schema rowset, specifying the path of the location backup files.
	Locks	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_LOCKS schema rowset.

CATEGORY	ITEM TEMPLATE	DESCRIPTION
	Memory Grant	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_MEMORYGRANT schema rowset.
	Performance Counters	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_PERFORMANCE_COUNTERS schema rowset.
	Sessions	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_SESSIONS schema rowset.
	Traces	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_TRACES schema rowset.
	Transactions	Demonstrates how to use the XMLA Discover method to retrieve the contents of the DISCOVER_TRANSACTIONS schema rowset.

Automate Analysis Services Administrative Tasks with SSIS

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Microsoft SQL Server Integration Services enables you to automate execution of DDL scripts, cube and mining model processing tasks, and data mining query tasks. Integration Services can be thought of as a collection of control flow and maintenance tasks, which can be linked to form sequential and parallel data processing jobs.

Integration Services is designed to perform data cleaning operations during data processing tasks, and to bring together data from different data sources. When working with cubes and mining models, Integration Services can transform non-numeric data to numeric data, and can ensure that data values fall within expected bounds, thus creating clean data from which to populate fact tables and dimensions.

Integration Services Tasks

There are two main elements in any Integration Services task or job: control flow elements and data flow elements. The control flow elements define the logical ordering of job progression by applying precedence constraints. The data flow elements concern connectivity between the output of a component to the input of the following component, plus any data transform that might operate on that data in between. As for the decision about where the data goes, precedence constraints contain logic to specify which component receives the output. The Integration Services tasks that are most relevant to Microsoft SQL Server Analysis Services include the Execute DDL Task, the Analysis Services Processing Task, and the Data Mining Query Task. For each of these tasks, the Send Mail Task can be used to send the administrator an e-mail message containing the task results.

The Execute DDL Task

The Execute DDL Task in Integration Services enables you to send DDL scripts directly to the Analysis Services server and to run them automatically. This allows the Analysis Services administrator to perform backup, restore, or sync operations from within an Integration Services package. A package is made up of the control and data flow elements described earlier, which all must be **run regularly**, as do other DDL statements that can be added to tasks. Because the tasks discussed here are frequently run at night, it is particularly useful to have packages that can easily be run from any scheduling application. You can schedule a package to be run at any time using Integration Services Agent. For more information about how to implement this task, see [Analysis Services Execute DDL Task](#).

Analysis Services Processing Task

The Analysis Services Processing Task in Integration Services enables you to automatically populate cubes with new information when you make regular updates to your source relational database. You can process at the dimension, cube, or partition level using the Analysis Services Processing Task. The processing itself can be of type **incremental** or **full**, which you select based on your job requirements. Incremental processing adds new data and performs enough recalculation to keep the target up-to-date, whereas full processing drops existing data for a complete reload and recalculation. Full processing takes more time, but is more complete. For more information about how to implement this task, see [Analysis Services Processing Task](#).

Data Mining Query Task

The Data Mining Query Task in Integration Services enables you to extract and store information from mining models. The information is often stored in a relational database and, for example, can be used to isolate a list of potential customers for a targeted marketing campaign. Data mining can identify the value of a customer and the probability that the customer will respond to a particular marketing pitch. You can use the Data Mining Query Task to extract and modify data to a preferred format. For more information about how to implement this task, see [Data Mining Query Task](#).

Connect to Analysis Services

9/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Use the information in this section to learn about connection string properties, client libraries used for connections, which authentication methods are supported by Analysis Services, and how to set up or clear connections before taking a server offline.

To learn about connecting to Azure Analysis Services, see [Connect to a server](#).

Analysis Services connections

Analysis Services uses TCP as the network protocol and XML for Analysis (XMLA) as a communication protocol. At the lowest level, all of the client libraries provided with Analysis Services implementing XMLA-over-TCP. Although it is possible to build applications based on raw XMLA, most applications and application developers use client libraries to take advantage of the object models and coding efficiencies that they provide. For client connections to Analysis Services, you can use IIS as an intermediary connection if you cannot use TCP across the stack. One advantage of using HTTP access via IIS is the ability to connect from applications that pass credentials on the connection string.

Any discussion involving connectivity typically includes authentication. In contrast with other SQL Server features, Analysis Services uses Windows credentials exclusively. You cannot use SQL Server database authentication, claims authentication, forms-based authentication, or digest on the backend connection to Analysis Services. More about authentication is provided in this section.

Connection Tasks

LINK	TASK DESCRIPTION
Connect from client applications (Analysis Services)	If you are new to Analysis Services, read this topic to get started with the tools and applications most often used with Analysis Services.
Connection String Properties (Analysis Services)	Analysis Services includes numerous server and database properties, allowing you to customize a connection for a specific application, independent of how the instance or database is configured.
Authentication methodologies supported by Analysis Services	This topic is a brief introduction to the authentication methods used by Analysis Services.
Configure Analysis Services for Kerberos constrained delegation	Many business intelligence solutions require impersonation to ensure that only authorized data is returned to each user. In this topic, learn the requirements for using impersonation. This topic also explains the steps for configuring Analysis Services for Kerberos constrained delegation.

LINK	TASK DESCRIPTION
SPN registration for an Analysis Services instance	Kerberos authentication requires a valid Service Principle Name (SPN) for services that impersonate or delegate user identities in multi-server solutions. Use the information in this topic to learn the construction and steps for SPN registration for Analysis Services.
Configure HTTP Access to Analysis Services on Internet Information Services (IIS) 8.0	Basic authentication or cross-domain boundaries are two important reasons for configuring Analysis Services for HTTP access.
Data providers used for Analysis Services connections	Analysis Services provides three client libraries for accessing server operations or Analysis Services data. This topic offers a brief introduction to ADOMD.NET, Analysis Services Management Objects (AMO), and the Analysis Services OLE DB provider (MSOLAP).
Disconnect Users and Sessions on Analysis Services Server	Clear existing connections and sessions before taking a server offline or conducting baseline performance tests.

[Server properties in Analysis Services](#)

Connect from client applications

10/22/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If you are new to Analysis Services, use the information in this topic to connect to an existing instance of Analysis Services using common tools and applications. This topic also explains how to connect under different user identities for testing purposes.

- [Connect using SQL Server Management Studio \(SSMS\)](#)
- [Connect using Excel](#)
- [Connect using Visual Studio](#)
- [Test connections](#)

Connection string reference documentation is provided separately. For more information, see [Connection String Properties \(Analysis Services\)](#).

Successful connections depend on a valid port configuration and appropriate user permissions. Click the following links to learn more about each requirement.

- [Configure the Windows Firewall to Allow Analysis Services Access](#)
- [Authorizing access to objects and operations \(Analysis Services\)](#)

Connect using SQL Server Management Studio (SSMS)

Connect to Analysis Services in SSMS to manage server instances and databases interactively. You can also run XMLA or MDX queries to perform administrative tasks or retrieve data. In contrast with other tools and applications that only load databases when a query is sent, SSMS loads all databases when you connect to the server, assuming you have permission to view the database. This means that if you have numerous tabular databases on the server, all are loaded into system memory when you connect using SSMS.

You can test permissions by running SSMS under a specific user identity and then connect to Analysis Services as that user.

Hold-down the Shift key and right-click the **SQL Server Management Studio** shortcut to access the **Run as different user** option.

1. Start SQL Server Management Studio. In the **Connect to Server** dialog box, select the Analysis Services server type.
2. In the Login tab, enter the server name by typing the name of the computer on which the server is running. You can specify the server using its network name or a fully-qualified domain name.

For a named instance, the server name must be specified in this format: `servername\instance name`. An example of this naming convention might be `ADV-SRV062\Finance` for a server that has a network name of `ADV-SRV062`, where Analysis Services was installed as a named instance entitled `Finance`.

For servers deployed in a failover cluster, connect using the network name of the SSAS cluster. This name is specified during SQL Server setup, as **SQL Server Network Name**. Note that if you installed SSAS as a named instance onto a Windows Server Failover Cluster (WSFC), you never add the instance name on the connection. This practice is unique to SSAS; in contrast, a named instance of a clustered relational database

engine does include the instance name. For example, if you installed both SSAS and the database engine as named instance (Contoso-Accounting) with a SQL Server Network Name of SQL-CLU, you would connect to SSAS using "SQL-CLU" and to the database engine as "SQL-CLU\Contoso-Accounting". See [How to Cluster SQL Server Analysis Services](#) for more information and examples.

For servers deployed in a network load balanced cluster, connect using the virtual server name of the NLB.

3. Authentication is always Windows authentication, and the user identity is always the Windows user who is connecting via Management Studio.

In order for the connection to succeed, you must have permission to access the server or a database on the server. Most tasks that you want to perform in Management Studio require administrative permissions. Ensure that the account you are connecting with is a member of the Server Administrator role. For more information, see [Grant server admin rights to an Analysis Services instance](#).

4. Click **Connection Properties** to specify a particular database, set timeout values, or encryption options. Optional connection information includes connection properties used for the current connection only.
5. Click **Additional Connection Parameters** tab to set connection properties not available in the Connect to Server dialog box. For example, you might type `Roles=Reader` in the text box.

Connecting through a role with less permission lets you test database behaviors when that role is in effect.

```
Provider=MSOLAP; Data Source=SERVERNAME; Initial Catalog=AdventureWorks2012; Roles=READER
```

Connect using Excel

Microsoft Excel is often used for analyzing business data. As part of an Excel installation, Office installs the Analysis Services OLE DB provider (MSOLAP DLL), ADOMD.NET, and other data providers so that you can more readily use the data on your network servers. If you are using a newer version of Analysis Services with an older version of Excel, you most likely need to install newer data providers on each workstation that connects to Analysis Services. See [Data providers used for Analysis Services connections](#) for more information.

When you set up a connection to an Analysis Services cube or tabular model database, Excel saves the connection information in .odc file for future use. The connection is made in security context of the current Windows user. The user account must have read permissions on the database in order for the connection to succeed.

When using Analysis Services data in an Excel workbook, connections are held for the duration of a query request. This is why you are likely to see lots of connections for each session, held for very short periods of time, when monitoring a query workload from Excel.

You can test permissions by starting Excel under a specific user identity.

Hold-down the Shift key and right-click the **Excel** shortcut to access the **Run as different user** option.

1. On the Data tab in Excel, click **From Other Sources**, and then click **From Analysis Services**. Enter the server name, and then select a cube or perspective to query.

For servers deployed in a load-balanced cluster, use the virtual server name assigned to the cluster.

2. When setting up a connection in Excel, on the last page of the Data Connection Wizard, you can specify authentication settings for Excel Services. These settings are used to set properties on the workbook should you upload it to a SharePoint server that has Excel Services. The settings are used in data refresh operations. Options include **Windows Authentication**, **Secure Store Service** (SSS), and **None**.

Avoid using **None**. Analysis Services does not let you specify a user name and password on the connection string unless you are connecting to a server that has been configured for HTTP access. Similarly, do not

use SSS unless you already know that the SSS target application ID is mapped to a set of Windows user credentials that have user access to the Analysis Services databases. For most scenarios, using the default option of Windows authentication is the best choice for an Analysis Services connection from Excel.

For more information, see [Connect to or import data from SQL Server Analysis Services](#).

Connect using Visual Studio

Visual Studio with Analysis Services projects is used for building BI solutions. When building reports or packages, you might need to specify a connection to Analysis Services.

The following links explain how to connect to Analysis Services from a Report Server project or an Integration Services project:

- [Analysis Services Connection Type for MDX \(SSRS\)](#)
- [Analysis Services Connection Manager](#)

NOTE

When using Visual Studio to work on an existing Analysis Services project, remember that you can connect offline using a local or version controlled project, or connect in online mode to update Analysis Services objects while the database is running. For more information, see [Connect in Online Mode to an Analysis Services Database](#). More commonly, connections from Visual Studio with Analysis Services projects are in project mode, where changes are deployed to the database only when you explicitly deploy the project.

Test connections

You can use SQL Server Profiler to monitor connections to Analysis Services. The Audit Login and Audit Logout events provide evidence of a connection. The identity column indicates the security context under which the connection is made.

1. Start **SQL Server Profiler** on the Analysis Services instance and then start a new trace.
2. In Events Selection, verify that **Audit Login** and **Audit Logout** are checked in the Security Audit section.
3. Connect to Analysis Services via an application service (such as SharePoint or Reporting Services) from a remote client computer. The Audit Login event will show the identity of the user connecting to Analysis Services.

Connection errors are often traced to an incomplete or invalid server configuration. Always check server configuration first:

- Ping the server from a remote computer to ensure it allows remote connections.
- **Firewall rules on the server allow inbound connections from clients in the same domain**

With the exception of Power Pivot for SharePoint, all connections to a remote server require that you have configured the firewall to allow access to the port that Analysis Services is listening on. If you are getting connection errors, verify that the port is accessible and that user permissions are granted to the appropriate databases.

To test, use Excel or SSMS to on a remote computer, specifying the IP address and port used by the Analysis Services instance. If you can connection, the firewall rules are valid for the instance and the instance allows remote connections.

Also, when using TCP/IP for the connection protocol, remember that Analysis Services requires client connections originate from the same domain or a trusted domain. If connections flow across security

boundaries, you will most likely need to configure HTTP access. For more information, see [Configure HTTP Access to Analysis Services on Internet Information Services \(IIS\) 8.0](#).

- Can you connect using some tools but not others? The problem might be the wrong version of a client library. You can get client libraries from the SQL Server Feature Pack download page.

Resources that can help you resolve connection failures include the following:

[Resolving Common Connectivity Issues in SQL Server 2005 Analysis Services Connectivity Scenarios](#). This document is a few years old, but the information and methodologies still apply.

Connection String Properties (Analysis Services)

7/16/2019 • 17 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes connection string properties you might set in one of the designer or administration tools, or see in connection strings built by client applications that connect to and query Analysis Services data. As such, it covers just a subset of the available properties. The complete list includes numerous server and database properties, allowing you to customize a connection for a specific application, independent of how the instance or database is configured on the server.

Developers who build custom connection strings in application code should review the API documentation for ADOMD.NET client to view a more detailed list: [ConnectionString](#)

The properties described in this topic are used by the Analysis Services client libraries, ADOMD.NET, AMO, and the OLE DB provider for Analysis Services. The majority of connection string properties can be used with all three client libraries. Exceptions are called out in the description.

NOTE

When setting properties, if you inadvertently set the same property twice, the last one in the connection string is used.

For more information about how to specify an Analysis Services connection in existing Microsoft applications, see [Connect from client applications \(Analysis Services\)](#).

Connection parameters in common use

The following table describes those properties most often used when building a connection string.

PROPERTY	DESCRIPTION	EXAMPLE
Data Source or DataSource	Specifies the server instance. This property is required for all connections. Valid values include the network name or IP address of the server, local or localhost for local connections, a URL if the server is configured for HTTP or HTTPS access, or the name of a local cube (.cub) file. Valid value for Azure Analysis Services, <code><protocol>://<region>/<servername></code> where protocol is string asazure, region is the Uri where the server was created (for example, westus.asazure.windows.net) and servername is the name of your unique server within the region.	<code>Data source=asazure://westus.asazure.windows.net/my</code> <code>Data source=AW-SRV01</code> for the default instance and port (TCP 2383). <code>Data source=AW-SRV01\$Finance:8081</code> for a named instance (\$Finance) and fixed port. <code>Data source=AW-SRV01.corp.Adventure-Works.com</code> for a fully qualified domain name, assuming the default instance and port. <code>Data source=172.16.254.1</code> for an IP address of the server, bypassing DNS server lookup, useful for troubleshooting connection problems.
Initial Catalog or Catalog	Specifies the name of the Analysis Services database to connect to. The database must be deployed on Analysis Services, and you must have permission to connect to it. This property is optional for AMO connections, but required for ADOMD.NET.	<code>Initial catalog=AdventureWorks2016</code>

PROPERTY	DESCRIPTION	EXAMPLE
Provider	<p>Valid values include MSOLAP.<version>, where <version> is either 4, 5, 6 or 7.</p> <ul style="list-style-type: none"> - MSOLAP.4 released in SQL Server 2008 and again SQL Server 2008 R2 (filename is msolap100.dll for SQL Server 2008 and 2008 R2) - MSOLAP.5 released in SQL Server 2012 (filename is msolap110.dll) - MSOLAP.6 released in SQL Server 2014 (filename is msolap1200.dll) - MSOLAP.7 released in SQL Server 2016 (filename is msolap130.dll) <p>This property is optional. By default, the client libraries read the current version of the OLE DB provider from the registry. You only need to set this property if you require a specific version of the data provider, for example to connect to a SQL Server 2012 instance.</p> <p>MSOLAP.4 was released in both SQL Server 2008 and SQL Server 2008 R2. The 2008 R2 version supports Power Pivot workbooks and sometimes needs to be installed manually on SharePoint servers. To distinguish between these versions, you must check the build number in the file properties of the provider: Go to Program files\Microsoft Analysis Services\AS OLEDB\10. Right-click msolap110.dll and select Properties. Click Details. View the file version information. The version should include 10.50.<buildnumber> for SQL Server 2008 R2. For more information, see Install the Analysis Services OLE DB Provider on SharePoint Servers and Data providers used for Analysis Services connections.</p>	<code>Provider=MSOLAP.7</code> is used for connections that require the SQL Server 2016 version of the OLE DB provider for Analysis Services.
Cube	Cube name or perspective name. A database can contain multiple cubes and perspectives. When multiple targets are possible, include the cube or perspective name on the connection string.	<code>Cube=SalesPerspective</code> shows that you can use the Cube connection string property to specify either the name of a cube or the name of a perspective.

Authentication and Security

This section includes connection string properties related to authentication and encryption. Analysis Services uses Windows Authentication only, but you can set properties on the connection string to pass in a specific user name and password.

Properties are listed in alphabetical order.

PROPERTY	DESCRIPTION
----------	-------------

PROPERTY	DESCRIPTION
EffectiveUserName	<p>Use when an end user identity must be impersonated on the server. Specify the account in a domain\user format. To use this property, the caller must have administrative permissions in Analysis Services. For more information about using this property in an Excel workbook from SharePoint, see Use Analysis Services EffectiveUserName in SharePoint Server 2013.</p> <p>EffectiveUserName is used in a Power Pivot for SharePoint installation to capture usage information. The user identity is provided to the server so that events or errors that include user identity can be recorded in the log files. In the case of Power Pivot, it is not used for authorization purposes.</p>
Encrypt Password	<p>Specifies whether a local password is to be used to encrypt local cubes. Valid values are True or False. The default is False.</p>
Encryption Password	<p>The password used to decrypt an encrypted local cube. Default value is empty. This value must be explicitly set by the user.</p>
Impersonation Level	<p>Indicates the level of impersonation that the server is allowed to use when impersonating the client. Valid values include:</p> <ul style="list-style-type: none"> - Anonymous. The client is anonymous to the server. The server process cannot obtain information about the client, nor can the client be impersonated. - Identify. The server process can get the client identity. The server can impersonate the client identity for authorization purposes but cannot access system objects as the client. - Impersonate. This is the default value. The client identity can be impersonated, but only when the connection is established, and not on every call. - Delegate. The server process can impersonate the client security context while acting on behalf of the client. The server process can also make outgoing calls to other servers while acting on behalf of the client.
Integrated Security	<p>The Windows identity of the caller is used to connect to Analysis Services. Valid values are blank, SSPI, and BASIC.</p> <p>Integrated Security=SSPI is the default value for TCP connections, allowing NTLM, Kerberos, or Anonymous authentication. Blank is the default value for HTTP connections.</p> <p>When using SSPI, ProtectionLevel must be set to one of the following: Connect, PktIntegrity, PktPrivacy.</p>
Persist Encrypted	<p>Set this property when the client application requires the data source object to persist sensitive authentication information, such as a password, in encrypted form. By default, authentication information is not persisted.</p>
Persist Security Info	<p>Valid values are True and False. When set to True, security information, such as the user identity or password previously specified on the connection string, can be obtained from the connection after the connection is made. The default value is False.</p>

PROPERTY	DESCRIPTION
Protection Level	<p>Determines the security level used on the connection. Valid values are:</p> <ul style="list-style-type: none"> - None. Unauthenticated or anonymous connections. Performs no authentication on data sent to the server. - Connect. Authenticated connections. Authenticates only when the client establishes a relationship with a server. - Pkt Integrity. Encrypted connections. Verifies that all data is received from the client and that it has not been changed in transit. - Pkt Privacy. Signed encryption, supported only for XMLA. Verifies that all data is received from the client, that it has not been changed in transit, and protects the privacy of the data by encrypting it. <p>For more information, see Establishing Secure Connections in ADOMD.NET</p>
Roles	<p>Specify a comma-delimited list of predefined roles to connect to a server or database using permissions conveyed by that role. If this property is omitted, all roles are used, and the effective permissions are the combination of all roles. Setting the property to an empty value (for example, Roles=' ') the client connection has no role membership.</p> <p>An administrator using this property connects using the permissions conveyed by the role. Some commands might fail if the role does not provide sufficient permission.</p>
SSPI	Explicitly specifies which security package to use for client authentication when Integrated Security is set to SSPI . SSPI supports multiple packages, but you can use this property to specify a particular package. Valid values are Negotiate, Kerberos, NTLM, and Anonymous User. If this property is not set, all packages will be available to the connection.
Use Encryption for Data	Encrypts data transmissions. Value values are True and False.
User ID=...; Password=	<p>User ID and Password are used together. Analysis Services impersonates the user identity specified through these credentials. On an Analysis Services connection, putting credentials on the command line is used only when the server is configured for HTTP access, and you specified Basic authentication instead of integrated security on the IIS virtual directory. When connecting directly to the server, UserID and Password connection string params are ignored and the connection is made using the context of the logged on user.</p> <p>The user name and password must be the credentials of a Windows identity, either a local or a domain user account. Notice that User ID has an embedded space. Other aliases for this property include UserName (no space), and UID. Alias for Password is PWD.</p>

Special-purpose parameters

This section describes the remainder of the connection string parameters. These are used to ensure specific connection behaviors required by an application.

Properties are listed in alphabetical order.

PROPERTY	DESCRIPTION

PROPERTY	DESCRIPTION
Application Name	<p>Sets the name of the application associated with the connection. This value can be useful when monitoring tracing events, especially when you have several applications accessing the same databases. For example, adding Application Name='test' to a connection string causes 'test' to appear in a SQL Server Profiler trace, as shown in the following screenshot:</p>  <p>Aliases for this property include sspropinitAppName, AppName. For more information, see Use Application Name parameter when connecting to SQL Server.</p>
AutoSyncPeriod	<p>Sets the frequency (in milliseconds) of client and server cache synchronization. ADO.NET provides client caching for frequently used objects that have minimal memory overhead. This helps reduce the number of round trips to the server. The default is 10000 milliseconds (or 10 seconds). When set to null or 0, automatic synchronization is turned off.</p>
Character Encoding	<p>Defines how characters are encoded on the request. Valid values are Default or UTF-8 (these are equivalent), and UTF-16</p>
CommitTimeout	<p>An XMLA property. Determines how long, in milliseconds, the commit phase of a currently running command waits before rolling back. When greater than 0, overrides the value of the corresponding CommitTimeout property in the server configuration.</p>
CompareCaseSensitiveStringFlags	<p>Adjusts case-sensitive string comparisons for a specified locale. For more information about setting this property, see CompareCaseSensitiveStringFlags Property.</p>
Compression Level	<p>If TransportCompression is XPRESS, you can set the compression level to control how much compression is used. Valid values are 0 through 9, with 0 having least compression, and 9 having the most compression. Increased compression slows performance. The default value is 0.</p>
Connect Timeout	<p>Determines the maximum amount of time (in seconds) the client attempts a connection before timing out. If a connection does not succeed within this period, the client quits trying to connect and generates an error.</p>
DbpropMsmdRequestMemoryLimit	<p>This property overrides the Memory\QueryMemoryLimit server property value for a connection. Specified in kilobytes.</p>
MDX Compatibility	<p>The purpose of this property is to ensure a consistent set of MDX behaviors for applications that issue MDX queries. Excel, which uses MDX queries to populate and calculate a PivotTable connected to Analysis Services, sets this property to 1, to ensure that placeholder members in ragged hierarchies are visible in a PivotTable. Valid values include 0, 1, 2.</p> <p>0 and 1 expose placeholder members; 2 does not. If this is empty, 0 is assumed.</p>
MDX Missing Member Mode=Error	<p>Indicates whether missing members are ignored in MDX statements. Valid values are Default, Error, and Ignore. Default uses a server-defined value. Error generates an error when a member does not exist. Ignore specifies that missing values should be ignored.</p>

PROPERTY	DESCRIPTION
Optimize Response	<p>A bitmask indicating which of the following query response optimizations are enabled.</p> <ul style="list-style-type: none"> - 0x01 Use the NormalTupleSet (this is the default) - 0x02 Use when slicers are empty
Packet Size	<p>A network packet size (in bytes) between 512 and 32,767. The default network packet size is 4096.</p>
Protocol Format	<p>Sets the format of the XML sent to the server. Valid values are Default, XML, or Binary. The protocol is XMLA. You can specify that the XML be sent in compressed form (this is the default), as raw XML, or in a binary format. Binary format encodes XML elements and attributes, making them smaller. Compression is a proprietary format that further reduces the size of requests and responses. Compression and binary formats are used to speed up data transfer requests and responses.</p> <p>You must use a client library on the connection if using binary or compressed format. OLE DB provider can format requests and responses in binary or compressed format. AMO and ADOMD.NET format the requests as Text, but accept responses in binary or compressed format.</p> <p>This connection string property is equivalent to the EnableBinaryXML and EnableCompression server configuration settings.</p>
Real Time Olap	<p>Set this property to bypass caching, causing all partitions to actively listen for query notifications. By default, this property is not set.</p>
Safety Options	<p>Sets the safety level for user-defined functions and actions. Valid values are 0, 1, 2. In an Excel connection this property is Safety Options=2. Details about this option can be found in ConnectionString.</p>
SQLQueryMode	<p>Specifies whether SQL queries include calculations. Valid values are Data, Calculated, IncludeEmpty. Data means that no calculations are allowed. Calculated allows calculations. IncludeEmpty allows calculations and empty rows to be returned in the query result.</p>
Timeout	<p>Specifies how long (in seconds) the client library waits for a command to complete before generating an error.</p>
Transport Compression	<p>Defines how client and server communications are compressed, when compression is specified via the Protocol Format property. Valid values are Default, None, Compressed and gzip. Default is no compression for TCP, or gzip for HTTP. None indicates that no compression is used. Compressed uses XPRESS compression (SQL Server 2008 and later). gzip is only valid for HTTP connections, where the HTTP request includes Accept-Encoding=gzip.</p>
UseExistingFile	<p>Used when connecting to a local cube. This property specifies whether the local cube is overwritten. Valid values are True or False. If set to True, the cube file must exist. The existing file will be the target of the connection. If set to False, the cube file is overwritten.</p>

PROPERTY	DESCRIPTION
VisualMode	<p>Set this property to control how members are aggregated when dimension security is applied.</p> <p>For cube data that everyone is allowed to see, aggregating all of the members makes sense because all of the values that contribute to the total are visible. However, if you filter or restrict dimensions based on user identity, showing a total based on all the members (combining both restricted and allowed values into a single total) might be confusing or show more information than should be revealed.</p> <p>To specify how members are aggregated when dimension security is applied, you can set this property to True to use only allowed values in the aggregation, or False to exclude restricted values from the total.</p> <p>When set on the connection string, this value applies to the cube or perspective level. Within a model, you can control visual totals at a more granular level.</p> <p>Valid values are 0, 1, and 2.</p> <ul style="list-style-type: none"> - 0 is the default. Currently, the default behavior is equivalent to 2, where aggregations include values that are hidden from the user. - 1 excludes hidden values from the total. This is the default for Excel. - 2 includes hidden values in the total. This is the default value on the server. <p>Aliases for this property include Visual Total or Default MDX Visual Mode.</p>

Reserved for future use

The following properties are allowed on a connection string, but are not operational in current releases of Analysis Services.

- Authenticated User
- Cache Authentication
- Cache Mode (Use of this property was investigated in earlier releases. Although you might find blog posts recommending its usage, you should avoid setting this property unless instructed by Microsoft Support).
- Cache Policy
- Cache Ratio
- Cache Ratio2
- Dynamic Debug Limit
- Debug Mode
- Mode
- SQLCompatibility
- Use Formula Cache

Example connection strings

This section shows the connection string that you'll most likely use when setting up an Analysis Services connection in commonly used applications.

Generic connection string

You might use a connection string like this one if you are configuring a connection from Reporting Services.

```
Data source=<servername>; initial catalog=<databasename>
```

Connection string in Excel

The default ADOMD.NET connection string in Excel specifies the data provider, server, database name, Windows integrated security. The MDX Compatibility level is always set to 1. Although you can change the value for the current session, Excel will reset MDX Compatibility to 1 when the file is next opened.

```
Provider=MSOLAP.5;Integrated Security=SSPI;Persist Security Info=True;Initial Catalog=Adventure Works DW 2008R2;Data Source=AW-SRV01;MDX Compatibility=1;Safety Options=2;MDX Missing Member Mode=Error
```

For more information, see [Data Connections, Data Sources, and Connection Strings \(Report Builder and SSRS\)](#) and [Data Authentication for Excel Services in SharePoint Server 2013](#).

Connection string formats used in Analysis Services

This section lists all of the connection string formats supported by Analysis Services. With the exception of connections to Power Pivot databases, you can specify these connection strings in applications that connect to Analysis Services.

Native (or direct) connections to the server

`Data Source=server[:port][\instance]` where "port" and "\instance" are optional. For example, specifying "Data Source=server1" opens a connection to the default instance (and default port 2383) on a server named "server1".

"Data Source=server1:port1" will open a connection to an Analysis Services instance running on port "port1" on "server1".

"Data Source=server1\instance1" will open a connection to SQL Browser (on its default port 2382), resolve the port for the named instance "instance1", then open the connection to that Analysis Services port.

"Data Source=server1:port1\instance1" will open a connection to SQL Browser on "port1", resolve the port for the "instance1" named instance, then open the connection to that Analysis Services port.

Local cube connections (.cub files)

`Data Source=<path>`, for example "Data Source=c:\temp\{a}.cub"

Http(s) connections to msmdpump.dll

`Data Source=<URL>`, where the URL is the HTTP or HTTPS address to the virtual IIS folder that contains the msmdpump.dll.

For more information, see [Configure HTTP Access to Analysis Services on Internet Information Services \(IIS\) 8.0](#).

Http(s) connections to Power Pivot workbooks (.xlsx, .xlst or .xlsm files)

`Data Source=<URL>`, where the URL is the SharePoint path to a Power Pivot workbook that has been published to a SharePoint library. For example, `Data Source=http://localhost/Shared Documents/Sales.xlsx`.

Http(s) connections to BI Semantic Model Connection files

`Data Source=<URL>` where the URL is the SharePoint path to the .bism file. For example,

`Data Source=http://localhost/Shared Documents/Sales.bism`.

Embedded Power Pivot connections

`Data Source=$Embedded$` where \$embedded\$ is a moniker that refers to an embedded Power Pivot data model inside the workbook. This connection string is created and managed internally. Do not modify it. Embedded connection strings are resolved by the Power Pivot for Excel add-in on client workstations, or by Power Pivot for SharePoint instances in a SharePoint farm.

Local server context in Analysis Services stored procedures

`Data Source=*`, where * resolves to the local instance.

Encrypting Connection Strings

Analysis Services uses its own encryption keys to encrypt connection strings. It does not generate a self-signed certificate.

Analysis Services encrypts and stores the connection strings it uses to connect to each of its data sources. If the connection to a data source requires a user name and password, you can have Analysis Services store the name and password with the

connection string, or prompt you for the name and password each time a connection to the data source is required. Having Analysis Services prompt you for user information means that this information does not have to be stored and encrypted. However, if you store this information in the connection string, this information does need to be encrypted and secured.

To encrypt and secure the connection string information, Analysis Services uses the Data Protection API.

Analysis Services uses a separate encryption key to encrypt connection string information for each Analysis Services database. Analysis Services creates this key when you create a database, and encrypts connection string information based on the Analysis Services startup account. When Analysis Services starts, the encrypted key for each database is read, decrypted, and stored. Analysis Services then uses the appropriate decrypted key to decrypt the data source connection string information when Analysis Services needs to connect to a data source.

Authentication methodologies supported by Analysis Services

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Connections from a client application to an Analysis Services instance require Windows authentication (integrated). You can provide a Windows user identity using any of the following methods:

- NTLM
- Kerberos (see [Configure Analysis Services for Kerberos constrained delegation](#))
- EffectiveUserName on the connection string
- Basic or Anonymous (requires configuration for HTTP access)
- Stored credentials

Notice that Claims authentication is not supported. You cannot use a Windows Claims token to access Analysis Services. The Analysis Services client libraries only work with Windows security principles. If your BI solution includes claims identities, you will need Windows identity shadow accounts for each user, or use stored credentials to access Analysis Services data.

For more information about BI and Analysis Services authentication flows, see [Microsoft BI Authentication and Identity Delegation](#).

Understanding your authentication alternatives

Connecting to an Analysis Services database requires a Windows user or group identity and associated permissions. The identity might be a general purpose login used by anyone who needs to view a report, but a more likely scenario includes the identity of individual users.

Often, a tabular or multidimensional model will have different levels of data access, by object or within the data itself, based on who is making the request. To meet this requirement, you can use NTLM, Kerberos, EffectiveUserName, or Basic authentication. All of these techniques offer an approach for passing in different user identities with each connection. However, most of these choices are subject to a single hop limitation. Only Kerberos with delegation allows the original user identity to flow across multiple computer connections to a backend data store on a remote server.

NTLM

For connections that specify `SSPI=Negotiate`, NTLM is the backup authentication subsystem used when a Kerberos domain controller is not available. Under NTLM, any user or client application can access a server resource as long as the request is a direct connection from a client to the server, the person requesting the connection has permission to the resource, and the client and server computers are in the same domain.

In multi-tier solutions, the single hop restriction of NTLM can be a major constraint. The user identity making the request can be impersonated on exactly one remote server, but travels no further. If the current operation requires services running on multiple computers, you will need to configure Kerberos constrained delegation to reuse the security token on backend servers. Alternatively, you can use stored credentials or Basic authentication to pass in new identity information over a single hop connection.

Kerberos Authentication and Kerberos Constrained Delegation

Kerberos authentication is the basis of Windows integrated security in Active Directory domains. As with NTLM, impersonation under Kerberos is limited to a single hop unless you enable delegation.

To support multi-hop connections, Kerberos provides both constrained and unconstrained delegation, but for most scenarios, constrained delegation is considered a security best practice. Constrained delegation allows a service to pass the security token of the user identity to a designated down-level service on a remote computer. For multi-tier applications, delegating a user identity from a middle tier application server to a backend database such as Analysis Services is a common requirement. For example, a tabular or multidimensional model that returns different data based on user identity would require identity delegation from a middle tier service to avoid having the user re-enter credentials, or getting security credentials some other way.

Constrained delegation requires additional configuration in Active Directory, where services on both the sending and receiving end of the request are explicitly authorized for delegation. Although there are configuration costs up front, once the service is configured, password updates are managed independently in Active Directory. You do not need to update stored account information in applications, as you would if using the stored credentials option described further on.

For more information about configuring Analysis Services for constrained delegation, see [Configure Analysis Services for Kerberos constrained delegation](#).

NOTE

Windows Server 2012 supports constrained delegation across domains. In contrast, configuring Kerberos constrained delegation in domains at lower functional levels, such as Windows Server 2008 or 2008 R2, require both client and server computers to be members of the same domain.

EffectiveUserName

EffectiveUserName is a connection string property used for passing identity information to Analysis Services. Power Pivot for SharePoint uses it to record user activity in the usage logs. Excel Services and PerformancePoint Services can use it to retrieve data used by workbooks or dashboards in SharePoint. It can also be used in custom applications or scripts that perform operations on an Analysis Services instance.

For more information about using EffectiveUserName in SharePoint, see [Use Analysis Services EffectiveUserName in SharePoint Server 2010](#).

Basic Authentication and Anonymous User

Basic authentication provides yet a fourth alternative for connecting to a backend server as a specific user. Using Basic authentication, the Windows user name and password are passed on the connection string, introducing additional wire encryption requirements to ensure sensitive information is protected while in transit. An important advantage to using Basic authentication is that the authentication request can cross domain boundaries.

For Anonymous authentication, you can set the anonymous user identity to a specific Windows user account (IUSR_GUEST by default) or an application pool identity. The anonymous user account will be used on the Analysis Services connection, and must have data access permissions on the Analysis Services instance. When you use this approach, only the user identity associated with the Anonymous account is used on the connection. If your application requires additional identity management, you will need to choose one of the other approaches, or supplement with an identity management solution that you provide.

Basic and Anonymous are available only when you configure Analysis Services for HTTP access, using IIS and the msmdpump.dll to establish the connection. For more information, see [Configure HTTP Access to Analysis Services on Internet Information Services \(IIS\) 8.0](#).

Stored Credentials

Most middle tier application services include functionality for storing a user name and password subsequently used to retrieve data from a down-level data store, such as Analysis Services or the SQL Server relational engine. As such, stored credentials provide a fifth alternative for retrieving data. Limitations with this approach include maintenance overhead associated with keeping user names and passwords up to date, and the use of a single identity on the connection. If your solution requires the identity of the original caller, then stored credentials would not be a viable alternative.

For more information about stored credentials, see [Create, Modify, and Delete Shared Data Sources \(SSRS\)](#) and [Use Excel Services with Secure Store Service in SharePoint Server 2013](#).

[Connect to Analysis Services](#)

Configure Analysis Services for Kerberos constrained delegation

7/16/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

When configuring Analysis Services for Kerberos authentication, you are most likely interested in achieving one or both of the following outcomes: having Analysis Services impersonate a user identity when querying data; or having Analysis Services delegate a user identity to a down-level service. Each scenario calls for slightly different configuration requirements. Both scenarios require verification to ensure configuration was done properly.

TIP

Microsoft Kerberos Configuration Manager for SQL Server is a diagnostic tool that helps troubleshoot Kerberos related connectivity issues with SQL Server. For more information, see [Microsoft Kerberos Configuration Manager for SQL Server](#).

This topic contains the following sections:

- [Allow Analysis Services to impersonate a user identity](#)
- [Configure Analysis Services for trusted delegation](#)
- [Test for impersonated or delegated identity](#)

NOTE

Delegation is not required if the connection to Analysis Services is a single hop, or your solution uses stored credentials provided by SharePoint Secure Store Service or Reporting Services. If all connections are direct connections from Excel to an Analysis Services database, or based on stored credentials, you can use Kerberos (or NTLM) without having to configure constrained delegation.

Kerberos constrained delegation is required if the user identity has to flow over multiple computer connections (known as "double-hop"). When Analysis Services data access is contingent upon user identity, and the connection request is from a delegating service, use the checklist in the next section to ensure that Analysis Services is able to impersonate the original caller. For more information about Analysis Services authentication flows, see [Microsoft BI Authentication and Identity Delegation](#).

As a security best practice, Microsoft always recommends constrained delegation over unconstrained delegation. Unconstrained delegation is a major security risk because it allows the service identity to impersonate another user on *any* downstream computer, service, or application (as opposed to just those services explicitly defined via constrained delegation).

Allow Analysis Services to impersonate a user identity

To allow up-level services such as Reporting Services, IIS, or SharePoint to impersonate a user identity on Analysis Services, you must configure Kerberos constrained delegation for those services. In this scenario, Analysis Services impersonates the current user using the identity provided by the delegating service, returning results based on role membership of that user identity.

TASK	DESCRIPTION
Step 1: Verify that accounts are suitable for delegation	<p>Ensure that the accounts used to run the services have the correct properties in Active Directory. Service accounts in Active Directory must not be marked as sensitive accounts, or specifically excluded from delegation scenarios. For more information, see Understanding User Accounts.</p> <p>Note: Generally, all accounts and servers must belong to the same Active Directory domain or to trusted domains in the same forest. However, because Windows Server 2012 supports delegation across domain boundaries, you can configure Kerberos constrained delegation across a domain boundary if the domain functional level is Windows Server 2012. Another alternative is to configure Analysis Services for HTTP access and use IIS authentication methods on the client connection. For more information, see Configure HTTP Access to Analysis Services on Internet Information Services (IIS) 8.0.</p>
Step 2: Register the SPN	<p>Before setting up constrained delegation, you must register a Service Principle Name (SPN) for the Analysis Services instance. You will need the Analysis Services SPN when configuring Kerberos constrained delegation for middle tier services. See SPN registration for an Analysis Services instance for instructions.</p> <p>A Service Principle Name (SPN) specifies the unique identity of a service in a domain configured for Kerberos authentication. Client connections using integrated security often request an SPN as part of SSPI authentication. The request is forwarded to an Active Directory Domain Controller (DC), with the KDC granting a ticket if the SPN presented by the client has a matching SPN registration in Active Directory.</p>

Task	Description
Step 3: Configure constrained delegation	<p>After validating the accounts you want to use and registering SPNs for those accounts, your next step is to configure up-level services, such as IIS, Reporting Services, or SharePoint web services for constrained delegation, specifying the Analysis Services SPN as the specific service for which delegation is allowed.</p> <p>Services that run in SharePoint, such as Excel Services or Reporting Services in SharePoint mode, often host workbooks and reports that consume Analysis Services multidimensional or tabular data. Configuring constrained delegation for these services is a common configuration task, and necessary for supporting data refresh from Excel Services. The following links provide instructions for SharePoint services, as well as other services likely to present a downstream data connection request for Analysis Services data:</p> <ul style="list-style-type: none"> Identity delegation for Excel Services (SharePoint Server 2010) or How to configure Excel Services in SharePoint Server 2010 for Kerberos authentication Identity delegation for PerformancePoint Services (SharePoint Server 2010) Identity delegation for SQL Server Reporting Services (SharePoint Server 2010) <p>For IIS 7.0 see Configure Windows Authentication (IIS 7.0) or How to configure SQL Server 2008 Analysis Services and SQL Server 2005 Analysis Services to use Kerberos authentication.</p>
Step 4: Test connections	<p>When testing, connect from remote computers, under different identities, and query Analysis Services using the same applications as business users. You can use SQL Server Profiler to monitor the connection. You should see the user identity on the request. For more information, see Test for impersonated or delegated identity in this section.</p>

Configure Analysis Services for trusted delegation

Configuring Analysis Services for Kerberos constrained delegation allows the service to impersonate a client identity on a down-level service, such as the relational database engine, so that data can be queried as if the client was connected directly.

Delegation scenarios for Analysis Services are limited to tabular models configured for **DirectQuery** mode. This is the only scenario in which Analysis Services can pass delegated credentials to another service. In all other scenarios, such as SharePoint scenarios mentioned in the previous section, Analysis Services is on the receiving end of the delegation chain. For more information about DirectQuery, see [DirectQuery Mode](#).

NOTE

A common misconception is that ROLAP storage, processing operations, or access to remote partitions somehow introduce requirements for constrained delegation. This is not the case. All of these operations are executed directly by the service account (also referred to as the processing account), on its own behalf. Delegation is not required for these operations in Analysis Services, given that permissions for such operations are granted directly to the service account (for example, granting db_datareader permissions on the relational database so that the service can process data). For more information about server operations and permissions, see [Configure Service Accounts \(Analysis Services\)](#).

This section explains how to set up Analysis Services for trusted delegation. After you complete this task, Analysis Services will be able to pass delegated credentials to SQL Server, in support of DirectQuery mode used in Tabular solutions.

Before you start:

- Verify that Analysis Services is started.
- Verify the SPN registered for Analysis Services is valid. For instructions, see [SPN registration for an Analysis Services instance](#)

When both prerequisites are satisfied, continue with the following steps. Note that you must be a domain administrator to set up constrained delegation.

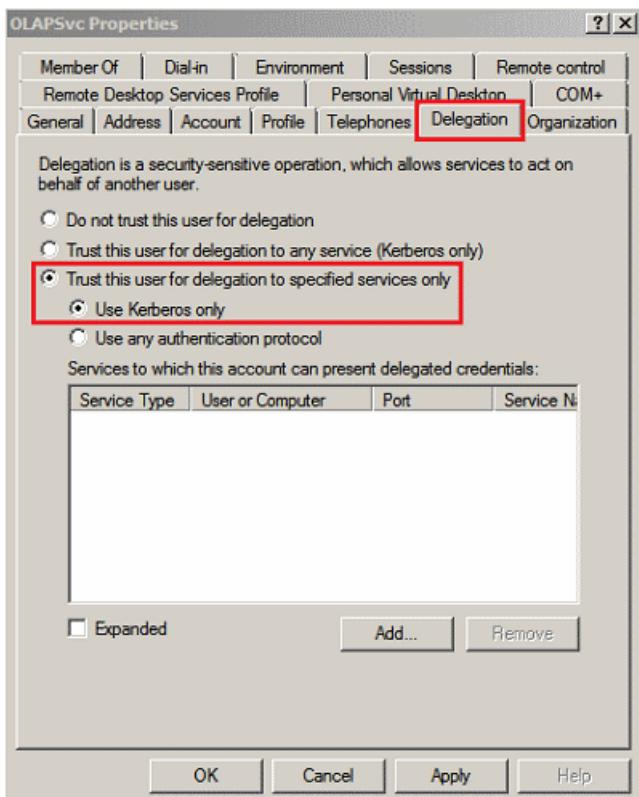

1. In Active Directory Users and Computers, find the service account under which Analysis Services runs. Right-click the service account and choose **Properties**.

For illustrative purposes, the following screenshots use OlapSvc and SQLSvc to represent Analysis Services and SQL Server, respectively.

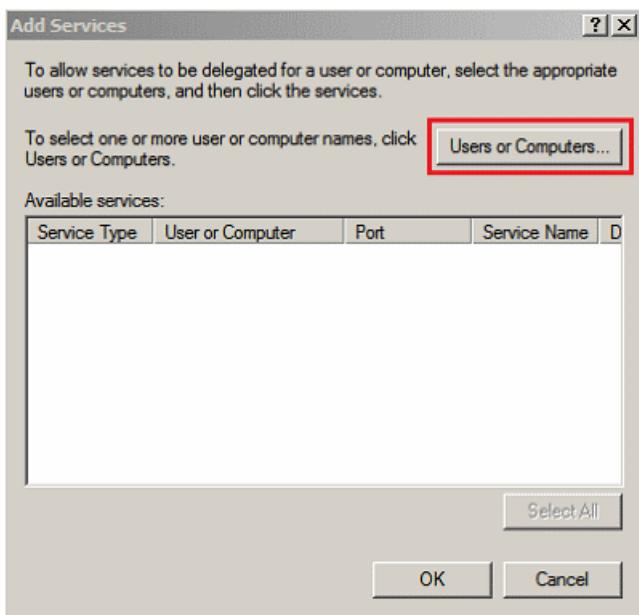

OlapSvc is the account that will be configured for constrained delegation to SQLSvc. When you complete this task, OlapSvc will have permission to pass delegated credentials on a service ticket to SQLSvc, impersonating the original caller when requesting data.

2. On the Delegation tab, select **Trust this user for delegation to specified services only**, followed by **Use Kerberos only**. Click **Add** to specify which service Analysis Services is permitted to delegate credentials.

Delegation tab appears only when the user account (OlapSvc) is assigned to a service (Analysis Services), and the service has an SPN registered for it. SPN registration requires that the service is running.

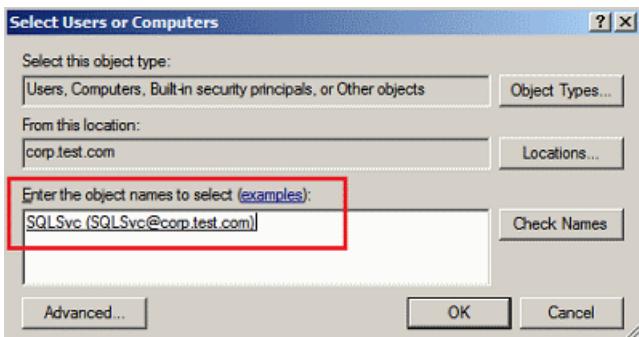

3. On the Add Services page, click **Users or Computers**.

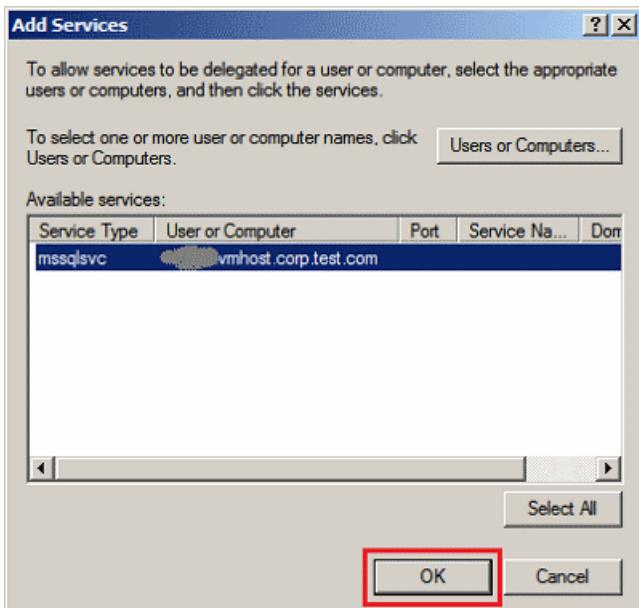

4. On the Select Users or Computer page, enter the account used to run the SQL Server instance providing data to Analysis Services tabular model databases. Click **OK** to accept the service account.

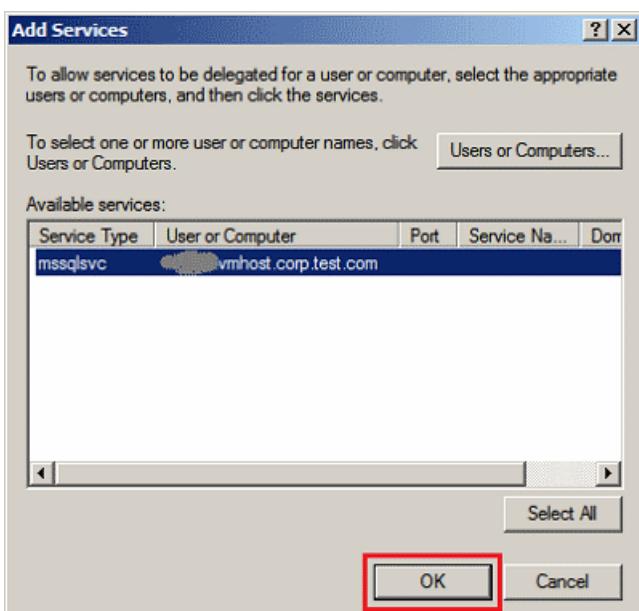

If you cannot select the account you want, verify that SQL Server is running and has an SPN registered for that account. For more information about SPNs for the database engine, see [Register a Service Principal Name for Kerberos Connections](#).

5. The SQL Server instance should now appear in Add Services. Any service also using that account will also appear in the list. Choose the SQL Server instance you want to use. Click **OK** to accept the instance.

6. The properties page of the Analysis Services service account should now look similar to the following screenshot. Click **OK** to save your changes.

7. Test for successful delegation by connecting from a remote client computer, under a different identity, and query the tabular model. You should see the user identity on the request in SQL Server Profiler.

Test for impersonated or delegated identity

Use SQL Server Profiler to monitor the identity of the user who is querying data.

1. Start **SQL Server Profiler** on the Analysis Services instance and then start a new trace.
2. In Events Selection, verify that **Audit Login** and **Audit Logout** are checked in the Security Audit section.
3. Connect to Analysis Services via an application service (such as SharePoint or Reporting Services) from a remote client computer. The Audit Login event will show the identity of the user connecting to Analysis Services.

Thorough testing will require the use of network monitoring tools that can capture Kerberos requests and responses on the network. The Network Monitor utility (netmon.exe), filtered for Kerberos, can be used for this task. For more information about using Netmon 3.4 and other tools for testing Kerberos authentication, see [Configuring Kerberos authentication: Core configuration \(SharePoint Server 2010\)](#).

7/16/2019 • 10 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A Service Principle Name (SPN) uniquely identifies a service instance in an Active Directory domain when Kerberos is used to mutually authenticate client and service identities. An SPN is associated with the logon account under which the service instance runs.

For client applications connecting to Analysis Services via Kerberos authentication, the Analysis Services client libraries construct an SPN using the host name from the connection string and other well-known variables, such as the service class, that are fixed in any given release of Analysis Services.

For mutual authentication to occur, the SPNs constructed by the client must match a corresponding SPN object on an Active Directory Domain Controller (DC). This means that you might need to register multiple SPNs for a single Analysis Services instance to cover all of the ways in which a user might specify the host name on a connection string. For example, you probably need two SPNs to handle both the fully-qualified domain name (FQDN) of a server, as well as the short computer name. Correctly registering the Analysis Services SPN is essential for a successful connection. If the SPN is non-existent, malformed, or duplicated, the connection will fail.

SPN registration is a manual task performed by the Analysis Services administrator. Unlike the SQL Server database engine, Analysis Services never auto-registers its SPN at service startup. Manual registration is required when Analysis Services runs under the default virtual account, a domain user account, or a built-in account, including a per-service SID.

SPN registration is not required if the service runs under a predefined managed service account created by a domain administrator. Note that depending on the functional level of your domain, registering an SPN can require domain administrator permissions.

TIP

Microsoft Kerberos Configuration Manager for SQL Server is a diagnostic tool that helps troubleshoot Kerberos related connectivity issues with SQL Server. For more information, see [Microsoft Kerberos Configuration Manager for SQL Server](#).

This topic contains the following sections:

[When SPN registration is required](#)

[SPN format for Analysis Services](#)

[SPN registration for a virtual account](#)

[SPN registration for a domain account](#)

[SPN registration for a built-in account](#)

[SPN registration for a named instance](#)

[SPN registration for an SSAS cluster](#)

[SPN registration for SSAS instances configured for HTTP access](#)

[SPN registration for SSAS instances listening on fixed ports](#)

When SPN registration is required

Any client connection that specifies "SSPI=Kerberos" on the connection string will introduce SPN registration requirements for an Analysis Services instance.

SPN registration is required under the following circumstances. For more detailed information, see [Configure Analysis Services for Kerberos constrained delegation](#).

- Identity delegation is necessary to flow the user identity from the client application or middle-tier service to Analysis Services. Identity delegation is typically used when per-user permissions or filters are defined on specific objects.

A common scenario involving identity delegation is configuring middle-tier services, such as Excel Services or Reporting Services, for constrained delegation for the purpose of impersonating a user identity when retrieving data in Analysis Services. To support this behavior, you must provide an Analysis Services SPN as the destination service when configuring Excel Services or Reporting Services for constrained delegation.

- Analysis Services delegates a user identity when retrieving data from a SQL Server relational database for tabular databases using DirectQuery mode. This is the only scenario in which Analysis Services will delegate the user identity to another service.

SPN format for Analysis Services

Use **setspn** to register an SPN. On newer operating systems, **setspn** is installed as a system utility. For more information, see [SetSPN](#).

The following table describes each part of an Analysis Services SPN.

ELEMENT	DESCRIPTION
Service class	MSOLAPSVc.3 identifies the service as an Analysis Services instance. The .3 is a reference to the version of the XMLA-over-TCP/IP protocol used in Analysis Services transmissions. It is unrelated to product release. As such, MSOLAPSVc.3 is the correct service class for SQL Server 2005, 2008, 2008 R2, 2012 and any future release of Analysis Services until the protocol itself is revised.
Host-name	<p>Identifies the computer on which the service is running. This can be a fully-qualified domain name or a NetBIOS name. You should register an SPN for both.</p> <p>When registering an SPN for the NetBIOS name of a server, be sure to use <code>SetupSPN -S</code> to check for duplicate registration. NetBIOS names are not guaranteed to be unique in a forest, and having a duplicate SPN registration will cause the connection to fail.</p> <p>For Analysis Services load balanced clusters, the host name should be the virtual name assigned to the cluster.</p> <p>Never create an SPN using the IP address. Kerberos uses the DNS resolution capabilities of the domain. Specifying an IP address bypasses that capability.</p>

ELEMENT	DESCRIPTION
Port-number	Although the port number is part of SPN syntax, you never specify a port number when registering an Analysis Services SPN. The colon (:) character, typically used to provide a port number in standard SPN syntax, is used by Analysis Services to specify the instance name. For an Analysis Services instance, the port is assumed to be the default port (TCP 2383) or a port assigned by the SQL Server Browser service (TCP 2382).
Instance-name	<p>Analysis Services is a replicable service that can be installed multiple times on the same computer. Each instance is identified through its instance name.</p> <p>The instance name is prefixed with a colon (:) character. For example, given a host computer named SRV01 and a named instance of SSAS-Tabular, the SPN should be SRV01:SSAS-Tabular.</p> <p>Note that the syntax for specifying a named Analysis Services instance differs from that used by other SQL Server instances. Other services use a backslash (\) to append the instance name in an SPN.</p>
Service-account	<p>This is the startup account of the MSSQLServerOLAPService Windows service. It can be a Windows domain user account, virtual account, managed service account (MSA) or a built-in account such as a per-service SID, NetworkService, or LocalSystem. A Windows domain user account can be formatted as domain\user or user@domain.</p>

SPN registration for a virtual account

Virtual accounts are the default account type for SQL Server services. The virtual account is **NT Service\MSOLAPService** for a default instance and **NT Service\MSOLAP\$<instance-name>** for a named instance.

As the name implies, these accounts do not exist in Active Directory. A virtual account exists only on the local computer. When connecting to external services, applications, or devices, the connection is made using the local machine account. For this reason, an SPN registration for Analysis Services running under a virtual account is actually an SPN registration for the machine account.

Example syntax for a default instance running as NT Service\MSOLAPService

This example shows **setspn** syntax for Analysis Services default instance running under the default virtual account. In this example, the computer host name is **AW-SRV01**. As noted, SPN registration must specify the *machine account* instead of the virtual account, **NT Service\MSOLAPService**.

```
Setspn -s MSOLAPSvc.3/AW-SRV01.AdventureWorks.com AW-SRV01
```

NOTE

Remember to create two SPN registrations, one for the NetBIOS host name and a second for a fully-qualified domain name of the host. Different client applications use different host name conventions when connecting to Analysis Services. Having two SPN registrations ensures that both versions of the host name are accounted for.

Example syntax for a named instance running as NT Service\MSOLAP\$<instance-name>

This example shows **setspn** syntax for a named instance running under the default virtual account. In this example, the computer host name is **AW-SRV02**, and the instance name is **AW-FINANCE**. Again, it is the machine account that is specified for the SPN, rather than the virtual account **NT Service\MSOLAP\$<instance-name>**.

```
Setspn -s MSOLAPSvc.3/AW-SRV02.AdventureWorks.com:AW-FINANCE AW-SRV02
```

SPN registration for a domain account

Using a domain account to run an Analysis Services instance is a common practice.

For Analysis Services instances that run in a network or hardware load balanced cluster, a domain account is required, with each instance in the cluster running under the same domain account.

Example syntax for a default instance running as a domain user

This example shows **setspn** syntax for Analysis Services default instance running under a domain user account, **SSAS-Service**, in the AdventureWorks domain.

```
Setspn -s msolapsvc.3/AW-SRV01.Adventureworks.com AdventureWorks\SSAS-Service
```

TIP

Verify whether the SPN was created for the Analysis Services server by running `Setspn -L <domain account>` or `Setspn -L <machinename>`, depending on how the SPN was registered. You should see `MSOLAPSVC.3/<hostname>` in the list.

SPN registration for a built-in account

Although this practice is not recommended, older Analysis Services installations are sometimes configured to run under built-in accounts like Network Service, Local Service, or Local System.

Example syntax for a default instance running under a built-in account

SPN registration for a service running under a built-in account or per-service SID is equivalent to the SPN syntax used for the virtual account. Instead of the account name, use the machine account:

```
Setspn -s MSOLAPSvc.3/AW-SRV01.AdventureWorks.com AW-SRV01
```

SPN registration for a named instance

Named instances of Analysis Services use dynamic port assignments that are detected by the SQL Server Browser service. When using a named instance, register an SPN for both the SQL Server Browser Service and the Analysis Services named instance. For more information, see [An SPN for the SQL Server Browser service is required when you establish a connection to a named instance of SQL Server Analysis Services or of SQL Server](#).

Example of SPN syntax for the SQL Browser Service running as LocalService

The service class is **MSOLAPDisco.3**. By default, this service runs as NT AUTHORITY\LocalService, which means SPN registration is set for the machine account. In this example, the machine account is **AW-SRV01**, corresponding to the computer name.

```
Setspn -S MSOLAPDisco.3/AW-SRV01.AdventureWorks.com AW-SRV01
```

SPN registration for an SSAS cluster

For Analysis Services failover clusters, the host name should be the virtual name assigned to the cluster. This is the SQL Server network name, specified during SQL Server Setup when you installed Analysis Services on top of an existing WSFC. You can find this name in Active Directory. You can also find it in **Failover Cluster Manager | Role | Resources** tab. The server name on the Resources tab is what should be used as the 'virtual name' in the SPN command.

SPN syntax for an Analysis Services cluster

```
Setspn -s msolapsvc.3/<virtualname.FQDN> <domain user account>
```

Recall that nodes in an Analysis Services cluster are required to use the default port (TCP 2383) and run under the same domain user account so that each node has the same SID. See [How to Cluster SQL Server Analysis Services](#) for more information.

SPN registration for SSAS instances configured for HTTP access

Depending on solution requirements, you might have configured Analysis Services for HTTP access. If your solution includes IIS as a middle tier component, and Kerberos authentication is a solution requirement, you might need to manually register an SPN for IIS. For more information, see "Configure the settings on the computer running IIS" in [How to configure SQL Server 2008 Analysis Services and SQL Server 2005 Analysis Services to use Kerberos authentication](#).

In terms of SPN registration for the Analysis Services instance, there is no difference between an instance configured for TCP or HTTP. The connection to Analysis Services from IIS, using the MSMDPUMP ISAPI extension, is always TCP.

This means that you can use the instructions from previous sections for default or named instance to register the SPN. When specifying the host name, be sure to use the host name you specified in the msmdpump.ini file when you configured the service for HTTP access.

For more information about HTTP access, see [Configure HTTP Access to Analysis Services on Internet Information Services \(IIS\) 8.0](#).

SPN registration for SSAS instances listening on fixed ports

You cannot specify a port number on an Analysis Services SPN registration. If you installed Analysis Services as the default instance and configured it to listen on a fixed port, you must now configure it to listen on the default port (TCP 2383). For named instances, you need to use SQL Server Browser service and dynamic port assignments.

An Analysis Services instance can only listen on a single port. Using multiple ports is not supported. For more information about port configuration, see [Configure the Windows Firewall to Allow Analysis Services Access](#).

Configure HTTP Access to Analysis Services on IIS 8.0

7/16/2019 • 18 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This article explains how to set up an HTTP endpoint for accessing an Analysis Services instance. You can enable HTTP access by configuring MSMDPUMP.dll, an ISAPI extension that runs in Internet Information Services (IIS) and pumps data to and from client applications and an Analysis Services server. This approach provides an alternative means for connecting to Analysis Services when your BI solution calls for the following capabilities:

- Client access is over Internet or extranet connections, with restrictions on which ports can be enabled.
- Client connections are from non-trusted domains in the same network.
- Client application runs in a network environment that allows HTTP but not TCP/IP connections.
- Client applications cannot use the Analysis Services client libraries (for example, a Java application running on a UNIX server). If you cannot use the Analysis Services client libraries for data access, you can use SOAP and XML/A over a direct HTTP connection to an Analysis Services instance.
- Authentication methods other than Windows integrated security are required. Specifically, you can use Anonymous connections and Basic authentication when configuring Analysis Services for HTTP access. Digest, Forms, and ASP.NET authentication are not supported. A requirement of Basic authentication is one of the primary reasons for enabling HTTP access. To learn more, see [Microsoft BI Authentication and Identity Delegation](#).

You can configure HTTP access for any supported version or edition of Analysis Services, running either tabular mode or multidimensional mode. Local cubes are an exception. You cannot connect to a local cube via an HTTP endpoint.

Setting up HTTP access is a post-installation task. Analysis Services must be installed before you can configure it for HTTP access. As the Analysis Services administrator, you will need to grant permissions to Windows accounts before HTTP access is possible. Additionally, it is a best practice to validate your installation first, ensuring that it is fully operational before configuring the server any further. After HTTP access is configured, you can use both the HTTP endpoint and the regular network name of the server over TCP/IP. Setting up HTTP access does not invalidate other approaches for data access.

As you move forward with MSMDPUMP configuration, remember there are two connections to consider: client-to-IIS, IIS-to-SSAS. The instructions in this article are about IIS-to-SSAS. Your client application might require additional configuration before it can connect to IIS. Decisions such as whether to use SSL, or how to configure bindings, are out of scope for this article. See [Web Server \(IIS\)](#) for more information about IIS.

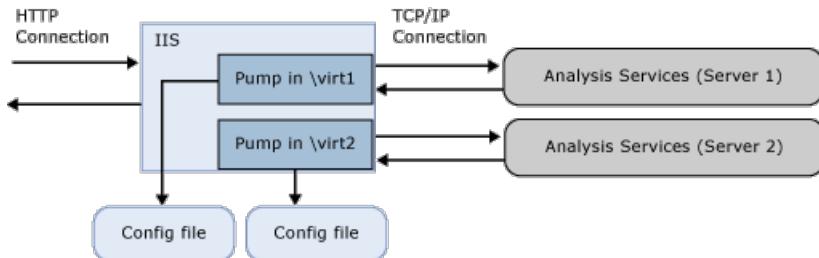

Overview

MSMDPUMP is an ISAPI extension that loads into IIS and provides redirection to a local or remote Analysis Services instance. By configuring this ISAPI extension, you create an HTTP endpoint to an Analysis Services instance.

You must create and configure one virtual directory for each HTTP endpoint. Each endpoint will need its own set of MSMDPUMP files, for each Analysis Services instance you want to connect to. A configuration file in this file set specifies the name of the Analysis Services instance used for each HTTP endpoint.

On IIS, MSMDPUMP connects to Analysis Services using the Analysis Services OLE DB provider over TCP/IP. Although client requests can originate outside of domain trust, both Analysis Services and IIS must be in the same domain or in trusted domains in order for the native connection to succeed.

When MSMDPUMP connects to Analysis Services, it does so under a Windows user identity. This account will either be the Anonymous account if you configured the virtual directory for anonymous connections, or a Windows user account. The account must have the appropriate data access rights on the Analysis Services server and database.

The following table lists additional considerations when you enable HTTP access for different scenarios.

SCENARIO	CONFIGURATION
IIS and Analysis Services on the same computer	This is the simplest configuration because it allows you to use the default configuration (where the server name is localhost), the local Analysis Services OLE DB provider, and Windows integrated security with NTLM. Assuming that the client is also in the same domain, authentication is transparent to the user, with no additional work on your part.
IIS and Analysis Services on different computers	<p>For this topology, you must install the Analysis Services OLE DB provider on the web server. You must also edit the msmdpump.ini file to specify the location of Analysis Services instance on the remote computer.</p> <p>This topology adds a double-hop authentication step, where credentials must flow from the client to the web server, and on to the backend Analysis Services server. If you are using Windows credentials and NTLM, you will get an error because NTLM does not allow delegation of client credentials to a second server. The most common solution is to use Basic authentication with Secure Sockets Layer (SSL), but this will require users to provide a user name and password when accessing the MSMDPUMP virtual directory. A more straightforward approach might be to enable Kerberos and configure Analysis Services constrained delegation so that users can access Analysis Services in a transparent manner. See Configure Analysis Services for Kerberos constrained delegation for details.</p> <p>Consider which ports to unblock in Windows Firewall. You will need to unblock ports on both servers to allow access to the web application on IIS, and to Analysis Services on a remote server.</p>

SCENARIO	CONFIGURATION
Client connections are from a non-trusted domain or an extranet connection	<p>Client connections from a non-trusted domain introduce further restrictions on authentication. By default, Analysis Services uses Windows integrated authentication, which requires users to be on the same domain as the server. If you have Extranet users who connect to IIS from outside the domain, those users will get a connection error if the server is configured to use the default settings.</p> <p>Workarounds include having Extranet users connect through a VPN using domain credentials. However, a better approach might be to enable Basic authentication and SSL on your IIS web site.</p>

Prerequisites

The instructions in this article assume IIS is already configured and that Analysis Services is already installed. Windows Server 2012 ships with IIS 8.x as a server role that you can enable on the system.

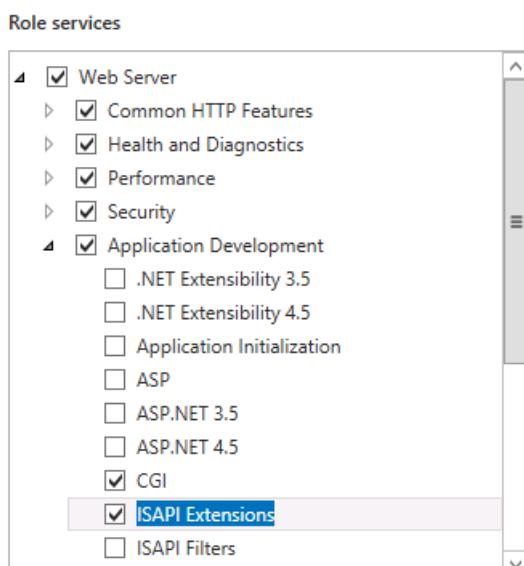

Extra configuration in IIS 8.0

The default configuration of IIS 8.0 is missing components that are necessary for HTTP access to Analysis Services. These components, found in the **Security** and **Application Development** feature areas of the **Web Server (IIS)** role, include the following:

- **Security | Windows Authentication**, or **Basic Authentication**, and any other security features required for your data access scenario.
- **Application Development | CGI**
- **Application Development | ISAPI Extensions**

To verify or add these components, use **Server Manager | Manage | Add Roles and Features**. Step through the wizard until you get to **Server Roles**. Scroll down to find **Web Server (IIS)**.

1. Open **Web Server | Security** and choose the authentication methods.
2. Open **Web Server | Application Development** and choose **CGI** and **ISAPI Extensions**.

When IIS is on a remote server

A remote connection between IIS and Analysis Services requires that you install the Analysis Services OLE DB provider (MSOLAP) on the Windows server running IIS.

1. Go to the download page for [SQL Server 2014 Feature Pack](#)
2. Click the red Download button.
3. Scroll down to find ENU\x64\SQL_AS_OLEDB.msi
4. Follow the instructions in the wizard to complete the installation.

NOTE

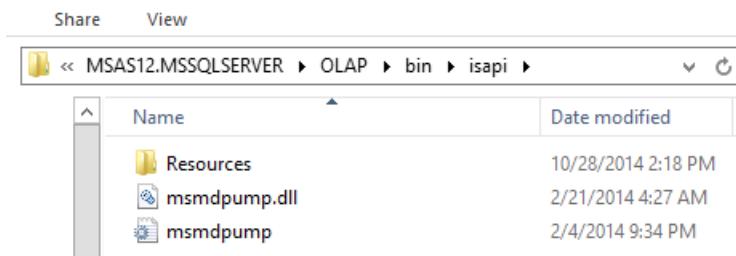

Remember to unblock the ports in Windows Firewall to allow client connections to a remote Analysis Services server. For more information, see [Configure the Windows Firewall to Allow Analysis Services Access](#).

Step 1: Copy the MSMDPUMP files to a folder on the Web server

Each HTTP endpoint that you create must have its own set of MSMDPUMP files. In this step, you copy the MSMDPUMP executable, configuration file, and resource folder from the Analysis Services program folders to a new virtual directory folder that you will create on the file system of the computer running IIS.

The drive must be formatted for the NTFS file system. The path to the folder that you create must not contain any spaces.

1. Copy the following files, found at <drive>:\Program Files\Microsoft SQL Server\<instance>\OLAP\bin\isapi: MSMDPUMP.DLL, MSMDPUMP.INI, and a Resources folder.

2. On the web server, create a new folder: <drive>:\inetpub\wwwroot\OLAP
3. Paste the files that you previously copied into this new folder.
4. Verify that the \inetpub\wwwroot\OLAP folder on your web server contains the following:
MSMDPUMP.DLL, MSMDPUMP.INI, and a Resources folder. Your folder structure should look like this:
 - <drive>:\inetpub\wwwroot\OLAP\MSMDPUMP.dll
 - <drive>:\inetpub\wwwroot\OLAP\MSMDPUMP.ini
 - <drive>:\inetpub\wwwroot\OLAP\Resources

NOTE

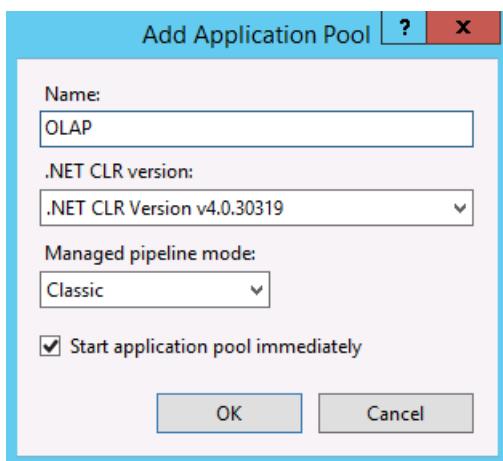

The IIS manager might not be able to connect to the Analysis Services in the current version if the Database is a backup from a previous one. This is caused by changes in the MSMDPUMP and should be solved by copying the msmdpump.dll file from the previous working version.

Step 2: Create an application pool and virtual directory in IIS

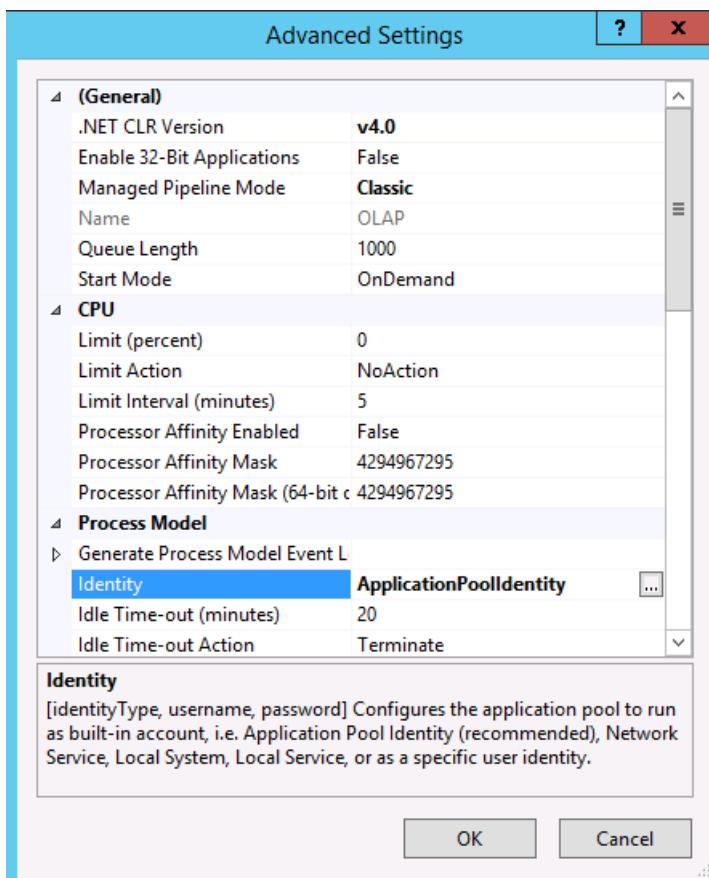

Next, create an application pool and an endpoint to the pump.

Create an application pool

1. Start IIS Manager.
2. Open the server folder, right-click **Application Pools** and then click **Add Application Pool**. Create an application pool named **OLAP**, using the .NET Framework, with Managed pipeline mode set to **Classic**.

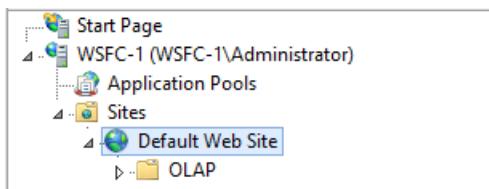

3. By default, IIS creates application pools using **ApplicationPoolIdentity** as the security identity, which is a valid choice for HTTP access to Analysis Services. If you have specific reasons for changing the identity, right-click **OLAP**, and then select **Advanced Settings**. Select **ApplicationPoolIdentity**. Click the **Change** button for this property to replace the built-in account with the custom account you want to use.

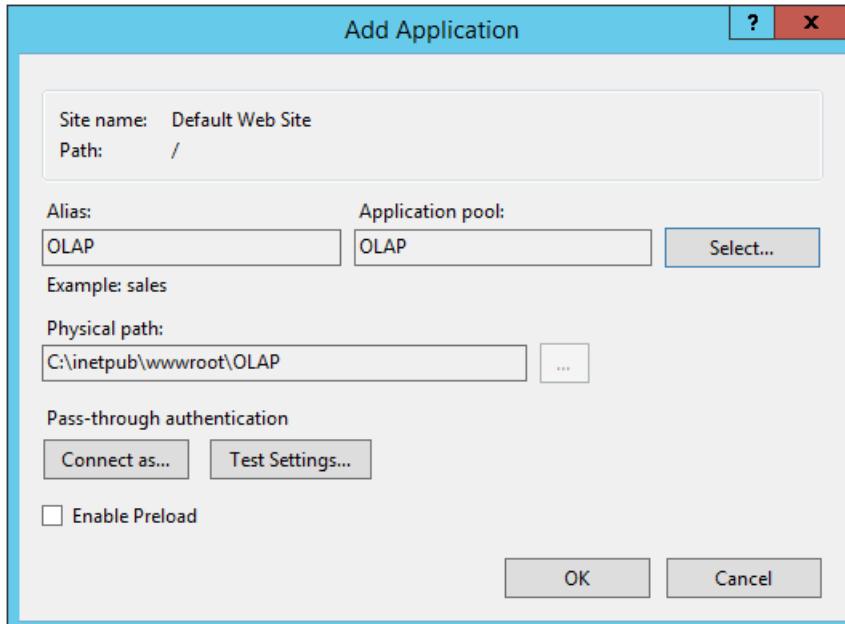

4. By default, on a 64-bit operating system, IIS sets the **Enable 32-bit Applications** property to **false**. If you copied msmdpump.dll from a 64-bit installation of Analysis Services, this is the correct setting for the MSMDPUMP extension on a 64-bit IIS server. If you copied the MSMDPUMP binaries from a 32-bit installation, set it to **true**. Check this property now in **Advanced Settings** to ensure it is set correctly.

Create an application

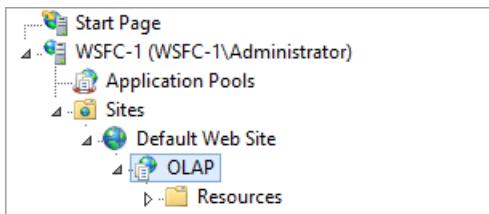

1. In IIS Manager, open **Sites**, open **Default Web Site**. You should see a folder named **OLAP**. This is a reference to the OLAP folder you created under \inetpub\wwwroot.

2. Right-click the folder and choose **Convert to Application**.
3. In Add Application, enter **OLAP** for the alias. Click **Select** to choose the OLAP application pool. Physical Path should be set to C:\inetpub\wwwroot\OLAP

4. Click **OK**. Refresh the web site and notice that the OLAP folder is now an application under the default web site. The virtual path to the MSMDPUMP file is now established.

NOTE

Previous versions of these instructions included steps for creating a virtual directory. That step is no longer necessary.

Step 3: Configure IIS authentication and add the extension

In this step, you further configure the SSAS virtual directory you just created. You will specify an authentication method and then add a script map. Supported authentication methods for Analysis Services over HTTP include:

- Windows authentication (Kerberos or NTLM)
- Basic authentication
- Anonymous authentication

Windows authentication is considered the most secure, and leverages existing infrastructure for networks that use Active Directory. To use Windows authentication effectively, all browsers, client applications, and server applications must support it. This is the most secure and recommended mode, but it requires that IIS be able to access a Windows domain controller that can authenticate the identity of the user requesting a connection.

For topologies that put Analysis Services and IIS on different computers, you will need to address double-hop issues that arise when a user identity needs to be delegated to a second service on a remote machine, typically by enabling Analysis Services for Kerberos constrained delegation. For more information, see [Configure Analysis Services for Kerberos constrained delegation](#).

Basic authentication is used when you have Windows identities, but user connections are from non-trusted domains, prohibiting the use of delegated or impersonated connections. Basic authentication lets you specify a user identity and password on a connection string. Instead of using the security context of the current user, credentials on the connection string are used to connect to Analysis Services. Because Analysis Services supports only Windows authentication, any credentials passed to it must be a Windows user or group that is a member of the domain in which Analysis Services is hosted.

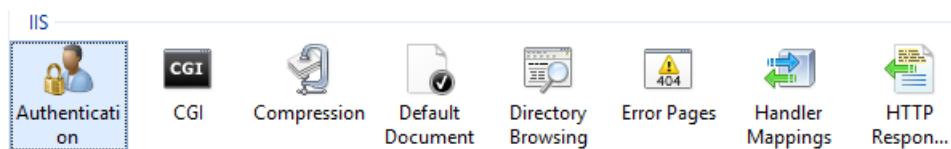

Anonymous authentication is often used during initial testing because its ease of configuration helps you to quickly validate HTTP connectivity to Analysis Services. In just a few steps, you can assign a unique user account as the identity, grant that account permissions in Analysis Services, use the account to verify data access in a client application, and then disable Anonymous authentication when testing is complete.

You can also use Anonymous authentication in a production environment if your users do not have Windows user accounts, but follow best practices by locking down permissions on the host system, as called out in this article: [Enable Anonymous Authentication \(IIS 7\)](#). Be sure that authentication is set on the virtual directory, and not on the parent web site, to further reduce the level of account access.

When Anonymous is enabled, any user connection to the HTTP endpoint is allowed to connect as the anonymous user. You won't be able to audit individual user connections, nor use the user identity to select data from a model. As you can see, using Anonymous impacts everything from model design, to data refresh and access. However, if users do not have a Windows user login to start with, using the Anonymous account might be your only option.

Set the authentication type and add a script map

1. In IIS Manager, open **Sites**, open **Default Web Site**, and then select the **OLAP** virtual directory.
2. Double-click **Authentication** in the IIS section of the main page.

3. Enable **Windows Authentication** if you are using Windows integrated security.

A screenshot of the "Authentication" settings page in IIS Manager. The title bar says "Authentication". Below the title, there's a dropdown menu "Group by: No Grouping". A table lists the authentication methods:

Name	Status	Response Type
Anonymous Authentication	Disabled	
ASP.NET Impersonation	Disabled	
Basic Authentication	Disabled	HTTP 401 Challenge
Windows Authentication	Enabled	HTTP 401 Challenge

4. Alternatively, enable **Basic Authentication** if your client and server applications are in different domains. This mode requires the user to enter a user name and password. The user name and password are transmitted over the HTTP connection to IIS. IIS will try to impersonate the user using the provided credentials when connecting to MSMDPUMP, but the credentials will not be delegated to Analysis

Services. Instead, you will need to pass a valid user name and password on a connection, as described in Step 6 in this document.

IMPORTANT

Please note that it is imperative for anyone building a system where the password is transmitted to have ways of securing the communication channel. IIS provides a set of tools that help you secure the channel. For more information, see [How to Set Up SSL on IIS 7](#).

5. Disable **Anonymous Authentication** if you are using Windows or Basic authentication. When Anonymous authentication is enabled, IIS will always use it first, even if other authentication methods are enabled.

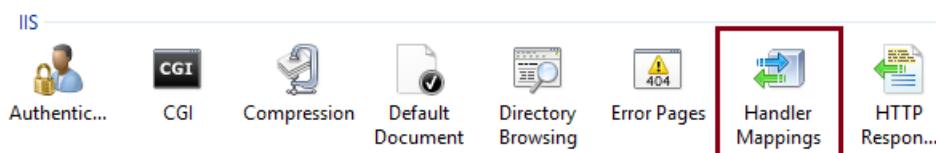

Under Anonymous authentication, the pump (msmdpump.dll) runs as the user account you established for anonymous user. There is no distinction between the user connecting to IIS and the user connecting to Analysis Services. By default, IIS uses the IUSR account, but you can change it to a domain user account that has network permissions. You'll need this capability if IIS and Analysis Services are on different computers.

For instructions on how to configure credentials for Anonymous authentication, see [Anonymous Authentication](#).

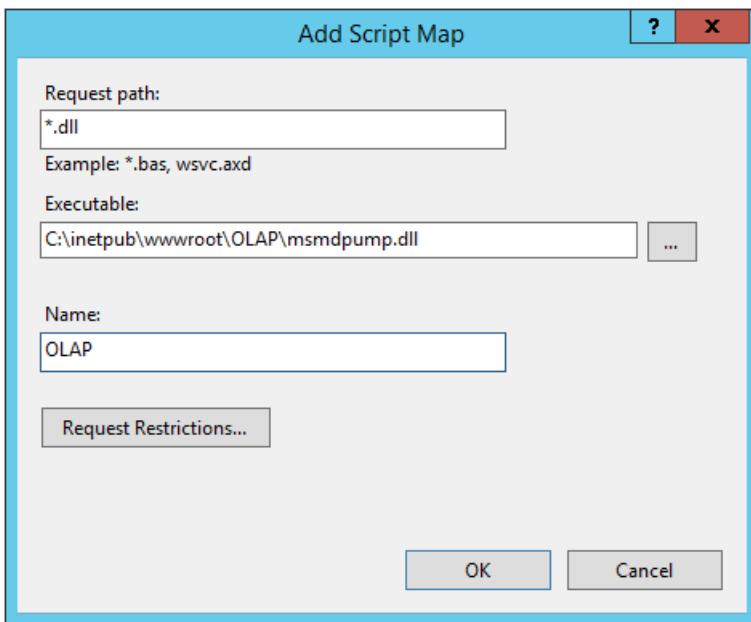

IMPORTANT

Anonymous authentication is most likely found in an extremely controlled environment, where users are given or denied access by way of access control lists in the file system. For best practices, see [Enable Anonymous Authentication \(IIS 7\)](#).

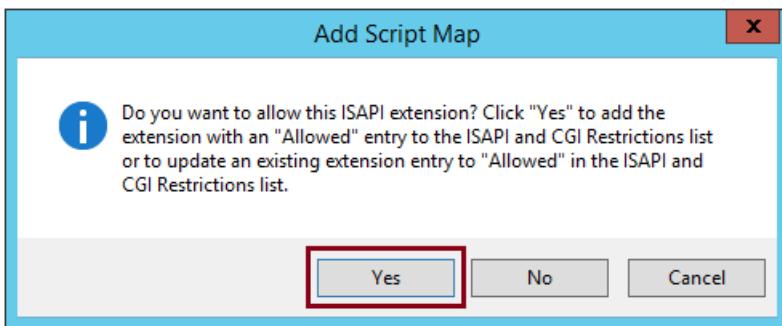

6. Click the **OLAP** virtual directory to open the main page. Double-click **Handler Mappings**.

7. Right-click anywhere on the page and then select **Add Script Map**. In the Add Script Map dialog box, specify ***.dll** as the request path, specify **c:\inetpub\wwwroot\OLAP\msmdpump.dll** as the executable, and type **OLAP** as the name. Keep all of the default restrictions associated with this script map.

- When prompted to allow the ISAPI extension, click **Yes**.

Step 4: Edit the MSMDPUMP.INI file to set the target server

The MSMDPUMP.INI file specifies the Analysis Services instance that MSMDPUMP.DLL connects to. This instance can be local or remote, installed as the default or as a named instance.

Open the msmdpump.ini file located in folder C:\inetpub\wwwroot\OLAP and take a look at the contents of this file. It should look like the following:

```
<ConfigurationSettings>
<ServerName>localhost</ServerName>
<SessionTimeout>3600</SessionTimeout>
<ConnectionPoolSize>100</ConnectionPoolSize>
</ConfigurationSettings>
```

If the Analysis Services instance for which you are configuring HTTP access is located on the local computer and installed as a default instance, there is no reason to change this setting. Otherwise, you must specify the server name (for example, <ServerName>ADWRKS-SRV01</ServerName>). For a server that is installed as a named instance, be sure to append the instance name (for example, <ServerName>ADWRKS-SRV01\Tabular</ServerName>).

By default, Analysis Services listens on TCP/IP port 2383. If you installed Analysis Services as the default instance, you do not need to specify any port in <ServerName> because Analysis Services knows how to listen on port 2383 automatically. However, you do need to allow inbound connections to that port in Windows Firewall. For more information, see [Configure the Windows Firewall to Allow Analysis Services Access](#).

If you configured a named or default instance of Analysis Services to listen on a fixed port, you must add the

port number to the server name (for example, <ServerName>AW-SRV01:55555</ServerName>) and you must allow inbound connections in Windows Firewall to that port.

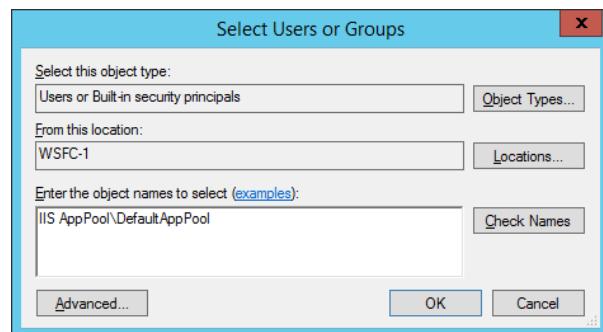

Step 5: Grant data access permissions

As previously noted, you will need to grant permissions on the Analysis Services instance. Each database object will have roles that provide a given level of permissions (read or read/write), and each role will have members consisting of Windows user identities.

To set permissions, you can use SQL Server Management Studio. Under the **Database | Roles** folder, you can create roles, specify database permissions, assign membership to Windows user or group accounts, and then grant read or write permissions on specific objects. Typically, **Read** permissions on a cube are sufficient for client connections that use, but do not update, model data.

Role assignment varies depending on how you configured authentication.

Anonymous	Add to the Membership list the account specified in Edit Anonymous Authentication Credentials in IIS. For more information, see Anonymous Authentication ,
Windows authentication	Add to the Membership list the Windows user or group accounts requesting Analysis Services data via impersonation or delegation. Assuming Kerberos constrained delegation is used, the only accounts that need permissions are the Windows user and group accounts requesting access. No permissions are necessary for the application pool identity.
Basic authentication	Add to the Membership list the Windows user or group accounts that will be passed on the connection string. In addition, if you are passing credentials via EffectiveUserName on the connection string, then the application pool identity must have administrator rights on the Analysis Services instance. In SSMS, right-click the instance Properties Security Add . Enter the application pool identity. If you used the built-in default identity, the account is specified as IIS AppPool\DefaultAppPool .

For more information about setting permissions, see [Authorizing access to objects and operations \(Analysis Services\)](#).

Step 6: Test your configuration

The connection string syntax for MSMDPUMP is the URL to the MSMDPUMP.dll file.

If the web application is listening on a fixed port, append the port number to the server name or IP address (for example, `http://my-web-srv01:8080/OLAP/msmdpump.dll` Or `http://123.456.789.012:8080/OLAP/msmdpump.dll`).

To quickly test the connection, you can open a connection using Internet Explorer, Microsoft Excel, or SQL Server Management Studio.

Troubleshoot connections using Internet Explorer

A connection request that terminates with this error might not give you much to go on: "Either a connection cannot be made to '<server name>', or Analysis Service is not running on the server".

To get a more informative error, do the following:

1. In **Internet Explorer > Internet Options > Advanced**, clear the checkbox for **Show Friendly HTTP messages**.
2. Retry the connection (for example, `http://my-web-srv01:8080/OLAP/msmdpump.dll`)

If you see an ERROR XML displayed in the browser window, you can eliminate MSMDPUMP as the potential cause and shift your focus to the certificate.

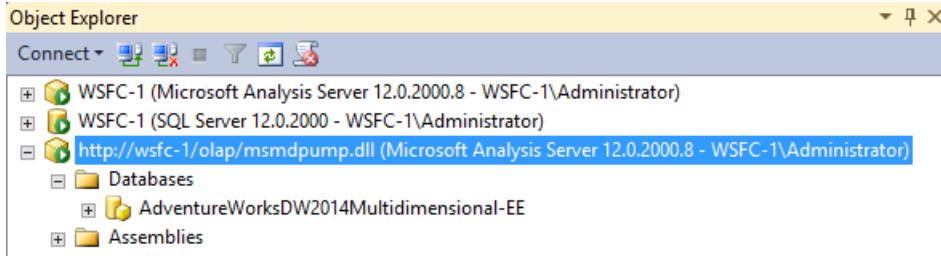

Test connections using SQL Server Management Studio

1. In Management Studio, in the Connect to Server dialog box, select **Analysis Services** as the server type.

In Server name, enter the HTTP address of the msmdpump extension:

`http://my-web-srv01/OLAP/msmdpump.dll`

Object Explorer displays the HTTP connection:

2. Authentication must be Windows authentication, and the person using Management Studio must be an Analysis Services administrator. An administrator can grant further permissions to enable access by other users.

Test connections using Excel

1. On the Data tab in Excel, in Get External Data, click **From Other Sources**, and then choose **From Analysis Services** to start the Data Connection wizard.

2. In Server name, enter the HTTP address of the msmdpump extension:

`http://my-web-srv01/OLAP/msmdpump.dll`

3. For Log on credentials, choose **Use Windows Authentication** if you are using Windows integrated security or NTLM, or Anonymous user.

For Basic authentication, choose **Use the following User Name and Password**, and then specify the credentials used to sign on. The credentials you provide will be passed on the connection string to Analysis Services.

Test connections using AMO

You can test HTTP access programmatically using AMO, substituting the URL of the endpoint for the server name. For details, see [Forum Post \(How to sync SSAS 2008 R2 databases via HTTPS across domain/forest and](#)

firewall boundaries).

An example connection string illustrating the syntax for HTTP(S) access using Basic authentication:

```
Data Source=https://<servername>/olap/msmdpump.dll; Initial Catalog=AdventureWorksDW2012; Integrated Security=Basic; User ID=XXXX; Password=XXXXX;
```

For more information about setting up the connection programmatically, see [Establishing Secure Connections in ADOMD.NET](#).

As a final step, be sure to follow-up with more rigorous testing by using a client computer that runs in the network environment from which the connections will originate.

Client libraries (data providers) used for Analysis Services connections

11/8/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Analysis Services provides three client libraries, also known as **data providers**, for server and data access from tools and client applications. Tools like SSMS and Analysis Services projects for Visual Studio, and applications like Power BI Desktop and Excel connect to Analysis Services by using these libraries. Two of the client libraries, ADOMD.NET and Analysis Services Management Objects (AMO), are managed client libraries. The Analysis Services OLE DB provider (MSOLAP DLL) is a native client library. Client libraries are the same for both SQL Server Analysis Services and Azure Analysis Services.

Where to get newer versions

The version installed on a client computer should match the major version of the server providing the data. If the server installation is newer than the data providers installed on the workstations in your network, you might need to install newer libraries.

Client libraries included in earlier SQL Server Feature Packs correspond to that SQL version; however, they may not be the latest. Connecting to Azure Analysis Services may require later versions. All versions are backward compatible.

To get the latest, see [Client libraries for connecting to Azure Analysis Services](#).

[Connect to Analysis Services](#)

Disconnect users and sessions from Analysis Services

8/6/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: ✓ SQL Server Analysis Services ✓ Azure Analysis Services ✗ Power BI Premium

As an administrator, you may want to end user activity as part of workload management. You do this by canceling sessions and connections. Sessions can be formed automatically when a query is run (implicit), or named at the time of creation by the administrator (explicit). Connections to SQL Server Analysis Services are open conduits over which queries can be run. Azure Analysis Services and Power BI workspaces use sessions over HTTP. Both sessions and connections can be ended while they are active. For example, you may want to end processing for a session if the processing is taking too long, or if some doubt has arisen as to whether the command being executed was written correctly.

Ending Sessions and Connections

To manage sessions and connections, use Dynamic Management Views (DMVs) and XMLA:

1. In SQL Server Management Studio, connect to an Analysis Services instance.
2. Paste any one of the following DMV queries in an MDX query window to get a list of all sessions, connections, and commands that are currently executing:

```
Select * from $System.Discover_Sessions
```

```
Select * from $System.Discover_Connections
```

 (This query does not apply to Azure Analysis Services)

```
Select * from $System.Discover_Commands
```

3. Press F5 to execute the query.

The DMV query returns session and connection information in a tabular result set that is easier read and copy from.

Keep the query window open. In the next step, you will want to return to this page to copy the SPIDs of the session you want to disconnect.

To end a session, open a second XMLA query window.

1. Paste the following syntax into an MDX query window, replacing the ConnectionID, SessionID, or SPID placeholder with a valid value copied from the previous step.

```
<Cancel xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">

    <ConnectionID>111</ConnectionID>
    <SessionID>222</SessionID>
    <SPID>333</SPID>

    <CancelAssociated>1</CancelAssociated>
</Cancel>
```

2. Press F5 to execute the cancel command.

Canceling a SPID/SessionID will cancel any active commands running on the session corresponding to the SPID/SessionID. Canceling a connection will identify the session associated with the connection, and cancel any

active commands running on that session. In rare cases, a connection is not closed if the engine cannot track all sessions and SPIDs associated with the connection; for example, when multiple sessions are open in an HTTP scenario.

To learn more about the XMLA referenced in this topic, see [Execute Method \(XMLA\)](#) and [Cancel Element \(XMLA\)](#).

Analysis Services Developer Documentation

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Analysis Services, almost every object and workload is programmable, and often there is more than one approach to choose from. Options include writing managed code, script, or using open standards like XMLA and MSOLAP if your solution requirements preclude using the .NET framework.

What you can accomplish in code

Typical programming scenarios include server and database deployment, administration, model and database creation, and data access from your custom applications and reports that consume Analysis Services data. Common to all these scenarios is a fixed architecture and object definition hierarchy, with well-understood operations that span data definition, processing, and query workloads.

Although objects and workloads are programmable, they are not extensible. Specifically, you cannot create custom data cartridges that retrieve data from unsupported data sources, customize or replace formula or storage engine behaviors, nor can you create new types of object metadata on a server, database, or model.

To further elaborate on the last point about creating new object types: while you cannot create a new type of object, you can create calculated objects built from expressions or code at run time. Not everything in your model needs to be predefined and mapped to an existing data structure. Additionally, you can extend the schema via Annotations in AMO to pass object-specific information to your client application.

Choose a platform or approach to development

Analysis Services provides many ways to customize a solution through code, but most developers use the managed APIs or script.

- Managed APIs include [AMO and TOM](#) for data definition and administrative tasks, and [ADOMD.NET](#) for query support from client code. In SQL Server 2016, AMO is updated to use the new Tabular metadata for models created or upgraded to compatibility level 1200 and higher.
- Script can often achieve the same results as a program executable, with possibly less work.
 - You can write PowerShell script using Analysis Services PowerShell components that call AMO types directly. Within PowerShell, you can also create and execute ASSL/XMLA or TMSL (in JSON) script.
 - ASSL and TMSL are script languages that provide objects used in discover and execute operations. Which type of script you use depends on the underlying server, database, or model.
 - Tabular models or databases at compatibility level 1200 and higher use the Tabular Model Scripting Language (TMSL), which is in JSON.
 - Multidimensional models and Tabular models at compatibility levels 1050-1103 use Analysis Services Scripting Language (ASSL), which is the Analysis Services extension of the XMLA open standard.
 - You can generate ASSL or TMSL script in Management Studio. You can also use **View Code** in SQL Server Data Tools to view the model definition in ASSL or TMSL.
- Although it is possible to build a solution based on the open standards of XMLA and MDX, it's quite rare to

do so. There is no documentation other than XMLA and MDX reference to help you, and most community and forum support draws from experiences with .NET or native (MSOLAP) technologies.

Programming in Analysis Services

[Data Mining Programming](#) Describes the approaches building solutions that include data mining objects.

[Multidimensional Model Programming](#) Describes the development tasks and approaches for integrating multidimensional model objects in a custom solution.

[Tabular Model Programming for Compatibility Level 1200 and higher](#) **New in SQL Server 2016**. Summarizes the interfaces and script languages used for working with Tabular 1200 and higher models programmatically.

[Tabular Model Programming for Compatibility Levels 1050 through 1103](#) This documentation is intended for developers who support tabular models at earlier compatibility levels. It describes the CSDL extensions that define a tabular model in XML syntax. It also includes information about tabular object model definitions and syntax.

[Analysis Services Management Objects \(AMO\)](#) Developer reference documentation for the managed provider, Analysis Services Management Objects (AMO), for data definition and administration, including processing.

[ADOMD.NET](#) Developer reference documentation for the managed provider, ADOMD.NET, used for programmatic data access and query workloads.

[Analysis Services Schema Rowsets](#) Describes the schema rowsets that provide information about server state, server operations, and database objects.

[XML for Analysis \(XMLA\) Reference](#) Describes XMLA concepts that can help you understand how XMLA contributes to your custom solution. It also describes the level of compliance with the XMLA 1.1 specification.

[Analysis Services Scripting Language \(ASSL for XMLA\)](#) Describes the ASSL extensions to XMLA. ASSL provides a data definition and manipulation language for Analysis Services multidimensional models that supplements the XMLA specification.

[Tabular Model Scripting Language \(TMSL\) Reference](#) TMSL is a JSON representation of Tabular models at compatibility level 1200 and higher. Object definitions are based on tabular metadata constructs like table, column, and relationship rather than multidimensional metadata that might be unfamiliar if you are new to Analysis Services data modeling in Tabular mode.

Tabular model programming for compatibility level 1200 and higher

10/22/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Beginning with compatibility level 1200, tabular metadata is used to describe model constructs, replacing historical multidimensional metadata as descriptors for tabular model objects. Metadata for tables, columns, and relationships are table, column, and relationship, rather than the multidimensional equivalents (dimension and attribute).

You can create new models at compatibility level 1200 or higher by using the `Microsoft.AnalysisServices.Tabular` APIs, the latest version of Visual Studio with Analysis Services projects, or by changing the **CompatibilityLevel** of an existing tabular model to upgrade it (also done in Visual Studio). Doing so binds the model to newer versions of the server, tools, and programming interfaces.

Upgrading an existing tabular solution is recommended but not required. Existing script and custom solutions that access or manage tabular models or databases can be used as-is. Azure Analysis Services supports compatibility level 1200 and higher only.

New Tabular models will require different code and script, summarized below.

Object model definitions as tabular metadata constructs

The Tabular Object Model for 1200 or higher models is exposed in JSON through the [Tabular Model Scripting Language](#) and through the AMO data definition language through a new namespace, `Microsoft.AnalysisServices.Tabular`.

Script for tabular models and databases

TMSL is a JSON scripting language for Tabular models, with support for create, read, update, and delete operations. You can refresh data via TMSL and invoke database operations for attach, detach, backup, restore, and synchronize.

AMO PowerShell accepts TMSL script as input.

See [Tabular Model Scripting Language \(TMSL\) Reference](#) and [Analysis Services PowerShell Reference](#) for more information.

Query languages

DAX and MDX are supported for all tabular models.

Expression language

Filters and expressions used to create calculated objects, including measures and KPIs, are formulated in DAX. See [Understanding DAX in Tabular Models](#) and [Data Analysis Expressions \(DAX\) in Analysis Services](#).

Managed code for tabular models and databases

AMO includes a new namespace, `Microsoft.AnalysisServices.Tabular`, for working with models programmatically.

See [Microsoft.AnalysisServices Namespace](#) for more information.

NOTE

Analysis Services Management Objects (AMO), ADOMD.NET, and Tabular Object Model (TOM) client libraries now target the .NET 4.0 runtime.

[Compatibility levels of Tabular models and databases](#)

Tabular Model Programming for Compatibility Levels 1050 through 1103

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Tabular models use relational constructs to model the Analysis Services data used by analytical and reporting applications. These models run on an Analysis Service instance that is configured for tabular mode, using an in-memory analytics engine for storage and fast table scans that aggregate and calculate data as it is requested.

If the requirements of your custom BI solution are best met by a tabular model database, you can use any of the Analysis Services client libraries and programming interfaces to integrate your application with tabular models on an Analysis Services instance. To query and calculate tabular model data, you can use either embedded MDX or DAX in your code.

For Tabular models created in earlier versions of Analysis Services, in particular models at compatibility levels 1050 through 1103, the objects you work with programmatically in AMO, ADOMD.NET, XMLA, or OLE DB are fundamentally the same for both tabular and multidimensional solutions. Specifically, the object metadata defined for multidimensional models is also used for tabular model compatibility levels 1050-1103.

Beginning with SQL Server 2016, Tabular models can be built or upgraded to the 1200 or higher compatibility level, which uses tabular metadata to define the model. Metadata and programmability are fundamentally different at this level. See [Tabular Model Programming for Compatibility Level 1200 and higher](#) and [Upgrade Analysis Services](#) for more information.

Connection Representation (Tabular)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The connection object defines the source of the data that populates the tabular model.

Connection Representation

The specification for the connection object follows the rules of OLE DB providers.

Connection in AMO

When using AMO to manage a tabular model database, the [DataSource](#) object in AMO matches one-to-one to the connection logical object.

The following code snippet shows how to create an AMO data source, or Connection object in a tabular model.

```
//Create an OLEDB connection string
StringBuilder SqlCnxStr = new StringBuilder();
SqlCnxStr.Append(String.Format("Data Source={0};", SQLServer.Text));
SqlCnxStr.Append(String.Format("Initial Catalog={0};", SQLDatabase.Text));
SqlCnxStr.Append(String.Format("Persist Security Info={0};", false));
SqlCnxStr.Append(String.Format("Integrated Security={0};", "SSPI"));
SqlCnxStr.Append(String.Format("Provider={0}", "SQLNCLI11"));
String DatasourceCnxString = SqlCnxStr.ToString();

//Verify connection string and connectivity
System.Data.OleDb.OleDbConnection OleDbCnx = new System.Data.OleDb.OleDbConnection(DatasourceCnxString);
try
{
    OleDbCnx.Open();
}
catch ()
{
    throw;
}
String newDataSourceName = (string.IsNullOrEmpty(DataSourceName.Text) ||
string.IsNullOrWhiteSpace(DataSourceName.Text)) ? SQLDatabase.Text : DataSourceName.Text;
AMO.DataSource newDatasource = newDatabase.DataSources.Add(newDataSourceName, newDataSourceName);
newDatasource.ConnectionString = DatasourceCnxString.Text;
if (impersonateServiceAccount.Checked)
    newDatasource.ImpersonationInfo = new
AMO.ImpersonationInfo(AMO.ImpersonationMode.ImpersonateServiceAccount);
else
{
    if (String.IsNullOrEmpty(impersonateAccountUserName.Text))
    {
        MessageBox.Show(String.Format("Account User Name cannot be blank when using 'ImpersonateAccount' mode"),
"AMO to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Information);
        return;
    }
    newDatasource.ImpersonationInfo = new AMO.ImpersonationInfo(AMO.ImpersonationMode.ImpersonateAccount,
impersonateAccountUserName.Text, impersonateAccountPassword.Text);
}
newDatasource.Update();
```

Tabular AMO 2012 sample

To have a better understanding on how to use AMO to create and manipulate connection representations, see source code in the Tabular AMO 2012 sample; specifically check in the following source file: Database.cs. The sample is available at [Codeplex](#). Sample code is provided only as a support to the logical concepts explained here, and should not be used in a production environment.

Database Representation(Tabular)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Tabular mode, the database is the container for all objects in the tabular model.

Database Representation

The database is the place where all objects that form a tabular model reside. Contained by the database, the developer finds objects like connections, tables, roles and many more.

Database in AMO

When using AMO to manage a tabular model database, the [Database](#) object in AMO matches one-to-one the database logical object in a tabular model.

NOTE

In order to gain access to a database object, in AMO, the user needs to have access to a server object and connect to it.

Database in ADOMD.Net

When using ADOMD to consult and query a tabular model database, connection to a specific database is obtained through the [AdomdConnection](#) object.

You can connect directly to a certain database using the following code snippet:

```
using ADOMD = Microsoft.AnalysisServices.AdomdClient;
...
ADOMD.AdomdConnection currrentCnx = new ADOMD.AdomdConnection("Data Source=<<server\instance>>;Catalog=
<<database>>");
currrentCnx.Open();
...
```

Also, over an existing connection object (that hasn't been closed), you can change the current database to another as shown in the following code snippet:

```
currentCnx.ChangeDatabase("myOtherDatabase");
```

Database in AMO

When using AMO to manage a database object, start with a [Server](#) object. Then search for your database in the databases collection or create a new database by adding one to the collection.

The following code snippet shows the steps to connect to a server and create an empty database, after checking the database doesn't exist:

```
AMO.Server CurrentServer = new AMO.Server();
try
{
    CurrentServer.Connect(currentServerName);
}
catch (Exception cnxException)
{
    MessageBox.Show(string.Format("Error while trying to connect to server: [{0}]\nError message: {1}",
        currentServerName, cnxException.Message), "AMO to Tabular message", MessageBoxButtons.OK,
        MessageBoxIcon.Error);
    return;
}
newDatabaseName = DatabaseName.Text;
if (CurrentServer.Databases.Contains(newDatabaseName))
{
    return;
}
try
{
    AMO.Database newDatabase = CurrentServer.Databases.Add(newDatabaseName);

    CurrentServer.Update();
}
catch (Exception createDBxc)
{
    MessageBox.Show(String.Format("Database [{0}] couldn't be created.\n{1}", newDatabaseName,
        createDBxc.Message), "AMO to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Error);
    newDatabaseAvailable = false;
}
```

For a practical understanding on how to use AMO to create and manipulate database representations, see source code in the Tabular AMO 2012 sample; specifically check in the following source file: Database.cs. The sample is available at Codeplex. Sample code is provided only as a support to the logical concepts explained here, and should not be used in a production environment.

Perspective Representation (Tabular)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A perspective is a mechanism to simplify or focus the model into a smaller portion of it for the client application.

See [Perspective Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the perspective representation.

WARNING

Perspectives are not a security mechanism; objects outside the perspective can still be accessed by the user through other interfaces.

Perspective Representation

In terms of AMO objects a perspective representation has a one to one mapping relationship with [Perspective](#) and no other main AMO objects are required.

Perspective in AMO

The following code snippet shows how to create a perspective in a Tabular model. The key element in this piece of code is the *perspectiveElements*; this object is a graphical representation of all the objects in the tabular model that are exposed to the user. *perspectiveElements* contains 4 columns and for this scenario only columns 1, 2 and 3 are relevant. Column 1 contains the type of element displayed -*elementTypeValue*-; column 2 contains the complete name of the element --, that probably will need to parsed to enter the element in the perspective; column 3 contains a checkbox item -*checkedElement*- that tells if the element is part of the perspective or not.

```
private void updatePerspective_Click(
    AMO.Cube modelCube
    , DataGridView perspectiveElements
    , string updatedPerspectiveID
)
{
    //Update is done by delete first, create new and insert after
    //if perspective doesn't exist then create first and insert after
    updatedPerspectiveID = updatedPerspectiveID.Trim();
    if (modelCube.Perspectives.Contains(updatedPerspectiveID))
    {
        modelCube.Perspectives.Remove(updatedPerspectiveID, true);
        newDatabase.Update(AMO.UpdateOptions.ExpandFull, AMO.UpdateMode.UpdateOrCreate);
    }
    AMO.Perspective currentPerspective = modelCube.Perspectives.Add(updatedPerspectiveID,
updatedPerspectiveID);

    foreach (DataGridViewRow currentDGVRow in perspectiveElements.Rows)
    {
        bool checkedElement = (bool)currentDGVRow.Cells[3].Value;
        if (checkedElement)
        {
            string elementTypeValue = currentDGVRow.Cells[1].Value.ToString();
            string elementNameValue = currentDGVRow.Cells[2].Value.ToString();
            switch (elementTypeValue)
            {
                case "Column: Attribute":
```

```

        case "Column: Calculated Column":
        {
            string perspectiveDimensionName = Regex.Match(elementNameValue, @"(?<=')(.*?)(?=')").ToString();
            string perspectiveDimensionAttributeName = Regex.Match(elementNameValue, @"(?<=\[)(.*?)(?=\\])").ToString();
            AMO.PerspectiveDimension currentPerspectiveDimension;
            if (!currentPerspective.Dimensions.Contains(perspectiveDimensionName))
            {
                currentPerspectiveDimension =
                currentPerspective.Dimensions.Add(perspectiveDimensionName);
            }
            else
            {
                currentPerspectiveDimension =
                currentPerspective.Dimensions[perspectiveDimensionName];
            }
            if
(!currentPerspectiveDimension.Attributes.Contains(perspectiveDimensionAttributeName))
            {
                currentPerspectiveDimension.Attributes.Add(perspectiveDimensionAttributeName);
            }
        }
        break;
    case "Hierarchy":
    {
        string perspectiveDimensionName = Regex.Match(elementNameValue, @"(?<=')(.*?)(?=')").ToString();
        string perspectiveDimensionHierarchyName = Regex.Match(elementNameValue, @"(?<=\[)(.*?)(?=\\])").ToString();
        AMO.PerspectiveDimension currentPerspectiveDimension;
        if (!currentPerspective.Dimensions.Contains(perspectiveDimensionName))
        {
            currentPerspectiveDimension =
            currentPerspective.Dimensions.Add(perspectiveDimensionName);
        }
        else
        {
            currentPerspectiveDimension =
            currentPerspective.Dimensions[perspectiveDimensionName];
        }
        if
(!currentPerspectiveDimension.Hierarchies.Contains(perspectiveDimensionHierarchyName))
        {
            currentPerspectiveDimension.Hierarchies.Add(perspectiveDimensionHierarchyName);
        }
    }
    break;
    case "Measure":
    {
        string perspectiveMeasureGroupName = Regex.Match(elementNameValue, @"(?<=')(.*?)(?=')").ToString();
        string measureName = Regex.Match(elementNameValue, @"(?<=\[)(.*?)(?=\\])").ToString();
        string perspectiveMeasureName = string.Format("[Measures].[{0"}]", measureName);
        AMO.PerspectiveCalculation currentPerspectiveCalculation = new
AMO.PerspectiveCalculation(perspectiveMeasureName, AMO.PerspectiveCalculationType.Member);
        if (!currentPerspective.Calculations.Contains(perspectiveMeasureName))
        {
            currentPerspective.Calculations.Add(currentPerspectiveCalculation);
        }
        if
(modelCube.MdxScripts["MdxScript"].CalculationProperties.Contains(string.Format("KPIs.[{0"}]", measureName)))
            {//Current Measure is also a KPI ==> will be added to the KPIs collection of the
perspective
            AMO.PerspectiveKpi currentPerspectiveKpi = new
AMO.PerspectiveKpi(perspectiveMeasureName);
            if (!currentPerspective.Kpis.Contains(perspectiveMeasureName))
            {
                currentPerspective.Kpis.Add(currentPerspectiveKpi);
            }
        }
    }
}

```

```
        }
    }
}
break;
default:
    break;
}
}

newDatabase.Update(AMO.UpdateOptions.ExpandFull, AMO.UpdateMode.CreateOrReplace);
MessageBox.Show(String.Format("Perspective successfully updated."), "AMO to Tabular message",
MessageBoxButtons.OK, MessageBoxIcon.Information);
}
```

AMO2Tabular sample

However, to have an understanding on how to use AMO to create and manipulate perspective representations see the source code of the AMO to Tabular sample. The sample is available at Codeplex. An important note about the code: the code is provided only as a support to the logical concepts explained here and should not be used in a production environment; nor should it be used for other purpose other than the pedagogical one.

Querying a Tabular Model

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

As a developer querying a tabular model means to retrieve data from the tabular database; to accomplish this goal you have two options: use table queries in DAX, or use MDX and retrieve the data as it were coming from a cube. However, depending on the underlying mode of your tabular model you might be restricted to use only DAX table queries; DirectQuery mode requires the usage of DAX table queries.

Querying with ADOMD.Net

Using ADOMD.Net to query a tabular model is simple and flexible; you can either send MDX statements or tabular query expressions from DAX to the server to get your results.

The following code shows how to pass your query statements to a tabular model and receive your results

```
//Function: tabularQueryExecute(string qry, ADOMD.AdomdConnection cnx)
//  - arg: qry, the tabular query or MDX expression to be evaluated
//  - arg: cnx, an active and opened ADOMD connection to the database where 'qry' is to be evaluated
//
// This function takes a query or mdx expression -qry-, a connection -cnx-
// and runs the query it against a Tabular Model using ADOMD.net
//
// Important note:
//    If the MDX query contains more than 2 axes (ON COLUMNS, ON ROWS), each axis will come as a new column
//    If the (All) value of the members in any axis have not been defined, a blank cell is returned. This might
// be misleading
//    if the model also has missing values... which are also represented with blank cells.
private DataTable tabularQueryExecute(string qry, ADOMD.AdomdConnection cnx)
{
    ADOMD.AdomdDataAdapter currentDataAdapter = new ADOMD.AdomdDataAdapter(qry, cnx);
    DataTable tabularResults = new DataTable();
    currentDataAdapter.Fill(tabularResults);
    return tabularResults;
}
```

Example

If the above code is used with the following MDX expression:

```
SELECT { [Measures].[Internet Total Sales], [Measures].[Reseller Total Sales], [Measures].[Total Sales] } ON
COLUMNS
    , NON EMPTY [Product Category].[Product Category Name].MEMBERS ON ROWS "
    , NON EMPTY [Date].[Calendar Year].members ON 2 \n"
FROM [Model]
```

Against the sample model 'Adventure Works DW Tabular Denali CTP3' you should receive the following values as the resulting table:

CALENDAR YEAR	PRODUCT CATEGORY NAME	INTERNET TOTAL SALES	RESELLER TOTAL SALES	TOTAL SALES
2007	Electronics	100000000	100000000	200000000

CALENDAR YEAR	PRODUCT CATEGORY NAME	INTERNET TOTAL SALES	RESELLER TOTAL SALES	TOTAL SALES
		\$ 29,358,677.22	\$ 80,450,596.98	\$ 109,809,274.20
	Accessories	\$ 700,759.96	\$ 571,297.93	\$ 1,272,057.89
	Bikes	\$ 28,318,144.65	\$ 66,302,381.56	\$ 94,620,526.21
	Clothing	\$ 339,772.61	\$ 1,777,840.84	\$ 2,117,613.45
	Components		\$ 11,799,076.66	\$ 11,799,076.66
2001		\$ 3,266,373.66	\$ 8,065,435.31	\$ 11,331,808.96
2001	Accessories		\$ 20,235.36	\$ 20,235.36
2001	Bikes	\$ 3,266,373.66	\$ 7,395,348.63	\$ 10,661,722.28
2001	Clothing		\$ 34,376.34	\$ 34,376.34
2001	Components		\$ 615,474.98	\$ 615,474.98
2002		\$ 6,530,343.53	\$ 24,144,429.65	\$ 30,674,773.18
2002	Accessories		\$ 92,735.35	\$ 92,735.35
2002	Bikes	\$ 6,530,343.53	\$ 19,956,014.67	\$ 26,486,358.20
2002	Clothing		\$ 485,587.15	\$ 485,587.15
2002	Components		\$ 3,610,092.47	\$ 3,610,092.47
2003		\$ 9,791,060.30	\$ 32,202,669.43	\$ 41,993,729.72
2003	Accessories	\$ 293,709.71	\$ 296,532.88	\$ 590,242.59
2003	Bikes	\$ 9,359,102.62	\$ 25,551,775.07	\$ 34,910,877.69
2003	Clothing	\$ 138,247.97	\$ 871,864.19	\$ 1,010,112.16
2003	Components		\$ 5,482,497.29	\$ 5,482,497.29
2004		\$ 9,770,899.74	\$ 16,038,062.60	\$ 25,808,962.34
2004	Accessories	\$ 407,050.25	\$ 161,794.33	\$ 568,844.58
2004	Bikes	\$ 9,162,324.85	\$ 13,399,243.18	\$ 22,561,568.03
2004	Clothing	\$ 201,524.64	\$ 386,013.16	\$ 587,537.80
2004	Components		\$ 2,091,011.92	\$ 2,091,011.92

If the MDX expression is replaced with this DAX table query expression:

```
DEFINE  
    MEASURE 'Product Category'[Internet Sales] = SUM( 'Internet Sales'[Sales Amount])  
    MEASURE 'Product Category'[Reseller Sales] = SUM('Reseller Sales'[Sales Amount]) \n"  
    EVALUATE ADDCOLUMNS('Product Category', \"Internet Sales - All Years\", 'Product Category'[Internet Sales],  
    \"Reseller Sales - All Years\", 'Product Category'[Reseller Sales])
```

And sent to the server using the above sample code, against the sample model 'Adventure Works DW Tabular Denali CTP3' you should receive the following values as the resulting table:

PRODUCT CATEGORY ID	PRODUCT CATEGORY ALTERNATE ID	PRODUCT CATEGORY NAME	INTERNET SALES	RESELLER SALES
4	4	Accessories	\$ 700,759.96	\$ 571,297.93
1	1	Bikes	\$ 28,318,144.65	\$ 66,302,381.56
3	3	Clothing	\$ 339,772.61	\$ 1,777,840.84
2	2	Components		\$ 11,799,076.66

Relationship Representation (Tabular)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A relationship is a connection between two tables of data. The relationship establishes how the data in the two tables should be correlated.

See [Relationship Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the relationship representation.

Relationship Representation

In tabular models, multiple relationships can be defined between two tables. When multiple relationships, between two tables, are defined only one can be defined as the default relationship for the model and it is named as the Active relationship; all other relationships are named as Inactive.

Relationship in AMO

In terms of AMO objects all inactive relationships have a representation of a one to one mapping relationship with [Relationship](#) and no other main AMO objects are required; for the active relationship other requirements exist and a mapping to the [ReferenceMeasureGroupDimension](#) is also required.

The following code snippets show how to create a relationship in Tabular models, how to activate a relationship and how to define a primary key in a table (other than "RowNumber"). To create an active relationship a primary key need to be defined in the primary key table - PKTableName - of the relationship (the one side of the relationship), the sample shown here creates the primary key on the PKColumnName if no primary key is defined in this column. Inactive relationships can be created without the need of having a primary key on the primary key column.

```
private Boolean createRelationship(string PKTableName, string PKColumnName, string MVTableName, string MVColumnName, AMO.Database tabularDb, string cubeName, Boolean forceActive)
{
    //verify input parameters
    if(      string.IsNullOrEmpty(PKTableName) || string.IsNullOrWhiteSpace(PKTableName)
        || string.IsNullOrEmpty(PKColumnName) || string.IsNullOrWhiteSpace(PKColumnName)
        || string.IsNullOrEmpty(MVTableName) || string.IsNullOrWhiteSpace(MVTableName)
        || string.IsNullOrEmpty(MVColumnName) || string.IsNullOrWhiteSpace(MVColumnName)
        || (tabularDb == null)
    ) return false;
    if(!tabularDb.Dimensions.ContainsName(PKTableName) || !tabularDb.Dimensions.ContainsName(MVTableName))
    return false;
    if(!tabularDb.Dimensions[PKTableName].Attributes.ContainsName(PKColumnName) ||
    !tabularDb.Dimensions[MVTableName].Attributes.ContainsName(MVColumnName)) return false;

    //Verify underlying cube structure
    if (!tabularDb.Cubes[cubeName].Dimensions.ContainsName(PKTableName) ||
    !tabularDb.Cubes[cubeName].Dimensions.ContainsName(MVTableName)) return false; //Should return an exception!!
    if (!tabularDb.Cubes[cubeName].MeasureGroups.ContainsName(PKTableName) ||
    !tabularDb.Cubes[cubeName].MeasureGroups.ContainsName(MVTableName)) return false; //Should return an exception!!

    //Make sure PKTableName.PKColumnName is set as PK ==> <attribute>.usage == AMO.AttributeUsage.Key
    if (tabularDb.Dimensions[PKTableName].Attributes[PKColumnName].Usage != AMO.AttributeUsage.Key)
    {
        //... here we are 'fixing', if there is an issue with PKTableName.PKColumnName not being the PK of
        the table
    }
}
```

```

        setPKColumn(tabularDb, PKTableName, PKColumnName);
    }

    //Terminology note:
    // - the many side of the relationship is named the From end in AMO
    // - the PK side of the relationship is named the To end in AMO
    //
    //It seems relationships flow FROM the many side of the relationship in TO the primary key side of the
    relationship in AMO
    //
    //Verify the relationship we are creating does not exist, regardless of name.
    //if it exists, return true (no need to recreate it)
    //if it doesn't exists it will be created after this validation

    //
    foreach (AMO.Relationship currentRelationship in tabularDb.Dimensions[MVTableName].Relationships)
    {
        if ((currentRelationship.FromRelationshipEnd.Attributes[0].AttributeID == MVColumnName)
            && (currentRelationship.ToRelationshipEnd.DimensionID == PKTableName)
            && (currentRelationship.ToRelationshipEnd.Attributes[0].AttributeID == PKColumnName))
        {
            if (forceActive)
            {
                //Activate the relationship
                setActiveRelationship(tabularDb.Cubes[cubeName], MVTableName, MVColumnName, PKTableName,
currentRelationship.ID);
                //Update server with changes made here
                tabularDb.Update(AMO.UpdateOptions.ExpandFull, AMO.UpdateMode.CreateOrReplace);
                tabularDb.Cubes[cubeName].MeasureGroups[MVTableName].Process(AMO.ProcessType.ProcessFull);
            }
            return true;
        }
    }

    //A relationship like the one to be created does not exist; ergo, let's create it:

    //First, create the INACTIVE relationship definitions in the MultipleValues end of the relationship
    #region define unique name for relationship
    string newRelationshipID = string.Format("Relationship _{0}_{1}_ to _{2}_{3}_", MVTableName, MVColumnName,
PKTableName, PKColumnName);
    int rootLen = newRelationshipID.Length;
    for (int i = 0; tabularDb.Dimensions[MVTableName].Relationships.Contains(newRelationshipID); )
    {
        newRelationshipID = string.Format("{0}_{1,8:0}", newRelationshipID.Substring(0, rootLen), i);
    }
    #endregion
    AMO.Relationship newRelationship = tabularDb.Dimensions[MVTableName].Relationships.Add(newRelationshipID);

    newRelationship.FromRelationshipEnd.DimensionID = MVTableName;
    newRelationship.FromRelationshipEnd.Attributes.Add(MVColumnName);
    newRelationship.FromRelationshipEnd.Multiplicity = AMO.Multiplicity.Many;
    newRelationship.FromRelationshipEnd.Role = string.Empty;
    newRelationship.ToRelationshipEnd.DimensionID = PKTableName;
    newRelationship.ToRelationshipEnd.Attributes.Add(PKColumnName);
    newRelationship.ToRelationshipEnd.Multiplicity = AMO.Multiplicity.One;
    newRelationship.ToRelationshipEnd.Role = string.Empty;

tabularDb.Dimensions[PKTableName].Process(AMO.ProcessType.ProcessDefault);

}

```

AMO2Tabular sample

However, to have an understanding on how to use AMO to create and manipulate relationship representations see the source code of the AMO to Tabular sample. The sample is available at [Codeplex](#). An important note about the

code: the code is provided only as a support to the logical concepts explained here and should not be used in a production environment; nor should it be used for other purpose other than the pedagogical one.

Tables - Calculated Column Representation

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A calculated column is DAX expression that creates a new column in a table and the obtained values are stored in the table. The calculated column expression is evaluated every time the table is processed.

Calculated Column Representation

Calculated Columns in AMO

When using AMO to manage a tabular model table, there is no one-to-one object match for a calculated column in AMO. A calculated column is represented by an attribute in [Dimension](#) and an attribute in [MeasureGroup](#).

The following code snippet shows how to add a calculated column to an existing tabular model. The code assumes you have an AMO database object, newDatabase, and an AMO cube object, modelCube.

```
private void addCalculatedColumn(
    AMO.Database newDatabase
    , AMO.Cube modelCube
    , String ccTableName
    , String ccName
    , String newCalculatedColumnExpression
)
{
    if (string.IsNullOrEmpty(ccName) || string.IsNullOrWhiteSpace(ccName))
    {
        MessageBox.Show(String.Format("Calculated Column name is not defined."), "AMO to Tabular message",
MessageButtons.OK, MessageBoxIcon.Error);
        return;
    }
    if (string.IsNullOrEmpty(newCalculatedColumnExpression) ||
string.IsNullOrWhiteSpace(newCalculatedColumnExpression))
    {
        MessageBox.Show(String.Format("Calculated Column expression is not defined."), "AMO to Tabular
message", MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    if (newDatabase.Dimensions[ccTableName].Attributes.Contains(ccName))
    {
        MessageBox.Show(String.Format("Calculated Column name already defined."), "AMO to Tabular message",
MessageButtons.OK, MessageBoxIcon.Error);
        return;
    }
    //Add CC attribute to the Dimension
    AMO.Dimension dim = newDatabase.Dimensions[ccTableName];
    AMO.DimensionAttribute currentAttribute = dim.Attributes.Add(ccName, ccName);
    currentAttribute.Usage = AMO.AttributeUsage.Regular;
    currentAttribute.KeyUniquenessGuarantee = false;

    currentAttribute.KeyColumns.Add(new AMO.DataItem(ccTableName, ccName, OleDbType.Empty));
    currentAttribute.KeyColumns[0].Source = new AMO.ExpressionBinding(newCalculatedColumnExpression);
    currentAttribute.KeyColumns[0].NullProcessing = AMO.NullProcessing.Preserve;
    currentAttribute.NameColumn = new AMO.DataItem(ccTableName, ccName, System.Data.OleDb.OleDbType.WChar);
    currentAttribute.NameColumn.Source = new AMO.ExpressionBinding(newCalculatedColumnExpression);
    currentAttribute.NameColumn.NullProcessing = AMO.NullProcessing.ZeroOrBlank;
```

```

currentAttribute.orderBy = AMO.OrderBy.Key;
AMO.AttributeRelationship currentAttributeRelationship =
dim.Attributes["RowNumber"].AttributeRelationships.Add(currentAttribute.ID);
currentAttributeRelationship.Cardinality = AMO.Cardinality.Many;
currentAttributeRelationship.OverrideBehavior = AMO.OverrideBehavior.None;

//Add CC as attribute to the MG
AMO.MeasureGroup mg = modelCube.MeasureGroups[ccTableName];
AMO.DegenerateMeasureGroupDimension currentMGDim =
(AMO.DegenerateMeasureGroupDimension)mg.Dimensions[ccTableName];
AMO.MeasureGroupAttribute mga = new AMO.MeasureGroupAttribute(ccName);

mga.KeyColumns.Add(new AMO.DataItem(ccTableName, ccName, OleDbType.Empty));
mga.KeyColumns[0].Source = new AMO.ExpressionBinding(newCalculatedColumnExpression);

currentMGDim.Attributes.Add(mga);

try
{
    //Update Dimension, CubeDimension and MG in server
    newDatabase.Update(AMO.UpdateOptions.ExpandFull, AMO.UpdateMode.UpdateOrCreate);
}
catch (AMO.OperationException amoOpXp)
{
    MessageBox.Show(String.Format("Calculated Column expression contains syntax errors, or references
undefined or misspelled elements.\nError message: {0}", amoOpXp.Message), "AMO to Tabular message",
MessageBoxButtons.OK, MessageBoxIcon.Warning);
    return;
}
catch (AMO.AmoException amoXp)
{
    MessageBox.Show(String.Format("AMO exception accessing the server.\nError message: {0}",
amoXp.Message), "AMO to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Warning);
    return;
}
catch (Exception)
{
    throw;
}
}
}

```

Tables - Calculated Measure Representation

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A calculated measure is a named DAX expression evaluated every time it is used.

Calculated Measure Representation

Calculated Measure in AMO

When using AMO to manage a tabular model calculated measure, there is a one-to-one match between the logical Calculated Measure object and a measure defined in a [Command](#) object of the [MdxScript](#) object. Each **Calculated Measure** is defined as a **CREATE MEASURE** expression inside a [Command](#) object and separated by a semicolon. All calculated measures in a tabular model correspond to the collection **CREATE MEASURE** string in one command object in a [MdxScript](#) object. For each calculated measure, there is one-to-one mapping with a [CalculationProperty](#).

The following code snippet shows how to create a calculated measure.

```
private void addCalculatedMeasure(
    AMO.Cube modelCube
    , string cmTableName
    , string cmName
    , string newCalculatedMeasureExpression
)
{
    //Verify input requirements
    if (string.IsNullOrEmpty(cmName) || string.IsNullOrWhiteSpace(cmName))
    {
        MessageBox.Show(String.Format("Calculated Measure name is not defined."), "AMO to Tabular message",
        MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }
    if (string.IsNullOrEmpty(newCalculatedMeasureExpression) ||
    string.IsNullOrWhiteSpace(newCalculatedMeasureExpression))
    {
        MessageBox.Show(String.Format("Calculated Measure expression is not defined."), "AMO to Tabular
message", MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    StringBuilder measuresCommand = new StringBuilder();

    AMO.MdxScript mdxScript = modelCube.MdxScripts["MdxScript"];

    //ToDo: Verify if measure already exists and ask user what wants to do next

    if (mdxScript.Commands.Count == 1)
    {
        measuresCommand.AppendLine("-----");
        measuresCommand.AppendLine("-- Tabular Model measures command (do not modify manually) --");
        measuresCommand.AppendLine("-----");
        measuresCommand.AppendLine();
        measuresCommand.AppendLine();
        mdxScript.Commands.Add(new AMO.Command(measuresCommand.ToString()));

    }
    else
```

```

{
    measuresCommand.Append(mdxScript.Commands[1].Text);
}
measuresCommand.AppendLine(string.Format("CREATE MEASURE '{0}'[{1}]={2};", cmTableName, cmName,
newCalculatedMeasureExpression));

mdxScript.Commands[1].Text = measuresCommand.ToString();

if (!mdxScript.CalculationProperties.Contains(cmName))
{
    AMO.CalculationProperty cp = new AMO.CalculationProperty(cmName, AMO.CalculationType.Member);
    cp.FormatString = ""; // ToDo: Get formatting attributes for the member
    cp.Visible = true;
    mdxScript.CalculationProperties.Add(cp);
}

try
{
    modelCube.Update(AMO.UpdateOptions.ExpandFull, AMO.UpdateMode.UpdateOrCreate);
    MessageBox.Show(String.Format("Calculated Measure successfully defined."), "AMO to Tabular message",

Tables - Hierarchy Representation

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In tabular models a hierarchy is navigation path from one attribute to another based on values selected by the user.

Hierarchy Representation

Hierarchy in AMO

When using AMO to manage a tabular model table, there is a one-to-one object match for a hierarchy in AMO. A hierarchy is represented by the [Hierarchy](#) object.

The following code snippet shows how to add a hierarchy to an existing tabular model. The code assumes you have an AMO database object, newDatabase, and an AMO cube object, modelCube.

```
private void addHierarchy(
    AMO.Database newDatabase
    , AMO.Cube modelCube
    , string tableName
    , string hierarchyName
    , string levelsText
)
{
    //Validate input
    if (string.IsNullOrEmpty(hierarchyName) || string.IsNullOrEmpty(levelsText))
    {
        MessageBox.Show(String.Format("Hierarchy Name or Layout must be provided."), "AMO to Tabular message",
        MessageBoxButtons.OK, MessageBoxIcon.Warning);
        return;
    }

    if (!overwriteHierarchy.Checked && newDatabase.Dimensions[tableName].Hierarchies.Contains(hierarchyName))
    {
        MessageBox.Show(String.Format("Hierarchy already exists.\nGive a new name or enable overwriting"), "AMO
to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Warning);
        return;
    }

    try
    {
        if (newDatabase.Dimensions[tableName].Hierarchies.Contains(hierarchyName))
        {
            //Hierarchy exists... deleting it to write it later
            newDatabase.Dimensions[tableName].Hierarchies.Remove(hierarchyName, true);
            newDatabase.Dimensions[tableName].Update(AMO.UpdateOptions.AlterDependents);
        }
        AMO.Hierarchy currentHierarchy = newDatabase.Dimensions[tableName].Hierarchies.Add(hierarchyName,
        hierarchyName);
        currentHierarchy.AllMemberName = string.Format("(All of {0})", hierarchyName);
        //Parse hierarchyLayout
        using (StringReader levels = new StringReader(levelsText))
        {
            //Each line:
            // must come with: The columnId of the attribute in the dimension --> this represents the
            SourceAttributeID
            // optional: A display name for the Level (if this argument doesn't come the default is the
            SourceAttributeID)
            string line:
```

```

        while ((line = levels.ReadLine()) != null)
    {
        if (string.IsNullOrEmpty(line) || string.IsNullOrWhiteSpace(line)) continue;
        line = line.Trim();
        string[] hierarchyData = line.Split(',');
        if (string.IsNullOrEmpty(hierarchyData[0])) continue; //first argument cannot be empty or
blank,
                                         //assume is a blank line and ignore it
        string levelSourceAttributeID = hierarchyData[0].Trim();
        string levelID = (hierarchyData.Length > 1 && !string.IsNullOrEmpty(hierarchyData[1])) ?
hierarchyData[1].Trim() : levelSourceAttributeID;
        currentHierarchy.Levels.Add(levelID).SourceAttributeID = levelSourceAttributeID;
    }
}

newDatabase.Dimensions[tableName].Update(AMO.UpdateOptions.AlterDependents);

}

catch (Exception ex)
{
    MessageBox.Show(String.Format("Error creating hierarchy [{0}].\nError message: {1}",
newHierarchyName.Text, ex.Message), "AMO to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Warning);
    if (newDatabase.Dimensions[tableName].Hierarchies.Contains(hierarchyName))
    {
        //Hierarchy was created but exception prevented complete hierarchy to be written... deleting
incomplete hierarchy
        newDatabase.Dimensions[tableName].Hierarchies.Remove(hierarchyName, true);
        newDatabase.Dimensions[tableName].Update(AMO.UpdateOptions.AlterDependents);
    }
}

newDatabase.Dimensions[tableName].Process(AMO.ProcessType.ProcessFull);
modelCube.MeasureGroups[tableName].Process(AMO.ProcessType.ProcessFull);
}

```

Tables - Key Performance Indicator Representation

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A KPI is used to gauge performance of a value, defined by a Base measure, against a Target value

Key Performance Indicator Representation

In tabular object models a key performance indicator -kpi- is a measure with additional information for the client application to display it graphically. A kpi usually has information about a goal to be obtained, the status of the measure compared to a the goal, and information for the client tool on how to display graphically the status.

Key Performance Indicator in AMO

When using AMO to manage a Tabular Model kpi there is no one-to-one object match for a kpi in AMO, the AMO [KpiObject](#) is not used for this purpose; in AMO, for tabular models, a kpi is represented the by a series of objects created in one of the elements in the [Commands](#) collection and in the [CalculationProperties](#).

The following code snippet shows how to create one of many possible kpi definitions.

```
private void addStaticKPI(object sender, EventArgs e)
{
    double KPIGoal = 0, status1ThresholdValue = 0, status2ThresholdValue = 0
        , redAreaValue = 0, yellowAreaValue = 0, greenAreaValue = 0;
    string clientStatusGraphicImageName = "Three Circles Colored";

    //Verify input requirements
    //Goal values
    if (staticTargetKPI.Checked)
    {//Static KPI Goal selected
        if (string.IsNullOrEmpty(staticTargetKPIGoal.Text)
            || string.IsNullOrWhiteSpace(staticTargetKPIGoal.Text)
            || !double.TryParse(staticTargetKPIGoal.Text, out KPIGoal))
        {
            MessageBox.Show(String.Format("Static Goal is not defined or is not a valid number."), "AMO to
Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Error);
            return;
        }
    }
    else
    {//Measure KPI Goal selected
        if (!TargetMeasureForKPISelected)
        {
            MessageBox.Show(String.Format("Measure Goal is not selected."), "AMO to Tabular message",
MessageBoxButtons.OK, MessageBoxIcon.Error);
            return;
        }
    }

    //Status
    if (string.IsNullOrEmpty(firstStatusThresholdValue.Text)
        || string.IsNullOrWhiteSpace(firstStatusThresholdValue.Text)
        || !double.TryParse(firstStatusThresholdValue.Text, out status1ThresholdValue)
        || string.IsNullOrEmpty(secondStatusThresholdValue.Text)
        || string.IsNullOrWhiteSpace(secondStatusThresholdValue.Text)
        || !double.TryParse(secondStatusThresholdValue.Text, out status2ThresholdValue))
    {
        MessageBox.Show(String.Format("Status Threshold are not defined or they are not a valid number."), "AMO
```

```

        to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    if (string.IsNullOrEmpty(statusValueRedArea.Text)
        || string.IsNullOrWhiteSpace(statusValueRedArea.Text)
        || !double.TryParse(statusValueRedArea.Text, out redAreaValue)
        || string.IsNullOrEmpty(statusValueYellowArea.Text)
        || string.IsNullOrWhiteSpace(statusValueYellowArea.Text)
        || !double.TryParse(statusValueYellowArea.Text, out yellowAreaValue)
        || string.IsNullOrEmpty(statusValueGreenArea.Text)
        || string.IsNullOrWhiteSpace(statusValueGreenArea.Text)
        || !double.TryParse(statusValueGreenArea.Text, out greenAreaValue))
    {
        MessageBox.Show(String.Format("Status Area values are not defined or they are not a valid number."),
        "AMO to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    //Set working variables
    string kpiTableName = ((DataRowView)MeasuresInModelList.CheckedItems[0])[0].ToString();
    string kpiMeasureName = ((DataRowView)MeasuresInModelList.CheckedItems[0])[1].ToString();

    //Verify if KPI is already defined
    if (modelCube.MdxScripts["MdxScript"].CalculationProperties.Contains(string.Format("KPIs.[{0}]",
    kpiMeasureName)))
    {

AMO2Tabular sample

To have an understanding on how to use AMO to create and manipulate Key Performance Indicator representations see the source code of the AMO to Tabular sample; specifically check in the following source file: AddKPIs.cs. The sample is available at [Codeplex](#). An important note about the code: the code is provided only as a support to the logical concepts explained here and should not be used in a production environment; nor should it be used for other purpose other than the pedagogical one.

Tables – Partition Representation

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

For operational purposes, a table can be divided in different subsets of rows that when combined together form the table; each of those subsets is a partition of the table.

Partition Representation

In terms of AMO objects a partition representation has a one to one mapping relationship with [Partition](#) and no other main AMO objects are required

Partition in AMO

When using AMO to manage a partition in a you need to find the measure group that represents the Tabular Model table and work from there.

The following code snippet shows how to add a partition to an existing tabular model table.

```

private void AddPartition(
            AMO.Cube modelCube
            , AMO.DataSource newDatasource
            , string mgName
            , string newPartitionName
            , string partitionSelectStatement
            , Boolean processPartition
        )
{
    mgName = mgName.Trim();
    newPartitionName = newPartitionName.Trim();
    partitionSelectStatement = partitionSelectStatement.Trim();
    //Validate Input
    if (string.IsNullOrEmpty(newPartitionName) || string.IsNullOrWhiteSpace(newPartitionName))
    {
        MessageBox.Show(String.Format("Partition Name cannot be empty or blank"), "AMO to Tabular message",
        MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    if (modelCube.MeasureGroups[mgName].Partitions.ContainsName(newPartitionName))
    {
        MessageBox.Show(String.Format("Partition Name already defined. Duplicated names are not allowed"), "AMO
        to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    if (string.IsNullOrEmpty(partitionSelectStatement) || string.IsNullOrWhiteSpace(partitionSelectStatement))
    {
        MessageBox.Show(String.Format("Select statement cannot be empty or blank"), "AMO to Tabular message",
        MessageBoxButtons.OK, MessageBoxIcon.Error);
        return;
    }

    //Input validated
    string partitionID = newPartitionName; //Using partition name as the ID
    AMO.Partition currentPartition = new AMO.Partition(partitionID, partitionID);
    currentPartition.StorageMode = AMO.StorageMode.InMemory;
    currentPartition.ProcessingMode = AMO.ProcessingMode.Regular;
    currentPartition.Source = new AMO.QueryBinding(newDatasource.ID, partitionSelectStatement);
    modelCube.MeasureGroups[mgName].Partitions.Add(currentPartition);
    try
    {
        modelCube.Update(AMO.UpdateOptions.ExpandFull, AMO.UpdateMode.UpdateOrCreate);
        if (processPartition)
        {
            modelCube.MeasureGroups[mgName].Partitions[partitionID].Process(AMO.ProcessType.ProcessFull);
            MessageBox.Show(String.Format("Partition successfully processed."), "AMO to Tabular message",
            MessageBoxButtons.OK, MessageBoxIcon.Information);
        }
    }
    catch (AMO.AmoException amoXp)
    {
        MessageBox.Show(String.Format("AMO exception accessing the server.\nError message: {0}",
        amoXp.Message), "AMO to Tabular message", MessageBoxButtons.OK, MessageBoxIcon.Warning);
        return;
    }
    catch (Exception)
    {
        throw;
    }
}

```

AMO2Tabular sample

However, to have an understanding on how to use AMO to create and manipulate partition representations see the source code of the AMO to Tabular sample. The sample is available at Codeplex. An important note about the code: the code is provided only as a support to the logical concepts explained here and should not be used in a production environment; nor should it be used for other purpose other than the pedagogical one.

Tables Representation (Tabular)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In tabular models, a table is the base representation of the data.

Tables Representation

Tables in AMO

When using AMO to manage a table, there is no one-to-one object match. In AMO, a table is represented by a **Dimension** and **MeasureGroup**. For a measure group to exist, a **Cube** must be defined to host the measure group. For a dimension, measure group, and cube to exist, a Data Source View object must be defined to hold the binding definitions to the data source.

From a procedural perspective, a Data Source View needs to be created before any other object is defined. The data source view object contains the mapping for all relevant objects in the data source. The mapping of the relational model is embedded in the data source view as a .Net DataSet object and stored in the Schema property of the DSV.

The following code snippet assumes you have a SQL client connection string, a dictionary of Select statements that map to all tables in the relational model you intend to represent in your tabular model, and a variable `newDataSourceViewName` with the name of the data source view (usually the name of your relational database).

```
DataSet newDataSourceViewDataSet = new DataSet(newDataSourceViewName);

Foreach( String tableName in listOfSqlStatements.Keys)
{
    String sqlStmt = listOfSqlStatements[tableName];

    DataTable newTable = new DataTable(tableName);

    using (SqlConnection SqlCnx = new SqlConnection(SqlCnxStr))
    {
        SqlDataAdapter dataAdapter = new SqlDataAdapter(sqlStmt, SqlCnx);
        dataAdapter.FillSchema(newTable, SchemaType.Source);
    }
    newDataSourceViewDataSet.Tables.Add(newTable);
}

AMO.DataSourceView newDatasourceView = newDatabase.DataSourceViews.AddNew(newDataSourceViewName,
newDataSourceViewName);
newDatasourceView.DataSourceID = newDatasource.ID; //This is the ID of the DataSource object
newDatasourceView.Schema = newDataSourceViewDataSet; //Here you are storing all the relational schema in the
DSV
newDatasourceView.Update();
```

Once the Data Source View has been created and updated, the cube object needs to be created, but not updated in the server until the first table is created. A cube object cannot be created empty. The following code snippet shows how to create a cube; the snippet assumes you have a non-empty string `newCubeName` with the name of the cube already validated for duplicates too.

```

modelCube = newDatabase.Cubes.Add(newCubeName, newCubeName);
modelCube.Source = new AMO.DataSourceViewBinding(newDatasourceView.ID);
modelCube.StorageMode = AMO.StorageMode.InMemory;
modelCube.Language = newDatabase.Language;
modelCube.Collation = newDatabase.Collation;
//Create initial MdxScript
AMO.MdxScript mdxScript = modelCube.MdxScripts.Add("MdxScript", "MdxScript");
StringBuilder initialCommand = new StringBuilder();
initialCommand.AppendLine("CALCULATE;");
initialCommand.AppendLine("CREATE MEMBER CURRENTCUBE.Measures.[__No measures defined] AS 1;");
initialCommand.AppendLine("ALTER CUBE CURRENTCUBE UPDATE DIMENSION Measures, Default_Member = [__No measures defined];");
mdxScript.Commands.Add(new AMO.Command(initialCommand.ToString()));

```

Once the cube is defined locally, tables can be created and updated. The following procedure outlines the necessary steps to create a table:

1. Create the dimension that represents the table and don't update the server yet.
2. Create the RowNumber attribute and define it as the key attribute of the dimension.
3. Create dimension attributes and mark them with a one-to-many relationship to RowNumber.
4. Add dimension to cube dimensions.
5. Create the measure group that also represents the table.
6. Add dimension to measure group.
7. Create AMO default measure object to the measure group. Note, this is the only time an AMO measure object is used; calculated measures, in tabular models, are defined in the AMO MdxScripts["MdxScript"] object.
8. Create default partition.
9. Update database.

The following code snippet shows how to create a table:

```

private Boolean CreateTable(
    AMO.Database db      //the AMO database object where dimension are created
    , AMO.Cube cb        //the AMO cube where measure group is created
    , DataTable dataTable //the schema of the table to be created
)
{
    String tableID = dataTable.TableName;

    if (db.Dimensions.Contains(tableID))
    {
        if (cb.MeasureGroups.Contains(tableID))
        {
            cb.MeasureGroups[tableID].Measures.Clear();
            cb.MeasureGroups[tableID].Partitions.Clear();
            cb.MeasureGroups.Remove(tableID, true);
        }
        if (cb.Dimensions.Contains(tableID))
        {
            cb.Dimensions.Remove(tableID, true);
        }
        db.Dimensions.Remove(tableID);
    }
}

```

```

#region Create Dimension
//Define Dimension general properties
AMO.Dimension currentDimension = db.Dimensions.AddNew(tableID, tableID);
currentDimension.Source = new AMO.DataSourceViewBinding(newDatasourceView.ID);
currentDimension.StorageMode = AMO.DimensionStorageMode.InMemory;
currentDimension.UnknownMember = AMO.UnknownMemberBehavior.AutomaticNull;
currentDimension.UnknownMemberName = "Unknown";
currentDimension.ErrorConfiguration = new AMO.ErrorConfiguration();
currentDimension.ErrorConfiguration.KeyNotFound = AMO.ErrorOption.IgnoreError;
currentDimension.ErrorConfiguration.KeyDuplicate = AMO.ErrorOption.ReportAndStop;
currentDimension.ErrorConfiguration.NullKeyNotAllowed = AMO.ErrorOption.ReportAndStop;
currentDimension.Language = db.Language;
currentDimension.Collation = db.Collation;
currentDimension.ProactiveCaching = new AMO.ProactiveCaching();
TimeSpan defaultProactiveChachingTimeSpan = new TimeSpan(0, 0, -1);
currentDimension.ProactiveCaching.SilenceInterval = defaultProactiveChachingTimeSpan;
currentDimension.ProactiveCaching.Latency = defaultProactiveChachingTimeSpan;
currentDimension.ProactiveCaching.SilenceOverrideInterval = defaultProactiveChachingTimeSpan;
currentDimension.ProactiveCaching.ForceRebuildInterval = defaultProactiveChachingTimeSpan;
currentDimension.ProactiveCaching.Source = new AMO.ProactiveCachingInheritedBinding();

//Manually add a "RowNumber" attribute as the key attribute of the dimension, until a primary key is defined
// "RowNumber" a required column for a tabular model and has to be of type AMO.AttributeType.RowNumber and
binding AMO.RowNumberBinding.
//The name of the "RowNumber" attribute can be any name, as long as type and binding are correctly set
//By default, the MS client tools set the column name and column ID of the RowNumber attribute to
"RowNumber"
//In this sample, to avoid problems, on any customer table that contains a column named 'RowNumber'
//the Id value of the column (in the dimension object) will be renamed to 'RowNumber_in_<TableName>' and
the Name of the column will remain "RowNumber"

AMO.DimensionAttribute currentAttribute = currentDimension.Attributes.Add("RowNumber", "RowNumber");
currentAttribute.Type = AMO.AttributeType.RowNumber;
currentAttribute.KeyUniquenessGuarantee = true;
currentAttribute.Usage = AMO.AttributeUsage.Key;

Understanding Tabular Object Model at Levels 1050 through 1103

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A tabular model is a logical representation of tables, relationships, hierarchies, perspectives, measures, and Key Performance. This section introduces the internal implementation using AMO. See [Developing with Analysis Management Objects \(AMO\)](#) if you haven't used AMO before.

The approach here is top-down, all relevant objects in the tabular model are logically mapped to AMO objects, and the required interaction or workflow explained. A source code sample to create a tabular model using AMO, AMO to Tabular sample is available from [Codeplex](#). An important note about the code in the sample: it is provided only to support the logical concepts explained here and should not be used in a production environment. The sample is provided without support or warranty.

Database Representation

A database provides the container object for the tabular model. All objects in a tabular model are contained in the database. In terms of AMO objects, a database representation has a one-to-one mapping relationship with `xref:Microsoft.AnalysisServices.Database`, and no other main AMO objects are required. It is important to note that this doesn't mean that all contained objects in the AMO database object can be used when modeling.

See [Database Representation\(Tabular\)](#) for a detailed explanation on how to create and manipulate the database representation.

Connection Representation

A connection establishes the relationship between the data to be included in a tabular model solution and the model itself. In terms of AMO objects, a connection has a one-to-one mapping relationship with `xref:Microsoft.AnalysisServices.DataSource`, and no other main AMO objects are required. It is important to note that this doesn't mean that all contained objects in the AMO datasource object can be used when modeling.

See [Connection Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the data source representation.

Table Representation

Tables are database objects that contain the data in the database. In terms of AMO objects, a table has a one-to-many mapping relationship. A table is represented by the usage of the following AMO objects:

`xref:Microsoft.AnalysisServices.DataSourceView`, `xref:Microsoft.AnalysisServices.Dimension`,
`xref:Microsoft.AnalysisServices.Cube`, `xref:Microsoft.AnalysisServices.CubeDimension`,
`xref:Microsoft.AnalysisServices.MeasureGroup` and `xref:Microsoft.AnalysisServices.Partition` are the main required objects. However, it is important to note that this doesn't mean that all contained objects in the previously mentioned AMO objects can be used when modeling.

See [Tables Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the table representation.

Calculated Column Representation

Calculated columns are evaluated expressions that generate a column in a table, where a new value is calculated and stored for each row in the table. In terms of AMO objects, a calculated column has a one-to-many mapping relationship. A calculated column is represented by the usage of the following AMO objects:

`xref:Microsoft.AnalysisServices.Dimension` and `xref:Microsoft.AnalysisServices.MeasureGroup` are the main required objects. It is important to note that this doesn't mean that all contained objects in the previously mentioned AMO objects can be used when modeling.

See [Calculated Column Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the calculated column representation.

Calculated Measure Representation

Calculated Measures are stored expressions that are evaluated upon request once the model is deployed. In terms of AMO objects, a calculated measure has a one-to-many mapping relationship. A calculated column is represented by the usage of the following AMO objects: `xref:Microsoft.AnalysisServices.MdxScript.Commands%2A` and `xref:Microsoft.AnalysisServices.MdxScript.CalculationProperties%2A` are the main required objects. It is important to note that this doesn't mean that all contained objects in the previously mentioned AMO objects can be used when modeling.

NOTE

The `xref:Microsoft.AnalysisServices.Measure` objects have no relationship with the calculated measures in tabular models, and are not supported in tabular models.

See [Calculated Measure Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the calculated measure representation.

Hierarchy Representation

Hierarchies are a mechanism to provide a richer drill-up and drill-down experience to the end user. In terms of AMO objects, a hierarchy representation has a one-to-one mapping relationship with

`xref:Microsoft.AnalysisServices.Hierarchy`, and no other main AMO objects are required. It is important to note that this doesn't mean that all contained objects in the AMO database object can be used when doing tabular modeling.

See [Hierarchy Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the hierarchy representation.

Key Performance Indicator -KPI- Representation

A KPI is used to gauge performance of a value, defined by a Base measure, against a Target value. In terms of AMO objects, a KPI representation has a one-to-many mapping relationship. A KPI is represented by the usage of the following AMO objects: `xref:Microsoft.AnalysisServices.MdxScript.Commands%2A` and `xref:Microsoft.AnalysisServices.MdxScript.CalculationProperties%2A` are the main required objects. It is important to note that this doesn't mean that all contained objects in the previously mentioned AMO objects can be used when modeling.

NOTE

Also, important distinction, the `xref:Microsoft.AnalysisServices.Kpi` objects have no relationship with the KPIs in tabular models. And, they are not supported in tabular models.

See [Key Performance Indicator Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the KPI representation.

Partition Representation

For operational purposes, a table can be divided in different subsets of rows that, when combined together, form the table. Each of those subsets is a partition of the table. In terms of AMO objects, a partition representation has a one-to-one mapping relationship with `xref:Microsoft.AnalysisServices.Partition` and no other main AMO objects are required. It is important to note that this doesn't mean that all contained objects in the AMO database object can be used when modeling.

See [Partition Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the partition representation.

Relationship Representation

A relationship is a connection between two tables of data. The relationship establishes how the data in the two tables should be correlated.

In tabular models, multiple relationships can be defined between two tables. When multiple relationships between two tables are defined, only one can be defined as the default Active relationship. All other relationships are Inactive.

In terms of AMO objects, all inactive relationships have a representation of a one-to-one mapping relationship with `xref:Microsoft.AnalysisServices.Relationship`, and no other main AMO objects are required. For the active relationship, other requirements exist and a mapping to the `xref:Microsoft.AnalysisServices.ReferenceMeasureGroupDimension` is also required. It is important to note that this doesn't mean that all contained objects in the AMO relationship or referenceMeasureGroupDimension object can be used when modeling.

See [Relationship Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the relationship representation.

Perspective Representation

A perspective is a mechanism to simplify or focus the mode. In terms of AMO objects, a relationship representation has a one-to-one mapping relationship with `xref:Microsoft.AnalysisServices.Perspective` and no other main AMO objects are required. It is important to note that this doesn't mean that all contained objects in the AMO perspective object can be used when doing tabular modeling.

See [Perspective Representation \(Tabular\)](#) for a detailed explanation on how to create and manipulate the perspective representation.

WARNING

Perspectives are not a security mechanism; objects outside the perspective can still be accessed by the user through other interfaces.

IMDEmbeddedData Interface

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The IMDEmbeddedData interface is a public interface used to manage an embedded Power Pivot database or a tabular model database. The interface inherits from the **IPersistStream** interface. The interface allows for the following operations:

- Get an identifier to the embedded stream in the container document.
- Set the URL of the containing document.
- Set a flag to indicate if the embedding application is in a hosted environment.
- Set the path to temporary files used by the embedding application.
- Cancel the current embedded operation.
- Get the estimated size (in bytes) of the stream to save the embedded object. Inherited from **IPersistStream**.
- Verify if the embedded database has changed since it was last saved. Inherited from **IPersistStream**.
- Load the embedded database to the local or in-process engine. Inherited from **IPersistStream**.
- Save the local or in-process database to the embedded stream in the container document. Inherited from **IPersistStream**.

Reference

The following reference documents the **IMDEmbeddedData** interface as presented in **msmd.h** header file.

Source file: **PXOEmbeddedData.idl**

```

[
    local,
    object,
    uuid(6B6691CF-5453-41c2-ADD9-4F320B7FD421),
    pointer_default(unique)
]
interface IMDEmbeddedData : IPersistStream
{
    [id(1), helpstring("Set flag indicating if the application is in a hosted environment")]
    HRESULT SetHosted(
        [in] BOOL in_fIsHosted);

    [id(2), helpstring("Set the URL for the document containing the embedded stream")]
    HRESULT SetContainerURL(
        [in] BSTR in_bstrURL);

    [id(3), helpstring("Get identifier used to look up embedded stream in container document")]
    HRESULT GetStreamIdentifier(
        [out, retval] BSTR* out_pbstrStreamId);

    [id(4), helpstring("Set the path used by the embedding application for temporary files")]
    HRESULT SetTempDirPath(
        [in] BSTR in_bstrPath);

    [id(5), helpstring("Cancel the current operation")]
    HRESULT Cancel();
};

```

IMDEmbeddedData::GetStreamIdentifier

```

HRESULT GetStreamIdentifier (
    [out, retval] BSTR * out_pbstrStreamId
)

```

Description

Gets the identifier used by the host application to the embedded stream in the container document.

Parameters

out_pbstrStreamId

Specifies the location of the stream identifier.

Return Value

S_OK

The stream identifier was successfully returned.

S_FALSE

There is no stream identifier.

E_FAIL

An error occurred accessing the stream identifier.

Remarks

To verify if the current connection contains an embedded database, the user should check the value of the DBPROP_MSMD_EMBEDDED_DATA property from the OLE DB connection properties.

The possible values for DBPROP_MSMD_EMBEDDED_DATA are:

NAME	VALUE	DEFINITION
DBPROPSVAL_EMBED_NONE	0x00	No embedded database available

NAME	VALUE	DEFINITION
DBPROPVAL_EMBED_EMBEDDED	0x01	The current application contains the embedded database
DBPROPVAL_EMBED_LINKED	0x02	The embedded database is hosted in a remote application (i.e. SharePoint Server)

Source

```
[id(1), helpstring("Get identifier used to look up embedded stream in container document")]
HRESULT GetStreamIdentifier(
    [out, retval] BSTR* out_pbstrStreamId);
```

IMDEmbeddedData::SetContainerURL

```
HRESULT SetContainerURL (
    [in] BSTR in_bstrURL
)
```

Description

Sets the URL for the file containing the embedded stream.

Parameters

in_bstrURL

Specifies the URL for the containing document.

Return Value

S_OK

The container URL was successfully set.

E_FAIL

An error occurred while setting the container URL.

Source

```
[id(2), helpstring("Set the URL for the document containing the embedded stream")]
HRESULT SetContainerURL(
    [in] BSTR in_bstrURL);
```

IMDEmbeddedData::SetHosted

```
HRESULT SetHosted (
    [in] BOOL in_fIsHosted
)
```

Description

Set a flag to indicate if the embedding application is in a hosted environment.

Parameters

in_ftHosted

TRUE if caller is in a hosted in a service application (like IIS).

Return Value

S_OK

The flag was successfully set.

E_FAIL

An error occurred while setting the flag.

Source

```
[id(5), helpstring("Set flag indicating if the application is in a hosted environment")]
HRESULT SetHosted(
    [in] BOOL in_fIsHosted);
```

IMDEmbeddedData::SetTempDirPath

```
HRESULT SetTempDirPath (
    [in] BSTR in_bstrPath
)
```

Description

Set the path to temporary files used by the embedding application.

Parameters

in_bstrPath

The path used by the host application for temporary files.

Return Value

S_OK

The temporary file directory was successfully set.

E_FAIL

An error occurred while setting the path.

Source

```
[id(4), helpstring("Set the path used by the host application for temporary files")]
HRESULT SetTempDirPath(
    [in] BSTR in_bstrPath);
```

IMDEmbeddedData::Cancel

```
HRESULT Cancel ( void )
```

Description

Cancels the current embedded database operation

Parameters

None.

Return Value

S_OK

The operation was successfully cancelled.

DB_E_CANTCANCEL

No cancellable operation is currently in progress.

E_FAIL

An error occurred while cancelling the embedded operation.

Source

```
[id(5), helpstring("Cancel the current operation")]
HRESULT Cancel();
```

IMDEmbeddedData::GetSizeMax (IPersistStream::GetSizeMax)

```
HRESULT GetSizeMax (
    [out] ULARGE_INTEGER * out_pcbSize
)
```

Description

Gets the estimated size (in bytes) of the stream to save the embedded object. Inherited from **IPersistStream**.

Parameters

in_bstrPath

The estimated size (in bytes) of the embedded database image.

Return Value

S_OK

The size was successfully obtained.

E_FAIL

An error occurred while obtaining the size.

IMDEmbeddedData::IsDirty (IPersistStream::IsDirty)

```
HRESULT IsDirty ( void )
```

Description

Verifies if the embedded database has changed since it was last saved. Inherited from **IPersistStream**.

Parameters

none

Return Value(s)

S_OK

The database has changed since it was last saved.

S_FALSE

The database has not changed since it was last saved.

E_FAIL

An error occurred while obtaining the database state.

IMDEmbeddedData::Load (IPersistStream::Load)

```
HRESULT Load (
    [in] IStream * in_pStm
)
```

Description

Loads the embedded database to the local or in-process engine. Inherited from **IPersistStream**.

Parameters

in_pStm

A pointer to a stream interface from where to load the embedded database.

Return Value(s)

S_OK

The database was successfully loaded.

E_OUTOFMEMORY

Not enough memory to load the database.

E_FAIL

An error occurred while loading the database, different than **E_OUTOFMEMORY**.

IMDEmbeddedData::Save (IPersistStream::Save)

```
HRESULT Save (
    [in] IStream * in_pStm,
    [in] BOOL in_fClearDirty
)
```

Description

Saves the local or in-process database to the embedded stream in the container document. Inherited from **IPersistStream**.

Parameters

in_pStm

A pointer to a stream interface to where to save the embedded database.

in_fClearDirty

A flag that indicates whether the dirty flag should be cleared after this operation.

Return Value(s)

S_OK

The database was successfully saved.

STG_E_CANTSAVE

An error occurred while saving the database, different than **STG_E_MEDIUMFULL**.

STG_E_MEDIUMFULL

The database could not be saved because there is no space left on the storage device.

Multidimensional Model Programming

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Analysis Services provides several APIs that you can use to program against an Analysis Services instance and the multidimensional databases that it makes available. This section describes the approaches available to developers who want to create custom applications using Analysis Services multidimensional solutions. You can use this information to choose the programming interface that best meets the requirements of a particular project. Analysis Services development projects can be based on managed or non-managed code that runs on a Windows platform, or other platforms that support HTTP access.

Multidimensional Model Assemblies Management

7/16/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Microsoft SQL Server Analysis Services supplies lots of intrinsic functions for use with the Multidimensional Expressions (MDX) and Data Mining Extensions (DMX) languages, designed to accomplish everything from standard statistical calculations to traversing members in a hierarchy. But, as with any other complex and robust product, there is always the need to extend the functionality of such a product further.

Therefore, Analysis Services lets you add assemblies to an Analysis Services instance or database. Assemblies let you create external, user-defined functions using any common language runtime (CLR) language, such as Microsoft Visual Basic .NET or Microsoft Visual C#. You can also use Component Object Model (COM) Automation languages such as Microsoft Visual Basic or Microsoft Visual C++.

IMPORTANT

COM assemblies might pose a security risk. Due to this risk and other considerations, COM assemblies were deprecated in SQL Server 2008 Analysis Services (SSAS). COM assemblies might not be supported in future releases.

Assemblies let you extend the business functionality of MDX and DMX. You build the functionality that you want into a library, such as a dynamic link library (DLL) and add the library as an assembly to an instance of Analysis Services or to an Analysis Services database. The public methods in the library are then exposed as user-defined functions to MDX and DMX expressions, procedures, calculations, actions, and client applications.

An assembly with new procedures and functions can be added to the server. You can use assemblies to enhance or add custom functionality that is not provided by the server. By using assemblies, you can add new functions to Multidimensional Expressions (MDX), Data Mining Extensions (DMX), or stored procedures. Assemblies are loaded from the location where the custom application is run, and a copy of the assembly binary file is saved along with the database data in the server. When an assembly is removed, the copied assembly is also removed from the server.

Assemblies can be of two different types: COM and CLR. CLR assemblies are assemblies developed in .NET Framework programming languages such as C#, Visual Basic .NET, managed C++. COM assemblies are COM libraries that must be registered in the server

Assemblies can be added to [Server](#) or [Database](#) objects. Server assemblies can be called by any user connected to the server or any object in the server. Database assemblies can be called only by [Database](#) objects or users connected to the database.

A simple [Assembly](#) object is composed of basic information (Name and Id), file collection, and security specifications.

The file collection refers to the loaded assembly files and their corresponding debugging (.pdb) files, if the debugging files were loaded with the assembly files. Assembly files are loaded from the location where the application defined the files to, and a copy is saved in the server along with the data. The copy of the assembly file is used to load the assembly every time the service is started.

Security specifications include the permission set and the impersonation used to run the assembly.

Calling User-Defined Functions

Calling a user-defined function in an assembly is performed just like calling an intrinsic function, except that you must use a fully qualified name. For example, a user-defined function that returns a type expected by MDX is included in an MDX query, as shown in the following example:

```
Select MyAssembly.MyClass.MyStoredProcedure(a, b, c) on 0 from Sales
```

User-defined functions can also be called using the CALL keyword. You must use the CALL keyword for user-defined functions which return recordsets or void values, and you cannot use the CALL keyword if the user-defined function depends on an object in the context of the MDX or DMX statement or script, such as the current cube or data mining model. A common use for a function called outside an MDX or DMX query is to use the AMO object model to perform administrative functions. If, for example, you wanted to use the function `MyVoidProcedure(a, b, c)` in an MDX statement, the following syntax would be employed:

```
Call MyAssembly.MyClass.MyVoidProcedure(a, b, c)
```

Assemblies simplify database development by enabling common code to be developed once and stored in a single location. Client software developers can create libraries of functions for Analysis Services and distribute them with their applications.

Assemblies and user-defined functions can duplicate the function names of the Analysis Services function library or of other assemblies. As long as you call the user-defined function by using its fully qualified name, Analysis Services will use the correct procedure. For security purposes, and to eliminate the chance of calling a duplicate name in a different class library, Analysis Services requires that you use only fully qualified names for stored procedures.

To call a user-defined function from a specific CLR assembly, the user-defined function is preceded by the assembly name, full class name, and procedure name, as demonstrated here:

`AssemblyName.FullClassName.ProcedureName(Argument1, Argument2, ...)`

For backward compatibility with earlier versions of Analysis Services, the following syntax is also acceptable:

`AssemblyName!FullClassName!ProcedureName(Argument1, Argument2, ...)`

If a COM library supports multiple interfaces, the interface ID can also be used to resolve the procedure name, as demonstrated here:

`AssemblyName!InterfaceID!ProcedureName(Argument1, Argument2, ...)`

Security

Security for assemblies is based on the .NET Framework security model, which is a code-access security model. .NET Framework supports a code-access security mechanism that assumes that the runtime can host both fully trusted and partially trusted code. The resources that are protected by .NET Framework code access security are typically wrapped by managed code which demands the corresponding permission before enabling access to the resource. The demand for the permission is satisfied only if all the callers (at the assembly level) in the call stack have the corresponding resource permission.

For assemblies, permission for execution is passed with the **PermissionSet** property on the **Assembly** object. The permissions that managed code receives are determined by the security policy in effect. There are already three levels of policy in effect in a non- Analysis Services hosted environment: enterprise, computer and user. The effective list of permissions that code receives is determined by the intersection of the permissions obtained by these three levels.

Analysis Services supplies a host-level security policy level to the CLR while hosting it; this policy is an additional

policy level below the three policy levels that are always in effect. This policy is set for every application domain that is created by Analysis Services.

The Analysis Services host-level policy is a combination of Analysis Services fixed policy for system assemblies and user-specified policy for user assemblies. The user-specified piece of the Analysis Services host policy is based on the assembly owner specifying one of three permission buckets for each assembly:

PERMISSION SETTING	DESCRIPTION
Safe	Provides internal computation permission. This permission bucket does not assign permissions to access any of the protected resources in the .NET Framework. This is the default permission bucket for an assembly if none is specified with the PermissionSet property.
ExternalAccess	Provides the same access as the Safe setting, with the additional ability to access external system resources. This permission bucket does not offer security guarantees (although it is possible to secure this scenario), but it does give reliability guarantees.
Unsafe	Provides no restrictions. No security or reliability guarantees can be made for managed code running under this permission set. Any permission, even a custom permission included by the administrator, is granted to code running at this level of trust.

When CLR is hosted by Analysis Services, the stack-walk based permission check stops at the boundary with native Analysis Services code. Any managed code in Analysis Services assemblies always falls into one of the three permission categories listed earlier.

COM (or unmanaged) assembly routines do not support the CLR security model.

Impersonation

Whenever managed code accesses any resource outside Analysis Services, Analysis Services follows the rules associated with the **ImpersonationMode** property setting of the assembly to make sure that the access occurs in an appropriate Windows security context. Because assemblies using the **Safe** permission setting cannot access resources outside Analysis Services, these rules are applicable only for assemblies using the **ExternalAccess** and **Unsafe** permission settings.

- If the current execution context corresponds to Windows Authenticated login and is the same as the context of the original caller (that is, there is no EXECUTE AS in the middle), Analysis Services will impersonate the Windows Authenticated login before accessing the resource.
- If there is an intermediate EXECUTE AS that changed the context from that of the original caller), the attempt to access external resource will fail.

The **ImpersonationMode** property can be set to **ImpersonateCurrentUser** or **ImpersonateAnonymous**. The default setting, **ImpersonateCurrentUser**, runs an assembly under the current user's network login account. If the **ImpersonateAnonymous** setting is used, the execution context corresponds to the Windows login user account IUSER_servername on the server. This is the Internet guest account, which has limited privileges on the server. An assembly running in this context can only access limited resources on the local server.

Application Domains

Analysis Services does not expose application domains directly. Because of a set of assemblies running in the same application domain, application domains can discover each other at execution time by using the **System.Reflection** namespace in the .NET Framework or in some other way, and can call into them in late-

bound manner. Such calls will be subject to the permission checks used by Analysis Services authorization-based security.

You should not rely on finding assemblies in the same application domain, because the application domain boundary and the assemblies that go into each domain are defined by the implementation.

[Setting Security for Stored Procedures](#)

[Defining Stored Procedures](#)

Developing with Analysis Services Scripting Language (ASSL)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Analysis Services Scripting Language (ASSL) is an extension to XMLA that adds an object definition language and command language for creating and managing Analysis Services structures directly on the server. You can use ASSL in custom application to communicate with Analysis Services over the XMLA protocol. ASSL is made up of two parts:

- A Data Definition Language (DDL), or object definition language, defines and describes an instance of Analysis Services, as well as the databases and database objects that the instance contains.
- A command language that sends action commands, such as **Create**, **Alter**, or **Process**, to an instance of Analysis Services. This command language is discussed in the [XML for Analysis \(XMLA\) Reference](#).

To view the ASSL that describes a multidimensional solution in Visual Studio with Analysis Services projects, you can use the View Code command at the project level. You can also create or edit ASSL script in Management Studio using the XMLA query editor. The scripts you build can be used to manage objects or run commands on the server.

[ASSL XML Conventions](#)

[Data Sources and Bindings \(SSAS Multidimensional\)](#)

ASSL Objects and Object Characteristics

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Objects in Analysis Services Scripting Language (ASSL) follow specific guidelines in regards to object groups, inheritance, naming, expansion, and processing.

Object Groups

All Microsoft SQL Server Analysis Services objects have an XML representation. The objects are divided into two groups:

Major objects

Major objects can be independently created, altered, and deleted. Major objects include:

- Servers
- Databases
- Dimensions
- Cubes
- Measure groups
- Partitions
- Perspectives
- Mining models
- Roles
- Commands associated with a server or database
- Data sources

Major objects have the following properties to track their history and status.

- **CreatedTimestamp**
- **LastSchemaUpdate**
- **LastProcessed** (where appropriate)

NOTE

The classification of an object as a major object affects how an instance of Analysis Services treats that object and how that object is handled in the object definition language. However, this classification does not guarantee that Analysis Services management and development tools will allow the independent creation, modification, or deletion of these objects.

Minor objects

Minor objects can only be created, altered, or deleted as part of creating, altering, or deleting the parent major object. Minor objects include:

- Hierarchies and levels
- Attributes
- Measures
- Mining model columns
- Commands associated with a cube
- Aggregations

Object Expansion

The **ObjectExpansion** restriction can be used to control the degree of expansion of ASSL XML returned by the server. This restriction has the options listed in the following table.

ENUMERATION VALUE	ALLOWED FOR <ALTER>	DESCRIPTION
<i>ReferenceOnly</i>	no	Returns only the name, ID, and timestamp for the requested object and for all contained major objects recursively.
<i>ObjectProperties</i>	yes	Expands the requested object and minor contained objects, but does not return major contained objects.
<i>ExpandObject</i>	no	Same as <i>ObjectProperties</i> , but also returns the name, ID, and timestamp for contained major objects.
<i>ExpandFull</i>	yes	Fully expands the requested object and all contained objects recursively.

This ASSL reference section describes the *ExpandFull* representation. All other **ObjectExpansion** levels are derived from this level.

Object Processing

ASSL includes read-only elements or properties (for example, **LastProcessed**) that can be read from the Analysis Services instance, but which are omitted when command scripts are submitted to the instance. Analysis Services ignores modified values for read-only elements without warning or error.

Analysis Services also ignores inappropriate or irrelevant properties without raising validation errors. For example, the X element should only be present when the Y element has a particular value. The Analysis Services instance ignores the X element instead of validating that element against the value of the Y element.

Backing Up, Restoring, and Synchronizing Databases (XMLA)

7/16/2019 • 10 minutes to read • [Edit Online](#)

In XML for Analysis, there are three commands that back up, restore, and synchronize databases:

- The **Backup** command backs up a Microsoft SQL Server Analysis Services database using an Analysis Services backup file (.abf), as described in the section, [Backing Up Databases](#).
- The **Restore** command restores an Analysis Services database from an .abf file, as described in the section, [Restoring Databases](#).
- The **Synchronize** command synchronizes one Analysis Services database with the data and metadata of another database, as described in the section, [Synchronizing Databases](#).

Backing Up Databases

As mentioned earlier, the **Backup** command backs up a specified Analysis Services database to a backup file. The **Backup** command has various properties that let you specify the database to be backed up, the backup file to use, how to back up security definitions, and the remote partitions to be backed up.

IMPORTANT

The Analysis Services service account must have permission to write to the backup location specified for each file. Also, the user must have one of the following roles: administrator role on the Analysis Services instance, or a member of a database role with Full Control (Administrator) permissions on the database to be backed up.

Specifying the Database and Backup File

To specify the database to be backed up, you set the **Object** property of the **Backup** command. The **Object** property must contain an object identifier for a database, or an error occurs.

To specify the file that is to be created and used by the backup process, you set the **File** property of the **Backup** command. The **File** property should be set to a UNC path and file name for the backup file to be created.

Besides specifying which file to use for backup, you can set the following options for the specified backup file:

- If you set the **AllowOverwrite** property to true, the **Backup** command overwrites the backup file if the specified file already exists. If you set the **AllowOverwrite** property to false, an error occurs if the specified backup file already exists.
- If you set the **ApplyCompression** property to true, the backup file is compressed after the file is created.
- If you set the **Password** property to any non-blank value, the backup file is encrypted by using the specified password.

IMPORTANT

If **ApplyCompression** and **Password** properties are not specified, the backup file stores user names and passwords that are contained in connection strings in clear text. Data that is stored in clear text may be retrieved. For increased security, use the **ApplyCompression** and **Password** settings to both compress and encrypt the backup file.

Backing Up Security Settings

The **Security** property determines whether the **Backup** command backs up the security definitions, such as roles and permissions, defined on an Analysis Services database. The **Security** property also determines whether the backup file includes the Windows user accounts and groups defined as members of the security definitions.

The value of the **Security** property is limited to one of the strings listed in the following table.

VALUE	DESCRIPTION
<i>SkipMembership</i>	Include security definitions, but exclude membership information, in the backup file.
<i>CopyAll</i>	Include security definitions and membership information in the backup file.
<i>IgnoreSecurity</i>	Exclude security definitions from the backup file.

Backing Up Remote Partitions

To back up remote partitions in the Analysis Services database, you set the **BackupRemotePartitions** property of the **Backup** command to true. This setting causes the **Backup** command to create a remote backup file for each remote data source that is used to store remote partitions for the database.

For each remote data source to be backed up, you can specify its corresponding backup file by including a **Location** element in the **Locations** property of the **Backup** command. The **Location** element should have its **File** property set to the UNC path and file name of the remote backup file, and its **DataSourceID** property set to the identifier of the remote data source defined in the database.

Restoring Databases

The **Restore** command restores a specified Analysis Services database from a backup file. The **Restore** command has various properties that let you specify the database to restore, the backup file to use, how to restore security definitions, the remote partitions to be stored, and the relocation relational OLAP (ROLAP) objects.

IMPORTANT

For each backup file, the user who runs the restore command must have permission to read from the backup location specified for each file. To restore an Analysis Services database that is not installed on the server, the user must also be a member of the server role for that Analysis Services instance. To overwrite an Analysis Services database, the user must have one of the following roles: a member of the server role for the Analysis Services instance or a member of a database role with Full Control (Administrator) permissions on the database to be restored.

NOTE

After restoring an existing database, the user who restored the database might lose access to the restored database. This loss of access can occur if, at the time that the backup was performed, the user was not a member of the server role or was not a member of the database role with Full Control (Administrator) permissions.

Specifying the Database and Backup File

The **DatabaseName** property of the **Restore** command must contain an object identifier for a database, or an error occurs. If the specified database already exists, the **AllowOverwrite** property determines whether the existing database is overwritten. If the **AllowOverwrite** property is set to false and the specified database already exists, an error occurs.

You should set the **File** property of the **Restore** command to a UNC path and file name for the backup file to be restored to the specified database. You can also set the **Password** property for the specified backup file. If the **Password** property is set to any non-blank value, the backup file is decrypted by using the specified password. If the backup file was not encrypted, or if the specified password does not match the password used to encrypt the backup file, an error occurs.

Restoring Security Settings

The **Security** property determines whether the **Restore** command restores the security definitions, such as roles and permissions, defined on an Analysis Services database. The **Security** property also determines whether the **Restore** command includes the Windows user accounts and groups defined as members of the security definitions as part of the restore process.

The value of this element is limited to one of the strings listed in the following table.

VALUE	DESCRIPTION
<i>SkipMembership</i>	Include security definitions, but exclude membership information, in the database.
<i>CopyAll</i>	Include security definitions and membership information in the database.
<i>IgnoreSecurity</i>	Exclude security definitions from the database.

Restoring Remote Partitions

For each remote backup file created during a previous **Backup** command, you can restore its associated remote partition by including a **Location** element in the **Locations** property of the **Restore** command. The **DataSourceType** property for each **Location** element must be excluded or explicitly set to *Remote*.

For each specified **Location** element, the Analysis Services instance contacts the remote data source specified in the **DataSourceID** property to restore the partitions defined in the remote backup file specified in the **File** property. Besides the **DataSourceID** and **File** properties, the following properties are available for each **Location** element used to restore a remote partition:

- To override the connection string for the remote data source specified in **DataSourceID**, you can set the **ConnectionString** property of the **Location** element to a different connection string. The **Restore** command will then use the connection string that is contained in the **ConnectionString** property. If **ConnectionString** is not specified, the **Restore** command uses the connection string stored in the backup file for the specified remote data source. You can use the **ConnectionString** setting to move a remote partition to a different remote instance. However, you cannot use the **ConnectionString** setting to restore a remote partition to the same instance that contains the restored database. In other words, you cannot use the **ConnectionString** property to make a remote partition into a local partition.
- For each original folder used to store the remote partitions on the remote data source, you can specify a **Folder** element to indicate the new folder in which to restore all the remote partitions stored in the original folder. If a **Folder** element is not specified, the **Restore** command uses the original folders specified for the remote partitions that are contained in the remote backup file.

Relocating ROLAP Objects

The **Restore** command cannot restore aggregations or data for objects that use ROLAP storage because such information is stored in tables on an underlying relational data source. However, the metadata for ROLAP objects can be restored. To restore the metadata for ROLAP object, the **Restore** command re-creates the table structure on a relational data source.

You can use the **Location** element in a **Restore** command to relocate ROLAP objects. For each **Location**

element used to relocate a data source, the **DataSourceType** property must be explicitly set to *Local*. You also have to set the **ConnectionString** property of the **Location** element to the connection string of the new location. During the restore, the **Restore** command will replace the connection string for the data source identified by the **DataSourceID** property of the **Location** element with the value of the **ConnectionString** property of the **Location** element.

Synchronizing Databases

The **Synchronize** command synchronizes the data and metadata of a specified Analysis Services database with another database. The **Synchronize** command has various properties that let you specify the source database, how to synchronize security definitions, the remote partitions to be synchronized, and the synchronization of ROLAP objects.

NOTE

The **Synchronize** command can be executed only by server administrators and database administrators. Both the source and destination database must have the same database compatibility level.

Specifying the Source Database

The **Source** property of the **Synchronize** command contains two properties, **ConnectionString** and **Object**. The **ConnectionString** property contains the connection string of the instance that contains the source database, and the **Object** property contains the object identifier for the source database.

The destination database is the current database for the session in which the **Synchronize** command runs.

If the **ApplyCompression** property of the **Synchronize** command is set to true, the information sent from the source database to the destination database is compressed before being sent.

Synchronizing Security Settings

The **SynchronizeSecurity** property determines whether the **Synchronize** command synchronizes the security definitions, such as roles and permissions, defined on the source database. The **SynchronizeSecurity** property also determines whether the **Synchronize** command includes the Windows user accounts and groups defined as members of the security definitions.

The value of this element is limited to one of the strings listed in the following table.

VALUE	DESCRIPTION
<i>SkipMembership</i>	Include security definitions, but exclude membership information, in the destination database.
<i>CopyAll</i>	Include security definitions and membership information in the destination database.
<i>IgnoreSecurity</i>	Exclude security definitions from the destination database.

Synchronizing Remote Partitions

For each remote data source that exists on the source database, you can synchronize each associated remote partition by including a **Location** element in the **Locations** property of the **Synchronize** command. For each **Location** element, the **DataSourceType** property must be excluded or explicitly set to *Remote*.

To define and connect to a remote data source in the destination database, the **Synchronize** command uses the connection string defined in the **ConnectionString** property of the **Location** element. The **Synchronize** command then uses the **DataSourceID** property of the **Location** element to identify which remote partitions to

synchronize. The **Synchronize** command synchronizes the remote partitions on the remote data source specified in the **DataSourceID** property on the source database with the remote data source specified in the **DataSourceID** property on the destination database.

For each original folder used to store the remote partitions on the remote data source on the source database, you can also specify a **Folder** element in the **Location** element. The **Folder** element indicates the new folder for the destination database in which to synchronize all the remote partitions stored in the original folder on the remote data source. If a **Folder** element is not specified, the Synchronize command uses the original folders specified for remote partitions that are contained in the source database.

Synchronizing ROLAP Objects

The **Synchronize** command cannot synchronize aggregations or data for objects that use ROLAP storage because such information is stored in tables on an underlying relational data source. However, the metadata for ROLAP objects can be synchronized. To synchronize the metadata, the **Synchronize** command recreates the table structure on a relational data source.

You can use the **Location** element in a Synchronize command to synchronize ROLAP objects. For each **Location** element used to relocate a data source, the **DataSourceType** property must be explicitly set to *Local*. You also have to set the **ConnectionString** property of the **Location** element to the connection string of the new location. During synchronization, the **Synchronize** command will replace the connection string for the data source identified by the **DataSourceID** property of the **Location** element with the value of the **ConnectionString** property of the **Location** element.

Cancelling Commands (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

Depending on the administrative permissions of the user issuing the command, the **Cancel** command in XML for Analysis (XMLA) can cancel a command on a session, a session, a connection, a server process, or an associated session or connection.

Cancelling Commands

A user can cancel the currently executing command within the context of the current explicit session by sending a **Cancel** command with no specified properties.

NOTE

A command running in an implicit session cannot be canceled by a user.

Cancelling Batch Commands

If a user cancels a **Batch** command, then all remaining commands not yet executed within the **Batch** command are canceled. If the **Batch** command was transactional, any commands that were executed before the **Cancel** command runs are rolled back.

Cancelling Sessions

By specifying a session identifier for an explicit session in the **SessionID** property of the **Cancel** command, a database administrator or server administrator can cancel a session, including the currently executing command. A database administrator can only cancel sessions for databases on which he or she has administrative permissions.

A database administrator can retrieve the active sessions for a specified database by retrieving the **DISCOVER_SESSIONS** schema rowset. To retrieve the **DISCOVER_SESSIONS** schema rowset, the database administrator uses the XMLA **Discover** method and specifies the appropriate database identifier for the **SESSION_CURRENT_DATABASE** restriction column in the **Restrictions** property of the **Discover** method.

Cancelling Connections

By specifying a connection identifier in the **ConnectionID** property of the **Cancel** command, a server administrator can cancel all of the sessions associated with a given connection, including all running commands, and cancel the connection.

NOTE

If the instance of Microsoft SQL Server Analysis Services cannot locate and cancel the sessions associated with a connection, such as when the data pump opens multiple sessions while providing HTTP connectivity, the instance cannot cancel the connection. If this case is encountered during the execution of a **Cancel** command, an error occurs.

A server administrator can retrieve the active connections for an Analysis Services instance by retrieving the **DISCOVER_CONNECTIONS** schema rowset using the XMLA **Discover** method.

Cancelling Server Processes

By specifying a server process identifier (SPID) in the [SPID](#) property of the **Cancel** command, a server administrator can cancel the commands associated with a given SPID.

Canceling Associated Sessions and Connections

You can set the [CancelAssociated](#) property to true to cancel the connections, sessions, and commands associated with the connection, session, or SPID specified in the **Cancel** command.

[Developing with XMLA in Analysis Services](#)

Creating and Altering Objects (XMLA)

7/16/2019 • 4 minutes to read • [Edit Online](#)

Major objects can be independently created, altered, and deleted. Major objects include the following objects:

- Servers
- Databases
- Dimensions
- Cubes
- Measure groups
- Partitions
- Perspectives
- Mining models
- Roles
- Commands associated with a server or database
- Data sources

You use the [Create](#) command to create a major object on an instance of Microsoft SQL Server Analysis Services, and the [Alter](#) command to alter an existing major object on an instance. Both commands are run using the [Execute](#) method.

Creating Objects

When you create objects by using the **Create** method, you must first identify the parent object that contains the Analysis Services object to be created. You identify the parent object by providing an object reference in the [ParentObject](#) property of the **Create** command. Each object reference contains the object identifiers needed to uniquely identify the parent object for the **Create** command. For more information about object references, see [Defining and Identifying Objects \(XMLA\)](#).

For example, you must provide an object reference to a cube to create a new measure group for the cube. The object reference for the cube in the **ParentObject** property contains both a database identifier and a cube identifier, as the same cube identifier could potentially be used on a different database.

The [ObjectDefinition](#) element contains Analysis Services Scripting Language (ASSL) elements that define the major object to be created. For more information about ASSL, see [Developing with Analysis Services Scripting Language \(ASSL\)](#).

If you set the **AllowOverwrite** attribute of the **Create** command to true, you can overwrite an existing major object that has the specified identifier. Otherwise, an error occurs if a major object that has the specified identifier already exists in the parent object.

For more information about the **Create** command, see [Create Element \(XMLA\)](#).

Creating Session Objects

Session objects are temporary objects that are available only to the explicit or implicit session used by a client application and are deleted when the session is ended. You can create session objects by setting the **Scope**

attribute of the **Create** command to *Session*.

NOTE

When using the *Session* setting, the **ObjectDefinition** element can only contain [Dimension](#), [Cube](#), or [MiningModel](#) ASSL elements.

Altering Objects

When modifying objects by using the **Alter** method, you must first identify the object to be modified by providing an object reference in the **Object** property of the **Alter** command. Each object reference contains the object identifiers needed to uniquely identify the object for the **Alter** command. For more information about object references, see [Defining and Identifying Objects \(XMLA\)](#).

For example, you must provide an object reference to a cube in order to modify the structure of a cube. The object reference for the cube in the **Object** property contains both a database identifier and a cube identifier, as the same cube identifier could potentially be used on a different database.

The **ObjectDefinition** element contains ASSL elements that define the major object to be modified. For more information about ASSL, see [Developing with Analysis Services Scripting Language \(ASSL\)](#).

If you set the **AllowCreate** attribute of the **Alter** command to true, you can create the specified major object if the object does not exist. Otherwise, an error occurs if a specified major object does not already exist.

Using the ObjectExpansion Attribute

If you are changing only the properties of the major object and are not redefining minor objects that are contained by the major object, you can set the **ObjectExpansion** attribute of the **Alter** command to *ObjectProperties*. The **ObjectDefinition** property then only has to contain the elements for the properties of the major object, and the **Alter** command leaves minor objects associated with the major object untouched.

To redefine minor objects for a major object, you must set the **ObjectExpansion** attribute to *ExpandFull* and the object definition must include all minor objects that are contained by the major object. If the **ObjectDefinition** property of the **Alter** command does not explicitly include a minor object that is contained by the major object, the minor object that was not included is deleted.

Altering Session Objects

To modify session objects created by the **Create** command, set the **Scope** attribute of the **Alter** command to *Session*.

NOTE

When using the *Session* setting, the **ObjectDefinition** element can only contain [Dimension](#), [Cube](#), or [MiningModel](#) ASSL elements.

Creating or Altering Subordinate Objects

Although a **Create** or **Alter** command creates or alters only one topmost major object, the major object being created or modified can contain definitions within the enclosing **ObjectDefinition** property for other major and minor objects that are subordinate to it. For example, if you define a cube, you specify the parent database in **ParentObject**, and within the cube definition in **ObjectDefinition** you can define measure groups for the cube, and within the measure groups you can define partitions for each measure group. A minor object can be defined only under the major object that contains it. For more information about major and minor objects, see [Database Objects \(Analysis Services - Multidimensional Data\)](#).

Examples

Description

The following example creates a relational data source that references the Adventure Works DW Multidimensional 2012 sample Microsoft SQL Server database.

Code

```
<Create xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
    <ParentObject>
        <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
    </ParentObject>
    <ObjectDefinition>
        <DataSource xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xsi:type="RelationalDataSource">
            <ID>AdventureWorksDW2012</ID>
            <Name>AdventureWorksDW2012</Name>
            <ConnectionString>Data Source=localhost;Initial Catalog=AdventureWorksDW2008R2;Integrated Security=True</ConnectionString>
            <ImpersonationInfo>
                <ImpersonationMode>ImpersonateServiceAccount</ImpersonationMode>
            </ImpersonationInfo>
            <ManagedProvider>System.Data.SqlClient</ManagedProvider>
            <Timeout>PT0S</Timeout>
        </DataSource>
    </ObjectDefinition>
</Create>
```

Description

The following example alters the relational data source created in the previous example to set the query time-out for the data source to 30 seconds.

Code

```
<Alter ObjectExpansion="ObjectProperties" xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
    <Object>
        <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
        <DataSourceID>AdventureWorksDW2012</DataSourceID>
    </Object>
    <ObjectDefinition>
        <DataSource xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xsi:type="RelationalDataSource">
            <ID>AdventureWorksDW2012</ID>
            <Name>AdventureWorksDW2012</Name>
            <ConnectionString>Data Source=fr-dwk-02;Initial Catalog=AdventureWorksDW2008R2;Integrated Security=True</ConnectionString>
            <ManagedProvider>System.Data.SqlClient</ManagedProvider>
            <Timeout>PT30S</Timeout>
        </DataSource>
    </ObjectDefinition>
</Alter>
```

Comments

The **ObjectExpansion** attribute of the **Alter** command was set to *ObjectProperties*. This setting allows the **ImpersonationInfo** element, a minor object, to be excluded from the data source defined in **ObjectDefinition**. Therefore, the impersonation information for that data source remains set to the service account, as specified in the first example.

[Execute Method \(XMLA\)](#)

[Developing with Analysis Services Scripting Language \(ASSL\)](#)

[Developing with XMLA in Analysis Services](#)

Defining and Identifying Objects (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

Objects are identified in XML for Analysis (XMLA) commands by using object identifiers and object references, and are defined by using Analysis Services Scripting Language (ASSL) elements XMLA commands.

Object Identifiers

An object is identified by using the unique identifier of the object as defined on an instance of Microsoft SQL Server Analysis Services. Object identifiers can either be explicitly specified or determined by the Analysis Services instance when Analysis Services creates the object. You can use the [Discover](#) method to retrieve object identifiers for subsequent [Discover](#) or [Execute](#) method calls.

Object References

Several XMLA commands, such as [Delete](#) or [Process](#), use an object reference to refer to an object in an unambiguous manner. An object reference contains the object identifier of the object on which a command is executed and the object identifiers of the ancestors for that object. For example, the object reference for a partition contains the object identifier of the partition, as well as the object identifiers of that partition's parent measure group, cube, and database.

Object Definitions

The [Create](#) and [Alter](#) commands in XMLA create or alter, respectively, objects on an Analysis Services instance. The definitions for those objects are represented by an [ObjectDefinition](#) element that contains elements from ASSL. Object identifiers can be explicitly specified for all major and many minor objects by using the [ID](#) element. If the [ID](#) element is not used, the Analysis Services instance provides a unique identifier, with a naming convention that depends on the object to be identified. For more information about how to use the [Create](#) and [Alter](#) commands to define objects, see [Creating and Altering Objects \(XMLA\)](#).

[Target Element \(XMLA\)](#)

[Developing with XMLA in Analysis Services](#)

Designing Aggregations (XMLA)

7/16/2019 • 7 minutes to read • [Edit Online](#)

Aggregation designs are associated with the partitions of a particular measure group to make sure that the partitions use the same structure when storing aggregations. Using the same storage structure for partitions lets you to easily define partitions that can be later merged using the [MergePartitions](#) command. For more information about aggregation designs, see [Aggregations and Aggregation Designs](#).

To define aggregations for an aggregation design, you can use the [DesignAggregations](#) command in XML for Analysis (XMLA). The **DesignAggregations** command has properties that identify which aggregation design to use as a reference and how to control the design process based upon that reference. Using the **DesignAggregations** command and its properties, you can design aggregations iteratively or in batch, and then view the resulting design statistics to evaluate the design process.

Specifying an Aggregation Design

The [Object](#) property of the **DesignAggregations** command must contain an object reference to an existing aggregation design. The object reference contains a database identifier, cube identifier, measure group identifier, and aggregation design identifier. If the aggregation design does not already exist, an error occurs.

Controlling the Design Process

You can use the following properties of the **DesignAggregations** command to control the algorithm used to define aggregations for the aggregation design:

- The [Steps](#) property determines how many iterations the **DesignAggregations** command should take before it returns control to the client application.
- The [Time](#) property determines how many milliseconds the **DesignAggregations** command should take before it returns control to the client application.
- The [Optimization](#) property determines the estimated percentage of performance improvement the **DesignAggregations** command should try to achieve. If you are iteratively designing aggregations, you only have to send this property on the first command.
- The [Storage](#) property determines the estimated amount of disk storage, in bytes, used by the **DesignAggregations** command. If you are iteratively designing aggregations, you only have to send this property on the first command.
- The [Materialize](#) property determines whether the **DesignAggregations** command should create the aggregations defined during the design process. If you are iteratively designing aggregations, this property should be set to false until you are ready to save the designed aggregations. When set to true, the current design process ends and the defined aggregations are added to the specified aggregation design.

Specifying Queries

The **DesignAggregations** command supports usage-based optimization command by including one or more [Query](#) elements in the [Queries](#) property. The **Queries** property can contain one or more [Query](#) elements. If the **Queries** property does not contain any [Query](#) elements, the aggregation design specified in the [Object](#) element uses a default structure that contains a general set of aggregations. This general set of aggregations is designed to meet the criteria specified in the [Optimization](#) and [Storage](#) properties of the **DesignAggregations** command.

Each **Query** element represents a goal query that the design process uses to define aggregations that target the most frequently used queries. You can either specify your own goal queries, or you can use the information stored by an instance of Microsoft SQL Server Analysis Services in the query log to retrieve information about the most frequently used queries. The Usage-Based Optimization Wizard uses the query log to retrieve goal queries based on time, usage, or a specified user when it sends a **DesignAggregations** command. For more information, see [Usage-Based Optimization Wizard F1 Help](#).

If you are iteratively designing aggregations, you only have to pass goal queries in the first **DesignAggregations** command because the Analysis Services instance stores these goal queries and uses these queries during subsequent **DesignAggregations** commands. After you pass goal queries in the first **DesignAggregations** command of an iterative process, any subsequent **DesignAggregations** command that contains goal queries in the **Queries** property generates an error.

The **Query** element contains a comma-delimited value that contains the following arguments:

Frequency, Dataset[, Dataset...]

Frequency

A weighting factor that corresponds to the number of times that the query has previously been executed. If the **Query** element represents a new query, the *Frequency* value represents the weighting factor used by the design process to evaluate the query. As the frequency value becomes larger, the weight that is put on the query during the design process increases.

Dataset

A numeric string that specifies which attributes from a dimension are to be included in the query. This string must have the same number of characters as the number of attributes in the dimension. Zero (0) indicates that the attribute in the specified ordinal position is not included in the query for the specified dimension, while one (1) indicates that the attribute in the specified ordinal position is included in the query for the specified dimension.

For example, the string "011" would refer to a query involving a dimension with three attributes, from which the second and third attributes are included in the query.

NOTE

Some attributes are excluded from consideration in the dataset. For more information about excluded attributes, see [Query Element \(XMLA\)](#).

Each dimension in the measure group that contains the aggregation design is represented by a *Dataset* value in the **Query** element. The order of *Dataset* values must match the order of dimensions included in the measure group.

Designing Aggregations Using Iterative or Batch Processes

You can use the **DesignAggregations** command as part of an iterative process or a batch process, depending on the interactivity required by the design process.

Designing Aggregations Using an Iterative Process

To iteratively design aggregations, you send multiple **DesignAggregations** commands to provide fine control over the design process. The Aggregation Design Wizard uses this same approach to provide fine control over the design process. For more information, see [Aggregation Design Wizard F1 Help](#).

NOTE

An explicit session is required to iteratively design aggregations. For more information about explicit sessions, see [Managing Connections and Sessions \(XMLA\)](#).

To start the iterative process, you first send a **DesignAggregations** command that contains the following information:

- The **Storage** and **Optimization** property values on which the whole design process is targeted.
- The **Steps** and **Time** property values on which the first step of the design process is limited.
- If you want usage-based optimization, the **Queries** property that contains the goal queries on which the whole design process is targeted.
- The **Materialize** property set to false. Setting this property to false indicates that the design process does not save the defined aggregations to the aggregation design when the command is completed.

When the first **DesignAggregations** command finishes, the command returns a rowset that contains design statistics. You can evaluate these design statistics to determine whether the design process should continue or whether the design process is finished. If the process should continue, you then send another

DesignAggregations command that contains the **Steps** and **Time** values with which this step of the design process is limited. You evaluate the resulting statistics and then determine whether the design process should continue. This iterative process of sending **DesignAggregations** commands and evaluating the results continues until you reach your goals and have an appropriate set of aggregations defined.

After you have reached the set of aggregations that you want, you send one final **DesignAggregations** command. This final **DesignAggregations** command should have its **Steps** property set to 1 and its **Materialize** property set to true. By using these settings, this final **DesignAggregations** command completes the design process and saves the defined aggregation to the aggregation design.

Designing Aggregations Using a Batch Process

You can also design aggregations in a batch process by sending a single **DesignAggregations** command that contains the **Steps**, **Time**, **Storage**, and **Optimization** property values on which the whole design process is targeted and limited. If you want usage-based optimization, the goal queries on which the design process is targeted should also be included in the **Queries** property. Also make sure that the **Materialize** property is set to true, so that the design process saves the defined aggregations to the aggregation design when the command finishes.

You can design aggregations using a batch process in either an implicit or explicit session. For more information about implicit and explicit sessions, see [Managing Connections and Sessions \(XMLA\)](#).

Returning Design Statistics

When the **DesignAggregations** command returns control to the client application, the command returns a rowset that contains a single row representing the design statistics for the command. The rowset contains the columns listed in the following table.

COLUMN	DATA TYPE	DESCRIPTION
Steps	Integer	The number of steps taken by the command before returning control to the client application.

COLUMN	DATA TYPE	DESCRIPTION
Time	Long integer	The number of milliseconds taken by the command before returning control to the client application.
Optimization	Double	The estimated percentage of performance improvement achieved by the command before returning control to the client application.
Storage	Long integer	The estimated number of bytes taken by the command before returning control to the client application.
Aggregations	Long integer	The number of aggregations defined by the command before returning control to the client application.
LastStep	Boolean	Indicates whether the data in the rowset represents the last step in the design process. If the Materialize property of the command was set to true, the value of this column is set to true.

You can use the design statistics that are contained in the rowset returned after each **DesignAggregations** command in both iterative and batch design. In iterative design, you can use the design statistics to determine and display progress. When you are designing aggregations in batch, you can use the design statistics to determine the number of aggregations created by the command.

[Developing with XMLA in Analysis Services](#)

Developing with XMLA in Analysis Services

7/16/2019 • 4 minutes to read • [Edit Online](#)

XML for Analysis (XMLA) is a SOAP-based XML protocol, designed specifically for universal data access to any standard multidimensional data source that can be accessed over an HTTP connection. Analysis Services uses XMLA as its only protocol when communicating with client applications. Fundamentally, all client libraries supported by Analysis Services formulate requests and responses in XMLA.

As a developer, you can use XMLA to integrate a client application with Analysis Services, without any dependencies on the .NET Framework or COM interfaces. Application requirements that include hosting on a wide range of platforms can be satisfied by using XMLA and an HTTP connection to Analysis Services.

Analysis Services is fully compliant with the 1.1 specification of XMLA, but also extends it to enable data definition, data manipulation, and data control support. Analysis Services extensions are referred to as the Analysis Services Scripting Language (ASSL). Using XMLA and ASSL together enables a broader set of functionality than what XMLA alone provides. For more information about ASSL, see [Developing with Analysis Services Scripting Language \(ASSL\)](#).

In This Section

TOPIC	DESCRIPTION
Managing Connections and Sessions (XMLA)	Describes how to connect to an Analysis Services instance, and how to manage sessions and statefulness in XMLA.
Handling Errors and Warnings (XMLA)	Describes how Analysis Services returns error and warning information for methods and commands in XMLA.
Defining and Identifying Objects (XMLA)	Describes object identifiers and object references, and how to use identifiers and references within XMLA commands.
Managing Transactions (XMLA)	Details how to use the <code>BeginTransaction</code> , <code>CommitTransaction</code> , and <code>RollbackTransaction</code> commands to explicitly define and manage a transaction on the current XMLA session.
Canceling Commands (XMLA)	Describes how to use the <code>Cancel</code> command to cancel commands, sessions, and connections in XMLA.
Performing Batch Operations (XMLA)	Describes how to use the <code>Batch</code> command to run multiple XMLA commands, in serial or in parallel, either within the same transaction or as separate transactions, using a single XMLA <code>Execute</code> method.
Creating and Altering Objects (XMLA)	Describes how to use the <code>Create</code> , <code>Alter</code> , and <code>Delete</code> commands, along with Analysis Services Scripting Language (ASSL) elements, to define, change, or remove objects from an Analysis Services instance.
Locking and Unlocking Databases (XMLA)	Details how to use the <code>Lock</code> and <code>Unlock</code> commands to lock and unlock an Analysis Services database.

TOPIC	DESCRIPTION
Processing Objects (XMLA)	Describes how to use the Process command to process an Analysis Services object.
Merging Partitions (XMLA)	Describes how to use the MergePartitions command to merge partitions on an Analysis Services instance.
Designing Aggregations (XMLA)	Describes how to use the DesignAggregations command, either in iterative or batch mode, to design aggregations for an aggregation design in Analysis Services.
Backing Up, Restoring, and Synchronizing Databases (XMLA)	Describes how to use the Backup and Restore commands to back up and restore an Analysis Services database from a backup file. Also describes how to use the Synchronize command to synchronize an Analysis Services database with an existing database on the same instance or on a different instance.
Inserting, Updating, and Dropping Members (XMLA)	Describes how to use the Insert , Update , and Drop commands to add, change, or delete members from a write-enabled dimension.
Updating Cells (XMLA)	Describes how to use the UpdateCells command to change the values of cells in a write-enabled partition.
Managing Caches (XMLA)	Details how to use the ClearCache command to clear the caches of Analysis Services objects.
Monitoring Traces (XMLA)	Describes how to use the Subscribe command to subscribe to and monitor an existing trace on an Analysis Services instance.

Data Mining with XMLA

XML for Analysis fully supports data mining schema rowsets. These rowsets provide information for querying data mining models using the [Discover](#) method. For more information about data mining schema rowsets, see [Data Mining Schema Rowsets](#)

For more information about DMX, see [Data Mining Extensions \(DMX\) Reference](#).

Namespace and Schema

Namespace

The schema defined in this specification uses the XML namespace

`http://schemas.microsoft.com/AnalysisServices/2003/Engine` and the standard abbreviation "DDL."

Schema

The definition of an XML Schema definition language (XSD) schema for the Analysis Services object definition language is based on the definition of the schema elements and hierarchy in this section.

Extensibility

Extensibility of the object definition language schema is provided by means of an [Annotation](#) element that is included on all objects. This element can contain any valid XML from any XML namespace (other than the

target namespace that defines the DDL), subject to the following rules:

- The XML can contain only elements.
- Each element must have a unique name. It is recommended that the value of **Name** reference the target namespace.

These rules are imposed so that the contents of the **Annotation** tag can be exposed as a set of Name/Value pairs through Decision Support Objects (DSO) 9.0.

Comments and white space within the **Annotation** tag that are not enclosed with a child element may not be preserved. In addition, all elements must be read-write; read-only elements are ignored.

The object definition language schema is closed, in that the server does not allow substitution of derived types for elements defined in the schema. Therefore, the server accepts only the set of elements defined here, and no other elements or attributes. Unknown elements cause the Analysis Services engine to raise an error.

[Understanding Microsoft OLAP Architecture](#)

Handling Errors and Warnings (XMLA)

7/16/2019 • 4 minutes to read • [Edit Online](#)

Error handling is required when an XML for Analysis (XMLA) [Discover](#) or [Execute](#) method call does not run, runs successfully but generates errors or warnings, or runs successfully but returns results that contain errors.

ERROR	REPORTING
The XMLA method call does not run	<p>Microsoft SQL Server Analysis Services returns a SOAP fault message that contains the details of the failure.</p> <p>For more information, see the section, Handling SOAP Faults.</p>
Errors or warnings on a successful method call	<p>Analysis Services includes an error or warning element for each error or warning, respectively, in the Messages property of the root element that contains the results of the method call.</p> <p>For more information, see the section, Handling Errors and Warnings.</p>
Errors in the result for a successful method call	<p>Analysis Services includes an inline error or warning element for the error or warning, respectively, within the appropriate Cell or row element of the results of the method call.</p> <p>For more information, see the section, Handling Inline Errors and Warnings.</p>

Handling SOAP Faults

Analysis Services returns a SOAP fault when the following situations occur:

- The SOAP message that contains the XMLA method was not well-formed or could not be validated by the Analysis Services instance.
- A communications or other error occurred involving the SOAP message that contains the XMLA method.
- The XMLA method did not run on the Analysis Services instance.

The SOAP fault codes for XMLstartA start with "XMLForAnalysis", followed by a period and the hexadecimal HRESULT result code. For example, an error code of "`0x80000005`" is formatted as "`XMLForAnalysis.0x80000005`".

For more information about the SOAP fault format, see Soap Fault in the W3C Simple Object Access Protocol (SOAP) 1.1.

Fault Code Information

The following table shows the XMLA fault code information that is contained in the detail section of the SOAP response. The columns are the attributes of an error in the detail section of a SOAP fault.

COLUMN NAME	TYPE	DESCRIPTION	NULL ALLOWED ¹
-------------	------	-------------	---------------------------

COLUMN NAME	TYPE	DESCRIPTION	NULL ALLOWED
ErrorCode	UnsignedInt	Return code that indicates the success or failure of the method. The hexadecimal value must be converted to an UnsignedInt value.	No
WarningCode	UnsignedInt	Return code that indicates a warning condition. The hexadecimal value must be converted to an UnsignedInt value.	Yes
Description	String	Error or warning text and description returned by the component that generated the error.	Yes
Source	String	Name of the component that generated the error or warning.	Yes
HelpFile	String	Path or URL to the Help file or topic that describes the error or warning.	Yes

¹ Indicates whether the data is required and must be returned, or whether the data is optional and a null string is allowed if the column does not apply.

The following is an example of a SOAP fault that occurred when a method call failed:

```
<?xml version="1.0"?>
<SOAP-ENV:Envelope
  xmlns:SOAP-ENV="http://schemas.xmlsoap.org/soap/envelope/"
  SOAP-ENV:encodingStyle="http://schemas.xmlsoap.org/soap/encoding/">
  <SOAP-ENV:Fault>
    <faultcode>XMLAnalysisError.0x80000005</faultcode>
    <faultstring>The XML for Analysis provider encountered an error.</faultstring>
    <faultactor>XML for Analysis Provider</faultactor>
    <detail>
      <Error
        ErrorCode="2147483653"
        Description="An unexpected error has occurred."
        Source="XML for Analysis Provider"
        HelpFile="" />
      </detail>
    </SOAP-ENV:Fault>
  </SOAP-ENV:Envelope>
```

Handling Errors and Warnings

Analysis Services returns the **Messages** property in the **root** element for a command if the following situations occur after that command runs:

- The method itself did not fail, but a failure occurred on the Analysis Services instance after the method call succeeded.
- The Analysis Services instance returns a warning when the command is successful.

The **Messages** property follows all other properties that are contained by the **root** element, and can contain one or more **Message** elements. In turn, each **Message** element can contain either a single **error** or **warning** element describing any errors or warnings, respectively, that occurred for the specified command.

For more information about errors and warnings that are contained in the **Messages** property, see [Messages Element \(XMLA\)](#).

Handling Errors During Serialization

If an error occurs after the Analysis Services instance has already begun serializing the output of a successfully run command, Analysis Services returns an **Exception** element in a different namespace at the point of the error. The Analysis Services instance then closes all open elements so that the XML document sent to the client is a valid document. The instance also returns a **Messages** element that contains the description of the error.

Handling Inline Errors and Warnings

Analysis Services returns an inline **error** or **warning** for a command if the XMLA method itself did not fail, but an error specific to a data element in the results returned by the method occurred on the Analysis Services instance after the XMLA method call succeeded.

Analysis Services supplies inline **error** and **warning** elements if issues specific to a cell or to other data that are contained within a **root** element using the **MDDDataSet** data type occur, such as a security error or formatting error for a cell. In these cases, Analysis Services returns an **error** or **warning** element in the **Cell** or **row** element that contains the error or warning, respectively.

The following example illustrates a result set that contains an error in the rowset returned from an **Execute** method using the **Statement** command.

```
<return>
  ...
<root>
  ...
  <CellData>
    ...
      <Cell CellOrdinal="10">
        <Value>
          <Error>
            <ErrorCode>2148497527</ErrorCode>
            <Description>Security Error.</Description>
          </Error>
        </Value>
      </Cell>
    </CellData>
    ...
  </root>
  ...
</return>
```

[Developing with XMLA in Analysis Services](#)

Inserting, Updating, and Dropping Members (XMLA)

7/16/2019 • 5 minutes to read • [Edit Online](#)

You can use the [Insert](#), [Update](#), and [Drop](#) commands in XML for Analysis (XMLA) to respectively insert, update, or delete members from a write-enabled dimension. For more information about write-enabled dimensions, see [Write-Enabled Dimensions](#).

Inserting New Members

The **Insert** command inserts new members into specified attributes in a write-enabled dimension.

Before constructing the **Insert** command, you should have the following information available for the new members to be inserted:

- The dimension in which to insert the new members.
- The dimension attribute in which to insert the new members.
- The names of the new members, including any applicable translations for the name.
- The keys of the new members. If an attribute uses a composite key, the key may require multiple values.
- Values for any applicable attribute properties that are not implemented as other attributes within the dimension. Such attribute properties include unary operations, translations, custom rollups, custom rollup properties, and skipped levels.

The **Insert** command takes only two properties:

- The [Object](#) property, which contains an object reference for the dimension in which the members are to be inserted. The object reference contains the database identifier, cube identifier, and dimension identifier for the dimension.
- The [Attributes](#) property, which contains one or more [Attribute](#) elements to identify the attributes in which members are to be inserted. Each **Attribute** element identifies an attribute and provides the name, value, translations, unary operator, custom rollup, custom rollup properties, and skipped levels for a single member to be added to the identified attribute.

NOTE

All properties for the **Attribute** element must be included. Otherwise, an error may occur.

Updating Existing Members

The **Update** command updates existing members in specified attributes, based on relationships with other members in other attributes, in a write-enabled dimension. The **Update** command can move members to other levels in hierarchies contained by the dimension, and can be used to restructure parent-child hierarchies defined by parent attributes.

Before constructing the **Update** command, you should have the following information available for the members to be updated:

- The dimension in which to update existing members.
- The dimension attributes in which to update existing members.

- The keys of the existing members. If an attribute uses a composite key, the key may require multiple values.
- Values for any applicable attribute properties that are not implemented as other attributes within the dimension. Such attribute properties include unary operations, translations, custom rollups, custom rollup properties, and skipped levels.

The **Update** command takes only three required properties:

- The **Object** property, which contains an object reference for the dimension in which the members are to be updated. The object reference contains the database identifier, cube identifier, and dimension identifier for the dimension.
- The **Attributes** property, which contains one or more **Attribute** elements to identify the attributes in which members are to be updated. The **Attribute** element identifies an attribute and provides the name, value, translations, unary operator, custom rollup, custom rollup properties, and skipped levels for a single member updated for the identified attribute.

NOTE

All properties for the **Attribute** element must be included. Otherwise, an error may occur.

- The **Where** property, which contains one or more **Attribute** elements that constrain the attributes in which members are to be updated. The **Where** property is crucial to limiting an **Update** command to specific instances of a member. If the **Where** property is not specified, all instances of a given member are updated. For example, there are three customers for whom you want to change the city name from Redmond to Bellevue. To change the city name, you must provide a **Where** property that identifies the three members in the Customer attribute for which the members in the City attribute should be changed. If you do not provide this **Where** property, every customer whose city name is currently Redmond would have the city name of Bellevue after the **Update** command runs.

NOTE

With the exception of new members, the **Update** command can only update attribute key values for attributes not included in the **Where** clause. For example, the city name cannot be updated when a customer is updated; otherwise, the city name is changed for all customers.

Updating Members in Parent Attributes

To support parent attributes, the **Update** command has the optional **MoveWithDescendants** property. Setting the **MoveWithDescendants** property to true indicates that the descendants of the parent member should also be moved with the parent member when the identifier of that parent member changes. If this value is set to false, moving a parent member causes the immediate descendants of that parent member to be promoted to the level in which the parent member formerly resided.

When updating members in a parent attribute, the **Update** command cannot update members in other attributes.

Dropping Existing Members

Before constructing the **Drop** command, you should have the following information available for the members to be dropped:

- The dimension in which to drop existing members.
- The dimension attributes in which to drop existing members.
- The keys of the existing members to be dropped. If an attribute uses a composite key, the key may require

multiple values.

The **Drop** command takes only two required properties:

- The **Object** property, which contains an object reference for the dimension in which the members are to be dropped. The object reference contains the database identifier, cube identifier, and dimension identifier for the dimension.
- The **Where** property, which contains one or more **Attribute** elements to constrain the attributes in which members are to be deleted. The **Where** property is crucial to limiting a **Drop** command to specific instances of a member. If the **Where** command is not specified, all instances of a given member are dropped. For example, there are three customers that you want to drop from Redmond. To drop these customers, you must provide a **Where** property that identifies the three members in the Customer attribute to be removed and the Redmond member of the City attribute from which the three customers are to be removed. If the **Where** property only specifies the Redmond member of the City attribute, every customer associated with Redmond would be dropped by the **Drop** command. If the **Where** property only specifies the three members in the Customer attribute, the three customers would be deleted entirely by the **Drop** command.

NOTE

The **Attribute** elements included in a **Drop** command must contain only the **AttributeName** and **Keys** properties. Otherwise, an error may occur.

Dropping Members in Parent Attributes

Setting the [DeleteWithDescendants](#) property indicates that the descendants of a parent member should also be deleted with the parent member. If this value is set to false, the immediate descendants of the parent member are instead promoted to the level in which the parent member formerly resided.

IMPORTANT

A user needs only to have delete permissions for the parent member to delete both the parent member and its descendants. A user does not need delete permissions on the descendants.

[Defining and Identifying Objects \(XMLA\)](#)

[Developing with XMLA in Analysis Services](#)

Locking and Unlocking Databases (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

You can lock and unlock databases using, respectively, the [Lock](#) and [Unlock](#) commands in XML for Analysis (XMLA). Typically, other XMLA commands automatically lock and unlock objects as needed to complete the command during execution. You can explicitly lock or unlock a database to perform multiple commands within a single transaction, such as a [Batch](#) command, while preventing other applications from committing a write transaction to the database.

Locking Databases

The **Lock** command locks an object, either for shared or exclusive use, within the context of the currently active transaction. A lock on an object prevents transactions from committing until the lock is removed. Microsoft SQL Server Analysis Services supports two types of locks, shared locks and exclusive locks. For more information about the lock types supported by Analysis Services, see [Mode Element \(XMLA\)](#).

Analysis Services allows only databases to be locked. The **Object** element must contain an object reference to an Analysis Services database. If the **Object** element is not specified or if the **Object** element refers to an object other than a database, an error occurs.

IMPORTANT

Only database administrators or server administrators can explicitly issue a **Lock** command.

Other commands implicitly issue a **Lock** command on an Analysis Services database. Any operation that reads data or metadata from a database, such as any [Discover](#) method or an [Execute](#) method running a [Statement](#) command, implicitly issues a shared lock on the database. Any transaction that commits changes in data or metadata to an object on an Analysis Services database, such as an [Execute](#) method running an [Alter](#) command, implicitly issues an exclusive lock on the database.

Unlocking Objects

The **Unlock** command removes a lock established within the context of the currently active transaction.

IMPORTANT

Only database administrators or server administrators can explicitly issue an **Unlock** command.

All locks are held in the context of the current transaction. When the current transaction is committed or rolled back, all locks defined within the transaction are automatically released.

[Developing with XMLA in Analysis Services](#)

Managing Caches (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

You can use the [ClearCache](#) command in XML for Analysis (XMLA) to clear the cache of a specified dimension or partition. Clearing the cache forces Microsoft SQL Server Analysis Services to rebuild the cache for that object.

Specifying Objects

The [Object](#) property of the **ClearCache** command can contain an object reference only for one of the following objects. An error occurs if an object reference is for an object other than one of following objects:

Database

Clears the cache for all dimensions and partitions contained in the database.

Dimension

Clears the cache for the specified dimension.

Cube

Clears the cache for all partitions contained in the measure groups for the cube.

Measure group

Clears the cache for all partitions contained in the measure group.

Partition

Clears the cache for the specified partition.

[Developing with XMLA in Analysis Services](#)

Managing Connections and Sessions (XMLA)

7/16/2019 • 3 minutes to read • [Edit Online](#)

Statefulness is a condition during which the server preserves the identity and context of a client between method calls. *Statelessness* is a condition during which the server does not remember the identity and context of a client after a method call finishes.

To provide statefulness, XML for Analysis (XMLA) supports *sessions* that allow a series of statements to be performed together. An example of such a series of statements would be the creation of a calculated member that is to be used in subsequent queries.

In general, sessions in XMLA follow the following behavior outlined by the OLE DB 2.6 specification:

- Sessions define transaction and command context scope.
- Multiple commands can be run in the context of a single session.
- Support for transactions in the XMLA context is through provider-specific commands sent with the [Execute](#) method.

XMLA defines a way to support sessions in a Web environment in a mode similar to the approach used by the Distributed Authoring and Versioning (DAV) protocol to implement locking in a loosely coupled environment. This implementation parallels DAV in that the provider is allowed to expire sessions for various reasons (for example, a timeout or connection error). When sessions are supported, Web services must be aware and ready to handle interrupted sets of commands that must be restarted.

The World Wide Web Consortium (W3C) Simple Object Access Protocol (SOAP) specification recommends using SOAP headers for building up new protocols on top of SOAP messages. The following table lists the SOAP header elements and attributes that XMLA defines for initiating, maintaining, and closing a session.

SOAP HEADER	DESCRIPTION
BeginSession	This header requests the provider to create a new session. The provider should respond by constructing a new session and returning the session ID as part of the Session header in the SOAP response.
SessionId	The value area contains the session ID that must be used in each method call for the rest of the session. The provider in the SOAP response sends this tag and the client must also send this attribute with each Session header element.
Session	For every method call that occurs in the session, this header must be used, and the session ID must be included in the value area of the header.
EndSession	To terminate the session, use this header. The session ID must be included with the value area.

NOTE

A session ID does not guarantee that a session stays valid. If the session expires (for example, if it times out or the connection is lost), the provider can choose to end and roll back that session's actions. As a result, all subsequent method calls from the client on a session ID fail with an error signaling a session that is not valid. A client should handle this condition and be prepared to resend the session method calls from the beginning.

Legacy Code Example

The following example shows how sessions are supported.

1. To begin the session, add a `BeginSession` header in SOAP to the outbound XMLA method call from the client. The value area is initially blank because the session ID is not yet known.

```
<SOAP-ENV:Envelope
  xmlns:SOAP-ENV="http://schemas.xmlsoap.org/soap/envelope/"
  SOAP-ENV:encodingStyle="http://schemas.xmlsoap.org/soap/encoding/">
  <SOAP-ENV:Header>
    <XA:BeginSession
      xmlns:XA="urn:schemas-microsoft-com:xml-analysis"
      xsi:type="xsd:int"
      mustUnderstand="1"/>
  </SOAP-ENV:Header>
  <SOAP-ENV:Body>
    ...!-- Discover or Execute call goes here.-->
  </SOAP-ENV:Body>
</SOAP-ENV:Envelope>
```

2. The SOAP response message from the provider includes the session ID in the return header area, using the XMLA header tag `<SessionId>`.

```
<SOAP-ENV:Header>
  <XA:Session
    xmlns:XA="urn:schemas-microsoft-com:xml-analysis"
    SessionId="581"/>
</SOAP-ENV:Header>
```

3. For each method call in the session, the Session header must be added, containing the session ID returned from the provider.

```
<SOAP-ENV:Header>
  <XA:Session
    xmlns:XA="urn:schemas-microsoft-com:xml-analysis"
    mustUnderstand="1"
    SessionId="581"/>
</SOAP-ENV:Header>
```

4. When the session is complete, the `<EndSession>` tag is used, containing the related session ID value.

```
<SOAP-ENV:Header>
  <XA:EndSession
    xmlns:XA="urn:schemas-microsoft-com:xml-analysis"
    xsi:type="xsd:int"
    mustUnderstand="1"
    SessionId="581"/>
</SOAP-ENV:Header>
```

Managing Transactions (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

Every XML for Analysis (XMLA) command sent to an instance of Microsoft SQL Server Analysis Services runs within the context of a transaction on the current implicit or explicit session. To manage each of these transactions, you use the **BeginTransaction**, **CommitTransaction**, and **RollbackTransaction** commands. By using these commands, you can create implicit or explicit transactions, change the transaction reference count, as well as start, commit, or roll back transactions.

Implicit and Explicit Transactions

A transaction is either implicit or explicit:

Implicit transaction

Analysis Services creates an *implicit* transaction for an XMLA command if the **BeginTransaction** command does not specify the start of a transaction. Analysis Services always commits an implicit transaction if the command succeeds, and rolls back an implicit transaction if the command fails.

Explicit transaction

Analysis Services creates an *explicit* transaction if the **BeginTransaction** command starts of a transaction. However, Analysis Services only commits an explicit transaction if a **CommitTransaction** command is sent, and rolls back an explicit transaction if a **RollbackTransaction** command is sent.

In addition, Analysis Services rolls back both implicit and explicit transactions if the current session ends before the active transaction completes.

Transactions and Reference Counts

Analysis Services maintains a transaction reference count for each session. However, Analysis Services does not support nested transactions in that only one active transaction is maintained per session. If the current session does not have an active transaction, the transaction reference count is set to zero.

In other words, each **BeginTransaction** command increments the reference count by one, while each **CommitTransaction** command decrements the reference count by one. If a **CommitTransaction** command sets the transaction count to zero, Analysis Services commits the transaction.

However, the **RollbackTransaction** command rolls back the active transaction regardless of the current value of the transaction reference count. In other words, a single **RollbackTransaction** command rolls back the active transaction, no matter how many **BeginTransaction** commands or **CommitTransaction** commands were sent, and sets the transaction reference count to zero.

Beginning a Transaction

The **BeginTransaction** command begins an explicit transaction on the current session and increments the transaction reference count for the current session by one. All subsequent commands are considered to be within the active transaction, until either enough **CommitTransaction** commands are sent to commit the active transaction or a single **RollbackTransaction** command is sent to roll back the active transaction.

Committing a Transaction

The **CommitTransaction** command commits the results of commands that are run after the **BeginTransaction**

command was run on the current session. Each **CommitTransaction** command decrements the reference count for active transactions on a session. If a **CommitTransaction** command sets the reference count to zero, Analysis Services commits the active transaction. If there is no active transaction (in other words, the transaction reference count for the current session is already set to zero), a **CommitTransaction** command results in an error.

Rolling Back a Transaction

The **RollbackTransaction** command rolls back the results of commands that are run after the **BeginTransaction** command was run on the current session. The **RollbackTransaction** command rolls back the active transaction, regardless of the current transaction reference count, and sets the transaction reference count to zero. If there is no active transaction (in other words, the transaction reference count for the current session is already set to zero), a **RollbackTransaction** command results in an error.

Merging Partitions (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

If partitions have the same aggregation design and structure, you can merge the partition by using the **MergePartitions** command in XML for Analysis (XMLA). Merging partitions is an important action to perform when you manage partitions, especially those partitions that contain historical data partitioned by date.

For example, a financial cube may use two partitions:

- One partition represents financial data for the current year, using real-time relational OLAP (ROLAP) storage settings for performance.
- Another partition contains financial data for previous years, using multidimensional OLAP (MOLAP) storage settings for storage.

Both partitions use different storage settings, but use the same aggregation design. Instead of processing the cube across years of historical data at the end of the year, you can instead use the **MergePartitions** command to merge the partition for the current year into the partition for previous years. This preserves the aggregation data without requiring a potentially time-consuming full processing of the cube.

Specifying Partitions to Merge

When the **MergePartitions** command runs, the aggregation data stored in the source partitions specified in the **Source** property is added to the target partition specified in the **Target** property.

NOTE

The **Source** property can contain more than one partition object reference. However, the **Target** property cannot.

To be successfully merged, the partitions specified in both the **Source** and **Target** must be contained by the same measure group and use the same aggregation design. Otherwise, an error occurs.

The partitions specified in the **Source** are deleted after the **MergePartitions** command is successfully completed.

Examples

Description

The following example merges all the partitions in the **Customer Counts** measure group of the **Adventure Works** cube in the **Adventure Works DW** sample Microsoft SQL Server Analysis Services database into the **Customers_2004** partition.

Code

```
<MergePartitions xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Sources>
    <Source>
      <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
      <CubeID>Adventure Works DW</CubeID>
      <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
      <PartitionID>Internet_Sales_2001</PartitionID>
    </Source>
    <Source>
      <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
      <CubeID>Adventure Works DW</CubeID>
      <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
      <PartitionID>Internet_Sales_2002</PartitionID>
    </Source>
    <Source>
      <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
      <CubeID>Adventure Works DW</CubeID>
      <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
      <PartitionID>Internet_Sales_2003</PartitionID>
    </Source>
  </Sources>
  <Target>
    <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
    <CubeID>Adventure Works DW</CubeID>
    <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
    <PartitionID>Internet_Sales_2004</PartitionID>
  </Target>
</MergePartitions>
```

Monitoring Traces (XMLA)

7/16/2019 • 3 minutes to read • [Edit Online](#)

You can use the **Subscribe** command in XML for Analysis (XMLA) to monitor an existing trace defined on an instance of Microsoft SQL Server Analysis Services. The **Subscribe** command returns the results of a trace as a rowset.

Specifying a Trace

The **Object** property of the **Subscribe** command must contain an object reference to either an Analysis Services instance or a trace on an Analysis Services instance. If the **Object** property is not specified, or a trace identifier is not specified in the **Object** property, the **Subscribe** command monitors the default session trace for the explicit session specified in the SOAP header for the command.

Returning Results

The **Subscribe** command returns a rowset containing the trace events captured by the specified trace. The **Subscribe** command returns trace results until the command is canceled by the **Cancel** command.

The rowset contains the columns listed in the following table.

COLUMN	DATA TYPE	DESCRIPTION
EventClass	Integer	The event class of the event received by the trace.
EventSubclass	Long integer	The event subclass of the event received by the trace.
CurrentTime	Datetime	The time at which the event started, when available. For filtering, expected formats are 'YYYY-MM-DD' and 'YYYY-MM-DD HH:MM:SS'.
StartTime	Datetime	The time at which the event started, when available. For filtering, expected formats are 'YYYY-MM-DD' and 'YYYY-MM-DD HH:MM:SS'.
EndTime	Datetime	The time at which the event ended, when available. For filtering, expected formats are 'YYYY-MM-DD' and 'YYYY-MM-DD HH:MM:SS'. This column is not populated for event classes that describe the start of a process or action.
Duration	Long integer	The amount of total time (in milliseconds) elapsed for the event.
CPUTime	Long integer	The amount of processor time (in milliseconds) elapsed for the event.

COLUMN	DATA TYPE	DESCRIPTION
JobID	Long integer	The job identifier for the process.
SessionID	String	The identifier of the session for which the event occurred.
SessionType	String	The type of the session for which the event occurred.
ProgressTotal	Long integer	The total number or amount of progress reported by the event.
IntegerData	Long integer	Integer data associated with the event. The contents of this column depend on the event class and subclass of the event.
ObjectID	String	The identifier of the object for which the event occurred.
ObjectType	String	The type of the object specified in ObjectName.
ObjectName	String	The name of the object for which the event occurred.
ObjectPath	String	The hierarchical path of the object for which the event occurred. The path is represented as a comma-delimited string of object identifiers for the parents of the object specified in ObjectName.
ObjectReference	String	The XML representation of the object reference for the object specified in ObjectName.
NestLevel	Integer	The level of the transaction for which the event occurred.
NumSegments	Long integer	The number of data segments affected or accessed by the command for which the event occurred.

COLUMN	DATA TYPE	DESCRIPTION
Severity	Integer	<p>The severity level of an exception for the event. The column can contain one of the following values:</p> <ul style="list-style-type: none"> 0: Success 1: Information 2: Warning 3: Error
Success	Boolean	Indicates whether a command succeeded or failed.
Error	Long integer	The error number of the event, if applicable.
ConnectionID	String	The identifier of the connection for which the event occurred.
DatabaseName	String	The name of the database for which the event occurred.
NTUserName	String	The Windows user name of the user associated with the event.
NTDomainName	String	The Windows domain of the user associated with the event.
ClientHostName	String	The name of the computer on which the client application is running. This column is populated with the values passed by the client application.
ClientProcessID	Long integer	The process identifier of the client application.
ApplicationName	String	The name of the client application that created the connection to the Analysis Services instance. This column is populated with the values passed by the client application, rather than the displayed name of the program.
NTCanonicalUserName	String	The Windows canonical user name of the user associated with the event.

COLUMN	DATA TYPE	DESCRIPTION
SPID	String	The server process ID (SPID) of the session for which the event occurred. The value of this column directly corresponds to the session ID specified in the SOAP header of the XMLA message for which the event occurred.
TextData	String	The text data associated with the event. The contents of this column depend on the event class and subclass of the event.
ServerName	String	The name of the Analysis Services instance for which the event occurred.
RequestParameters	String	The parameters of the parameterized query or XMLA command for which the event occurred.
RequestProperties	String	The properties of the XMLA method for which the event occurred.

[Developing with XMLA in Analysis Services](#)

Performing Batch Operations (XMLA)

7/16/2019 • 6 minutes to read • [Edit Online](#)

You can use the **Batch** command in XML for Analysis (XMLA) to run multiple XMLA commands using a single XMLA **Execute** method. You can run multiple commands contained in the **Batch** command either as a single transaction or in individual transactions for each command, in serial or in parallel. You can also specify out-of-line bindings and other properties in the **Batch** command for processing multiple Microsoft SQL Server Analysis Services objects.

Running Transactional and Nontransactional Batch Commands

The **Batch** command executes commands in one of two ways:

Transactional

If the **Transaction** attribute of the **Batch** command is set to true, the **Batch** command runs all of the commands contained by the **Batch** command in a single transaction—a *transactional* batch.

If any command fails in a transactional batch, Analysis Services rolls back any command in the **Batch** command that ran before the command that failed and the **Batch** command immediately ends. Any commands in the **Batch** command that have not yet run are not executed. After the **Batch** command ends, the **Batch** command reports any errors that occurred for the failed command.

Nontransactional

If the **Transaction** attribute is set to false, the **Batch** command runs each command contained by the **Batch** command in a separate transaction—a *nontransactional* batch. If any command fails in a nontransactional batch, the **Batch** command continues to run commands after the command which failed. After the **Batch** command tries to run all the commands that the **Batch** command contains, the **Batch** command reports any errors that occurred.

All results returned by commands contained in a **Batch** command are returned in the same order in which the commands are contained in the **Batch** command. The results returned by a **Batch** command vary based on whether the **Batch** command is transactional or nontransactional.

NOTE

If a **Batch** command contains a command that does not return output, such as the **Lock** command, and that command successfully runs, the **Batch** command returns an empty **root** element within the results element. The empty **root** element ensures that each command contained in a **Batch** command can be matched with the appropriate **root** element for that command's results.

Returning Results from Transactional Batch Results

Results from commands run within a transactional batch are not returned until the entire **Batch** command is completed. The results are not returned after each command runs because any command that fails within a transactional batch would cause the entire **Batch** command and all containing commands to be rolled back. If all commands start and run successfully, the **return** element of the **ExecuteResponse** element returned by the **Execute** method for the **Batch** command contains one **results** element, which in turn contains one **root** element for each successfully run command contained in the **Batch** command. If any command in the **Batch** command cannot be started or fails to complete, the **Execute** method returns a SOAP fault for the **Batch** command that contains the error of the command that failed.

Returning Results from Nontransactional Batch Results

Results from commands run within a nontransactional batch are returned in the order in which the commands are

contained within the **Batch** command and as they are returned by each command. If no command contained in the **Batch** command can be successfully started, the **Execute** method returns a SOAP fault that contains an error for the **Batch** command. If at least one command is successfully started, the **return** element of the **ExecuteResponse** element returned by the **Execute** method for the **Batch** command contains one **results** element, which in turn contains one **root** element for each command contained in the **Batch** command. If one or more commands in a nontransactional batch cannot be started or fails to complete, the **root** element for that failed command contains an **error** element describing the error.

NOTE

As long as at least one command in a nontransactional batch can be started, the nontransactional batch is considered to have successfully run, even if every command contained in the nontransactional batch returns an error in the results of the **Batch** command.

Using Serial and Parallel Execution

You can use the **Batch** command to run included commands in serial or in parallel. When the commands are run in serial, the next command included in the **Batch** command cannot start until the currently running command in the **Batch** command is completed. When the commands are run in parallel, multiple commands can be executed simultaneously by the **Batch** command.

To run commands in parallel, you add the commands to be run in parallel to the **Parallel** property of the **Batch** command. Currently, Analysis Services can run only contiguous, sequential **Process** commands in parallel. Any other XMLA command, such as **Create** or **Alter**, included in the **Parallel** property is run serially.

Analysis Services tries to run all **Process** commands included in the **Parallel** property in parallel, but cannot guarantee that all included **Process** commands can be run in parallel. The instance analyzes each **Process** command and, if the instance determines that the command cannot be run in parallel, the **Process** command is run in serial.

NOTE

To run commands in parallel, the **Transaction** attribute of the **Batch** command must be set to true because Analysis Services supports only one active transaction per connection and nontransactional batches run each command in a separate transaction. If you include the **Parallel** property in a nontransactional batch, an error occurs.

Limiting Parallel Execution

An Analysis Services instance tries to run as many **Process** commands in parallel as possible, up to the limits of the computer on which the instance runs. You can limit the number of concurrently executing **Process** commands by setting the **maxParallel** attribute of the **Parallel** property to a value indicating the maximum number of **Process** commands that can be run in parallel.

For example, a **Parallel** property contains the following commands in the sequence listed:

1. **Create**
2. **Process**
3. **Alter**
4. **Process**
5. **Process**
6. **Process**

7. Delete

8. Process

9. Process

The **maxParallel** attribute of this **Parallel** property is set to 2. Therefore, the instance runs the previous lists of commands as described in the following list:

- Command 1 runs serially because command 1 is a **Create** command and only **Process** commands can be run in parallel.
- Command 2 runs serially after command 1 is completed.
- Command 3 runs serially after command 2 is completed.
- Commands 4 and 5 run in parallel after command 3 is completed. Although command 6 is also a **Process** command, command 6 cannot run in parallel with commands 4 and 5 because the **maxParallel** property is set to 2.
- Command 6 runs serially after both commands 4 and 5 are completed.
- Command 7 runs serially after command 6 is completed.
- Commands 8 and 9 run in parallel after command 7 is completed.

Using the Batch Command to Process Objects

The **Batch** command contains several optional properties and attributes specifically included to support processing multiple Analysis Services projects:

- The **ProcessAffectedObjects** attribute of the **Batch** command indicates whether the instance should also process any object that requires reprocessing as a result of a **Process** command included in the **Batch** command processing a specified object.
- The **Bindings** property contains a collection of out-of-line bindings used by all of the **Process** commands in the **Batch** command.
- The **DataSource** property contains an out-of-line binding for a data source used by all of the **Process** commands in the **Batch** command.
- The **DataSourceView** property contains an out-of-line binding for a data source view used by all of the **Process** commands in the **Batch** command.
- The **ErrorConfiguration** property specifies the way in which the **Batch** command handles errors encountered by all **Process** commands contained in the **Batch** command.

IMPORTANT

A **Process** command cannot include the **Bindings**, **DataSource**, **DataSourceView**, or **ErrorConfiguration** properties, if the **Process** command is contained in a **Batch** command. If you must specify these properties for a **Process** command, provide the necessary information in the corresponding properties of the **Batch** command that contains the **Process** command.

[Processing a multidimensional model \(Analysis Services\)](#)

Processing Objects (XMLA)

7/16/2019 • 5 minutes to read • [Edit Online](#)

In Microsoft SQL Server Analysis Services, processing is the step or series of steps that turn data into information for business analysis. Processing is different depending on the type of object, but processing is always part of turning data into information.

To process an Analysis Services object, you can use the [Process](#) command. The **Process** command can process the following objects on an Analysis Services instance:

- Cubes
- Databases
- Dimensions
- Measure groups
- Mining models
- Mining structures
- Partitions

To control the processing of objects, the **Process** command has various properties that can be set. The **Process** command has properties that control: how much processing will be done, which objects will be processed, whether to use out-of-line bindings, how to handle errors, and how to manage writeback tables.

Specifying Processing Options

The [Type](#) property of the **Process** command specifies the processing option to use when processing the object. For more information about processing options, see [Processing Options and Settings \(Analysis Services\)](#).

The following table lists the constants for the **Type** property and the various objects that can be processed using each constant.

TYPE VALUE	APPLICABLE OBJECTS
<i>ProcessFull</i>	Cube, database, dimension, measure group, mining model, mining structure, partition
<i>ProcessAdd</i>	Dimension, partition
<i>ProcessUpdate</i>	Dimension
<i>ProcessIndexes</i>	Dimension, cube, measure group, partition
<i>ProcessData</i>	Dimension, cube, measure group, partition
<i>ProcessDefault</i>	Cube, database, dimension, measure group, mining model, mining structure, partition

TYPE VALUE	APPLICABLE OBJECTS
<i>ProcessClear</i>	Cube, database, dimension, measure group, mining model, mining structure, partition
<i>ProcessStructure</i>	Cube, mining structure
<i>ProcessClearStructureOnly</i>	Mining structure
<i>ProcessScriptCache</i>	Cube

For more information about processing Analysis Services objects, see [Processing a multidimensional model \(Analysis Services\)](#).

Specifying Objects to be Processed

The **Object** property of the **Process** command contains the object identifier of the object to be processed. Only one object can be specified in a **Process** command, but processing an object also processes any child objects. For example, processing a measure group in a cube processes all the partitions for that measure group, while processing a database processes all the objects, including cubes, dimensions, and mining structures, that are contained by the database.

If you set the **ProcessAffectedObjects** attribute of the **Process** command to true, any related object affected by processing the specified object is also processed. For example, if a dimension is incrementally updated by using the *ProcessUpdate* processing option in the **Process** command, any partition whose aggregations are invalidated because of members being added or deleted is also processed by Analysis Services if **ProcessAffectedObjects** is set to true. In this case, a single **Process** command can process multiple objects on an Analysis Services instance, but Analysis Services determines which objects besides the single object specified in the **Process** command must also be processed.

However, you can process multiple objects, such as dimensions, at the same time by using multiple **Process** commands within a **Batch** command. Batch operations provide a finer level of control for serial or parallel processing of objects on an Analysis Services instance than using the **ProcessAffectedObjects** attribute, and let you to tune your processing approach for larger Analysis Services databases. For more information about performing batch operations, see [Performing Batch Operations \(XMLA\)](#).

Specifying Out-of-Line Bindings

If the **Process** command is not contained by a **Batch** command, you can optionally specify out-of-line bindings in the **Bindings**, **DataSource**, and **DataSourceView** properties of the **Process** command for the objects to be processed. Out-of-line bindings are references to data sources, data source views, and other objects in which the binding exists only during the execution of the **Process** command, and which override any existing bindings associated with the objects being processed. If out-of-line bindings are not specified, the bindings currently associated with the objects to be processed are used.

Out-of-line bindings are used in the following circumstances:

- Incrementally processing a partition, in which an alternative fact table or a filter on the existing fact table must be specified to make sure that rows are not counted twice.
- Using a data flow task in Microsoft SQL Server Integration Services to provide data while processing a dimension, mining model, or partition.

Out-of-line bindings are described as part of the Analysis Services Scripting Language (ASSL). For more information about out-of-line bindings in ASSL, see [Data Sources and Bindings \(SSAS Multidimensional\)](#).

Incrementally Updating Partitions

Incrementally updating an already processed partition typically requires an out-of-line binding because the binding specified for the partition references fact table data already aggregated within the partition. When incrementally updating an already processed partition by using the **Process** command, Analysis Services performs the following actions:

- Creates a temporary partition with a structure identical to that of the partition to be incrementally updated.
- Processes the temporary partition, using the out-of-line binding specified in the **Process** command.
- Merges the temporary partition with the existing selected partition.

For more information about merging partitions using XML for Analysis (XMLA), see [Merging Partitions \(XMLA\)](#).

Handling Processing Errors

The **ErrorConfiguration** property of the **Process** command lets you specify how to handle errors encountered while processing an object. For example, while processing a dimension, Analysis Services encounters a duplicate value in the key column of the key attribute. Because attribute keys must be unique, Analysis Services discards the duplicate records. Based on the **KeyDuplicate** property of **ErrorConfiguration**, Analysis Services could:

- Ignore the error and continue processing the dimension.
- Return a message that states Analysis Services encountered a duplicate key and continue processing.

There are many similar conditions for which **ErrorConfiguration** provides options during a **Process** command.

Managing Writeback Tables

If the **Process** command encounters a write-enabled partition, or a cube or measure group for such a partition, that is not already fully processed, a writeback table may not already exist for that partition. The **WritebackTableCreation** property of the **Process** command determines whether Analysis Services should create a writeback table.

Examples

Description

The following example fully processes the Adventure Works DW Multidimensional 2012 sample Analysis Services database.

Code

```
<Process xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object>
    <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
  </Object>
  <Type>ProcessFull</Type>
  <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
</Process>
```

Description

The following example incrementally processes the **Internet_Sales_2004** partition in the **Internet Sales** measure group of the **Adventure Works DW** cube in the Adventure Works DW Multidimensional 2012 sample Analysis Services database. The **Process** command is adding aggregations for order dates later than December 31, 2006 to the partition by using an out-of-line query binding in the **Bindings** property of the **Process** command to retrieve the fact table rows from which to generate aggregations to add to the partition.

Code

```
<Process ProcessAffectedObjects="true" xmlns="http://schemas.microsoft.com/analysisservices/2003/engine">
  <Object>
    <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
    <CubeID>Adventure Works DW</CubeID>
    <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
    <PartitionID>Internet_Sales_2006</PartitionID>
  </Object>
  <Bindings>
    <Binding>
      <DatabaseID>Adventure Works DW Multidimensional 2012</DatabaseID>
      <CubeID>Adventure Works DW</CubeID>
      <MeasureGroupID>Fact Internet Sales 1</MeasureGroupID>
      <PartitionID>Internet_Sales_2006</PartitionID>
      <Source xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xsi:type="QueryBinding">
        <DataSourceID>Adventure Works DW</DataSourceID>
        <QueryDefinition>
          SELECT
            [dbo].[FactInternetSales].[ProductKey],
            [dbo].[FactInternetSales].[OrderDateKey],
            [dbo].[FactInternetSales].[DueDateKey],
            [dbo].[FactInternetSales].[ShipDateKey],
            [dbo].[FactInternetSales].[CustomerKey],
            [dbo].[FactInternetSales].[PromotionKey],
            [dbo].[FactInternetSales].[CurrencyKey],
            [dbo].[FactInternetSales].[SalesTerritoryKey],
            [dbo].[FactInternetSales].[SalesOrderNumber],
            [dbo].[FactInternetSales].[SalesOrderLineNumber],
            [dbo].[FactInternetSales].[RevisionNumber],
            [dbo].[FactInternetSales].[OrderQuantity],
            [dbo].[FactInternetSales].[UnitPrice],
            [dbo].[FactInternetSales].[ExtendedAmount],
            [dbo].[FactInternetSales].[UnitPriceDiscountPct],
            [dbo].[FactInternetSales].[DiscountAmount],
            [dbo].[FactInternetSales].[ProductStandardCost],
            [dbo].[FactInternetSales].[TotalProductCost],
            [dbo].[FactInternetSales].[SalesAmount],
            [dbo].[FactInternetSales].[TaxAmt],
            [dbo].[FactInternetSales].[Freight],
            [dbo].[FactInternetSales].[CarrierTrackingNumber],
            [dbo].[FactInternetSales].[CustomerPONumber]
          FROM [dbo].[FactInternetSales]
          WHERE OrderDateKey > '1280'
        </QueryDefinition>
      </Source>
    </Binding>
  </Bindings>
  <Type>ProcessAdd</Type>
  <WriteBackTableCreation>UseExisting</WriteBackTableCreation>
</Process>
```

Updating Cells (XMLA)

7/16/2019 • 2 minutes to read • [Edit Online](#)

You can use the [UpdateCells](#) command to change the value of one or more cells in a cube enabled for cube writeback. Microsoft SQL Server Analysis Services stores the updated information in a separate writeback table for each partition that contains cells to be updated.

NOTE

The **UpdateCells** command does not support allocations during cube writeback. To use allocated writeback, you should use the [Statement](#) command to send a Multidimensional Expressions (MDX) UPDATE statement. For more information, see [UPDATE CUBE Statement \(MDX\)](#).

Specifying Cells

The [Cell](#) property of the **UpdateCells** command contains the cells to be updated. You identify each cell in the **Cell** property using that cell's ordinal number. Conceptually, Analysis Services numbers cells in a cube as if the cube were a p -dimensional array, where p is the number of axes. Cells are addressed in row-major order. The following illustration shows the formula for calculating the ordinal number of a cell.

If axis k has U_k members, the ordinal number of a cell whose tuple ordinals are $(S_0, S_1, S_2, \dots, S_{p-1})$ is

$$\sum_{i=0}^{p-1} S_i \times E_i \text{ where } E_0 = 1 \text{ and } E_i = \prod_{k=0}^{i-1} U_k$$

Σ represents the sum of the terms in the series and Π the product.

Once you know a cell's ordinal number, you can indicate the intended value of the cell in the [Value](#) property of the [Cell](#) property.

ASSL XML Conventions

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services Scripting Language (ASSL) represents the hierarchy of objects as a set of element types, each of which defines the child elements they can contain.

To represent the object hierarchy, ASSL uses the following XML conventions:

- All objects and properties are represented as elements, except for standard XML attributes such as 'xml:lang'.
- Both element names and enumeration values follow the Microsoft .NET Framework naming convention of Pascal casing with no underscores.
- The case of all values is preserved. Values for enumerations are also case-sensitive.

In addition to this list of conventions, Analysis Services also follows certain conventions regarding cardinality, inheritance, whitespace, data types, and default values.

Cardinality

When an element has a cardinality that is greater than 1, there is an XML element collection that encapsulates this element. The name of collection uses the plural form of the elements contained in the collection. For example, the following XML fragment represents the **Dimensions** collection within a **Database** element:

```
<Database>
...
<Dimensions>
  <Dimension>
    ...
  </Dimension>
  <Dimension>
    ...
  </Dimension>
  ...
  </Dimensions>
</Database>
``
```

The order in which elements appear is unimportant.

Inheritance

Inheritance is used when there are distinct objects that have overlapping but significantly different sets of properties. Examples of such overlapping but distinct objects are virtual cubes, linked cubes, and regular cubes. For

overlapping but distinct object, Analysis Services uses the standard **type** attribute from the XML Instance Namespace to indicate the inheritance. For example, the following XML fragment shows how the **type** attribute identifies whether a **Cube** element inherits from a regular cube or from a virtual cube:

```
<Cubes>
  <Cube xsi:type="RegularCube">
    <Name>Sales</Name>
    ...
  </Cube>
  <Cube xsi:type="VirtualCube">
    <Name>SalesAndInventory</Name>
    ...
  </Cube>
</Cubes>
``
```

Inheritance is generally not used when multiple types have a property of the same name. For example, the **Name** and **ID** properties appear on many elements, but these properties have not been promoted to an abstract type.

Whitespace

Whitespace within an element value is preserved. However, leading and trailing whitespace is always trimmed. For example, the following elements have the same text but differing amounts of whitespace within that text, and are therefore treated as if they have different values:

```
<Description>My text<Description>
<Description>My text<Description>
``
```

However, the following elements vary only in leading and trailing whitespace, and are therefore treated as if they have equivalent values:

```
<Description>My text<Description>
<Description> My text <Description>
``
```

Data Types

Analysis Services uses the following standard XML Schema definition language (XSD) data types:

Int

An integer value in the range of -2³¹ to 2³¹ - 1.

Long

An integer value in range of -2⁶³ to 2⁶³ - 1.

String

A string value that conforms to the following global rules:

- Control characters are stripped out.
- Leading and trailing white space is trimmed.
- Internal white space is preserved.

Name and **ID** properties have special limitations on valid characters in string elements. For additional information about **Name** and **ID** conventions, see [ASSL Objects and Object Characteristics](#).

DateTime

A **DateTime** structure from the .NET Framework. A **DateTime** value cannot be NULL. The lowest date supported by the **DateTime** data type is January 1, 1601, which is available to programmers as **DateTime.MinValue**. The lowest supported date indicates that a **DateTime** value is missing.

Boolean

An enumeration with only two values, such as {true, false} or {0, 1}.

Default Values

Analysis Services uses the defaults listed in the following table.

XML DATA TYPE	DEFAULT VALUE
Boolean	False
String	"" (empty string)
Integer or Long	0 (zero)
Timestamp	12:00:00 AM, 1/1/0001 (corresponding to a the .NET Frameworks System.DateTime with 0 ticks)

An element that is present but empty is interpreted as having a value of a null string, not the default value.

Inherited Defaults

Some properties that are specified on an object provide default values for the same property on child or descendant objects. For example, **Cube.StorageMode** provides the default value for **Partition.StorageMode**. The rules that Analysis Services applies for inherited default values are as follows:

- When the property for the child object is null in the XML, its value defaults to the inherited value. However, if you query the value from the server, the server returns the null value of the XML element.
- It is not possible to determine programmatically whether the property of a child object has been set directly on the child object or inherited.

Some elements have defined defaults that apply when the element is missing. For example, the **Dimension** elements in the following XML fragment are equivalent even though one **Dimension** element contains a **Visible** element, but the other **Dimension** element does not.

```
<Dimension>
  <Name>Product</Name>
</Dimension>
<Dimension>
```

```
<Name>Product</ Name>
```

```
<Visible>true</Visible>
```

```
</Dimension>
```

For more information on inherited defaults, see [ASSL Objects and Object Characteristics](#).

Database Objects (Analysis Services - Multidimensional Data)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A Microsoft SQL Server Analysis Services instance contains database objects and assemblies for use with online analytical processing (OLAP) and data mining.

- Databases contain OLAP and data mining objects, such as data sources, data source views, cubes, measures, measure groups, dimensions, attributes, hierarchies, mining structures, mining models and roles.
- Assemblies contain user-defined functions that extend the functionality of the intrinsic functions provided with the Multidimensional Expressions (MDX) and Data Mining Extensions (DMX) languages.

The [Database](#) object is the container for all data objects that are needed for a business intelligence project (such as OLAP cubes, dimensions, and data mining structures), and their supporting objects (such as [DataSource](#), [Account](#), and [Role](#)).

A [Database](#) object provides access to objects and attributes that include the following:

- All cubes that you can access, as a collection.
- All dimensions that you can access, as a collection.
- All mining structures that you can access, as a collection.
- All data sources and data source views, as two collections.
- All roles and database permissions, as two collections.
- The collation value for the database.
- The estimated size of the database.
- The language value of the database.
- The visible setting for the database.

In This Section

The following topics describe objects shared by both OLAP and data mining features in Analysis Services.

TOPIC	DESCRIPTION
Data Sources in Multidimensional Models	Describes a data source in Analysis Services.
Data Source Views in Multidimensional Models	Describes a logical data model based on one or more data sources, in Analysis Services.

TOPIC	DESCRIPTION
Cubes in Multidimensional Models	Describes cubes and cube objects, including measures, measure groups, dimension usage relationships, calculations, key performance indicators, actions, translations, partitions, and perspectives.
Dimensions (Analysis Services - Multidimensional Data)	Describes dimensions and dimension objects, including attributes, attribute relationships, hierarchies, levels, and members.
Mining Structures (Analysis Services - Data Mining)	Describes mining structures and mining objects, including mining models.
Security Roles (Analysis Services - Multidimensional Data)	Describes a role, the security mechanism used to control access to objects in Analysis Services.
Multidimensional Model Assemblies Management	Describes an assembly, a collection of user-defined functions used to extend the MDX and DMX languages, in Analysis Services.

Attribute Relationships

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, attributes within a dimension are always related either directly or indirectly to the key attribute. When you define a dimension based on a star schema, which is where all dimension attributes are derived from the same relational table, an attribute relationship is automatically defined between the key attribute and each non-key attribute of the dimension. When you define a dimension based on a snowflake schema, which is where dimension attributes are derived from multiple related tables, an attribute relationship is automatically defined as follows:

- Between the key attribute and each non-key attribute bound to columns in the main dimension table.
- Between the key attribute and the attribute bound to the foreign key in the secondary table that links the underlying dimension tables.
- Between the attribute bound to foreign key in the secondary table and each non-key attribute bound to columns from the secondary table.

However, there are a number of reasons why you might want to change these default attribute relationships. For example, you might want to define a natural hierarchy, a custom sort order, or dimension granularity based on a non-key attribute. For more information, see [Dimension Attribute Properties Reference](#).

NOTE

Attribute relationships are known in Multidimensional Expressions (MDX) as member properties.

Natural Hierarchy Relationships

A hierarchy is a natural hierarchy when each attribute included in the user-defined hierarchy has a one to many relationship with the attribute immediately below it. For example, consider a Customer dimension based on a relational source table with eight columns:

- CustomerKey
- CustomerName
- Age
- Gender
- Email
- City
- Country
- Region

The corresponding Analysis Services dimension has seven attributes:

- Customer (based on CustomerKey, with CustomerName supplying member names)
- Age, Gender, Email, City, Region, Country

Relationships representing natural hierarchies are enforced by creating an attribute relationship between the attribute for a level and the attribute for the level below it. For Analysis Services, this specifies a natural relationship and potential aggregation. In the Customer dimension, a natural hierarchy exists for the Country, Region, City, and Customer attributes. The natural hierarchy for `{Country, Region, City, Customer}` is described by adding the following attribute relationships:

- The Country attribute as an attribute relationship to the Region attribute.
- The Region attribute as an attribute relationship to the City attribute.
- The City attribute as an attribute relationship to the Customer attribute.

For navigating data in the cube, you can also create a user-defined hierarchy that does not represent a natural hierarchy in the data (which is called an *ad hoc* or *reporting* hierarchy). For example, you could create a user-defined hierarchy based on `{Age, Gender}`. Users do not see any difference in how the two hierarchies behave, although the natural hierarchy benefits from aggregating and indexing structures - hidden from the user - that account for the natural relationships in the source data.

The **SourceAttribute** property of a level determines which attribute is used to describe the level. The **KeyColumns** property on the attribute specifies the column in the data source view that supplies the members. The **NameColumn** property on the attribute can specify a different name column for the members.

To define a level in a user-defined hierarchy using Visual Studio with Analysis Services projects, the **Dimension Designer** allows you to select a dimension attribute, a column in a dimension table, or a column from a related table included in the data source view for the cube. For more information about creating user-defined hierarchies, see [Create User-Defined Hierarchies](#).

In Analysis Services, an assumption is usually made about the content of members. Leaf members have no descendants and contain data derived from underlying data sources. Nonleaf members have descendants and contain data derived from aggregations performed on child members. In aggregated levels, members are based on aggregations of subordinate levels. Therefore, when the **IsAggregatable** property is set to **False** on a source attribute for a level, no aggregatable attributes should be added as levels above it.

Defining an Attribute Relationship

The main constraint when you create an attribute relationship is to make sure that the attribute referred to by the attribute relationship has no more than one value for any member in the attribute to which the attribute relationship belongs. For example, if you define a relationship between a City attribute and a State attribute, each city can only relate to a single state.

Attribute Relationship Queries

You can use MDX queries to retrieve data from attribute relationships, in the form of member properties, with the **PROPERTIES** keyword of the MDX **SELECT** statement. For more information about how to use MDX to retrieve member properties, see [Using Member Properties \(MDX\)](#).

[User Hierarchy Properties](#)

Attributes and Attribute Hierarchies

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Dimensions are collections of attributes, which are bound to one or more columns in a table or view in the data source view.

Key Attribute

Each dimension contains a key attribute. Each attribute is bound to one or more columns in a dimension table. The key attribute is the attribute in a dimension that identifies the columns in the dimension main table that are used in foreign key relationships to the fact table. Typically, the key attribute represents the primary key column or columns in the dimension table. You can define a logical primary key on a table in a data source view which has no physical primary key in the underlying data source. **For more information**, see [Define Logical Primary Keys in a Data Source View \(Analysis Services\)](#). When defining key attributes, the Cube Wizard and Dimension Wizard try to use the primary key columns of the dimension table in the data source view. If the dimension table does not have a logical primary key or physical primary key defined, the wizards may not be able to correctly define the key attributes for the dimension.

Binding an Attribute to Columns in Data Source View Tables or Views

An attribute is bound to columns in one or more data source view tables or views. An attribute is always bound to one or more key columns, which determines the members that are contained by the attribute. By default, this is the only column to which an attribute is bound. An attribute can also be bound to one or more additional columns for specific purposes. For example, an attribute's **NameColumn** property determines the name that appears to the user for each attribute member - this property of the attribute can be bound to a particular dimension column through a data source view or can be bound to a calculated column in the data source view. For more information, see [Dimension Attribute Properties Reference](#).

Attribute Hierarchies

By default, attribute members are organized into two level hierarchies, consisting of a leaf level and an All level. The All level contains the aggregated value of the attribute's members across the measures in each measure group to which the dimension of which the attribute is related is a member. However, if the **IsAggregatable** property is set to False, the All level is not created. For more information, see [Dimension Attribute Properties Reference](#).

Attributes can be, and typically are, arranged into user-defined hierarchies that provide the drill-down paths by which users can browse the data in the measure groups to which the attribute is related. In client applications, attributes can be used to provide grouping and constraint information. When attributes are arranged into user-defined hierarchies, you define relationships between hierarchy levels when levels are related in a many-to-one or a one-to-one relationship (called a *natural* relationship). For example, in a Calendar Time hierarchy, a Day level should be related to the Month level, the Month level related to the Quarter level, and so on. Defining relationships between levels in a user-defined hierarchy enables Analysis Services to define more useful aggregations to increase query performance and can also save memory during processing performance, which can be important with large or complex cubes. For more information, see [User Hierarchies](#), [Create User-Defined Hierarchies](#), and [Define Attribute Relationships](#).

Attribute Relationships, Star Schemas, and Snowflake Schemas

By default, in a star schema, all attributes are directly related to the key attribute, which enables users to browse the facts in the cube based on any attribute hierarchy in the dimension. In a snowflake schema, an attribute is either directly linked to the key attribute if their underlying table is directly linked to the fact table or is indirectly linked by means of the attribute that is bound to the key in the underlying table that links the snowflake table to the directly linked table.

Database Dimension Properties - Types

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The **Type** property setting provides information about the contents of a dimension to server and client applications. In some cases, the **Type** setting only provides guidance for client applications and is optional. In other cases, such as **Accounts** or **Time** dimensions, the **Type** property settings for the dimension and its attributes determine specific server-based behaviors and may be required to implement certain behaviors in the cube. For example, the **Type** property of a dimension can be set to **Accounts** to indicate to client applications that the standard dimension contains account attributes. For more information about time, account, and currency dimensions, see [Create a Date type Dimension](#), [Create a Finance Account of parent-child type Dimension](#), and [Create a Currency type Dimension](#).

The default setting for the dimension type is **Regular**, which makes no assumptions about the contents of the dimension. This is the default setting for all dimensions when you initially define a dimension unless you specify **Time** when defining the dimension using the Dimension Wizard. You should also leave **Regular** as the dimension type if the Dimension Wizard does not list an appropriate type for Dimension type.

Available Dimension Types

The following table describes the dimension types available in Microsoft SQL Server Analysis Services.

DIMENSION TYPE	DESCRIPTION
Regular	A dimension whose type has not been set to a special dimension type.
Time	A dimension whose attributes represent time periods, such as years, semesters, quarters, months, and days.
Organization	A dimension whose attributes represent organizational information, such as employees or subsidiaries.
Geography	A dimension whose attributes represent geographic information, such as cities or postal codes.
BillOfMaterials	A dimension whose attributes represent inventory or manufacturing information, such as parts lists for products.
Accounts	A dimension whose attributes represent a chart of accounts for financial reporting purposes.
Customers	A dimension whose attributes represent customer or contact information.
Products	A dimension whose attributes represent product information.
Scenario	A dimension whose attributes represent planning or strategic analysis information.

DIMENSION TYPE	DESCRIPTION
Quantitative	A dimension whose attributes represent quantitative information.
Utility	A dimension whose attributes represent miscellaneous information.
Currency	This type of dimension contains currency data and metadata.
Rates	A dimension whose attributes represent currency rate information.
Channel	A dimension whose attributes represent channel information.
Promotion	A dimension whose attributes represent marketing promotion information.

Database Dimension Properties

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, the characteristics of a dimension are defined by the metadata for the dimension, based on the settings of various dimension properties, and on the attributes or hierarchies that are contained by the dimension. The following table describes the dimension properties in Analysis Services.

PROPERTY	DESCRIPTION
AttributeAllMemberName	Specifies the name of the All member for attributes in a dimension.
Collation	Determines the collation used by the dimension.
CurrentStorageMode	Contains the current storage mode for the dimension.
DependsOnDimension	Contains the ID of another dimension on which the dimension depends, if any.
Description	Contains the description of the dimension.
ErrorConfiguration	Configurable error handling settings for handling of duplicate keys, unknown keys, error limits, action upon error detection, error log file, and null key handling.
ID	Contains the unique identifier (ID) of the dimension.
Language	Specifies the default language for the dimension.
MdxMissingMemberMode	Determines how missing members are handled for Multidimensional Expressions (MDX) statements.
MiningModelID	Contains the ID of the mining model with which the data mining dimension is associated. This property is applicable only if the dimension is a mining model dimension.
Name	Specifies the name of the dimension.
ProactiveCaching	Defines the proactive cache settings for the dimension.
ProcessingGroup	Specifies the processing group. Values are ByAttribute or ByTable. Default is ByAttribute .
ProcessingMode	Indicates whether Analysis Services should index and aggregate during or after processing.
ProcessingPriority	Determines the processing priority of the dimension during background operations such as lazy aggregation, indexing, or clustering.

PROPERTY	DESCRIPTION
Source	Identifies the data source view to which the dimension is bound.
StorageMode	Determines the storage mode for the dimension.
Type	Specifies the type of the dimension.
UnknownMember	Indicates whether the unknown member is visible.
UnknownMemberName	Specifies the caption, in the default language of the dimension, for the unknown member of the dimension.
WriteEnabled	Indicates whether dimension writebacks are available (subject to security permissions).

NOTE

For more information about setting values for the ErrorConfiguration and UnknownMember properties when working with null values and other data integrity issues, see [Handling Data Integrity Issues in Analysis Services 2005](#).

Dimension Objects (Analysis Services - Multidimensional Data)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A simple [Dimension](#) object is composed of basic information, attributes, and hierarchies. Basic information includes the name of the dimension, the type of the dimension, the data source, the storage mode, and others. Attributes define the actual data in the dimension. Attributes do not necessarily belong to a hierarchy, but hierarchies are built from attributes. A hierarchy creates ordered lists of levels, and defines the ways a user can explore the dimension.

In This Section

The following topics provide more information about how to design and implement dimension objects.

Topic	Description
Dimensions (Analysis Services - Multidimensional Data)	In Microsoft SQL Server Analysis Services, dimensions are a fundamental component of cubes. Dimensions organize data with relation to an area of interest, such as customers, stores, or employees, to users.
Attributes and Attribute Hierarchies	Dimensions are collections of attributes, which are bound to one or more columns in a table or view in the data source view.
Attribute Relationships	<p>In Microsoft SQL Server Analysis Services, attributes within a dimension are always related either directly or indirectly to the key attribute. When you define a dimension based on a star schema, which is where all dimension attributes are derived from the same relational table, an attribute relationship is automatically defined between the key attribute and each non-key attribute of the dimension. When you define a dimension based on a snowflake schema, which is where dimension attributes are derived from multiple related tables, an attribute relationship is automatically defined as follows:</p> <p>Between the key attribute and each non-key attribute bound to columns in the main dimension table.</p> <p>Between the key attribute and the attribute bound to the foreign key in the secondary table that links the underlying dimension tables.</p> <p>Between the attribute bound to foreign key in the secondary table and each non-key attribute bound to columns from the secondary table.</p>

Dimension Translations

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A translation is a simple mechanism to change the displayed labels and captions from one language to another. Each translation is defined as a pair of values: a string with the translated text, and a number with the language ID. Translations are available for all objects in Analysis Services. Dimensions can also have the attribute values translated. The client application is responsible for finding the language setting that the user has defined, and switch to display all captions and labels to that language. An object can have as many translations as you want.

A simple [Translation](#) object is composed of: language ID number, and translated caption. The language ID number is an **Integer** with the language ID. The translated caption is the translated text.

In Microsoft SQL Server Analysis Services, a dimension translation is a language-specific representation of the name of a dimension, the name of an Analysis Services object or one of its members, such as a caption, member, or hierarchy level. SQL Server Analysis Services also supports translations of cube objects.

Translations provide server support for client applications that can support multiple languages. Frequently, users from different countries view a cube and its dimensions. It is useful to be able to translate various elements of a cube and its dimensions into a different language so that these users can view and understand the cube. For example, a business user in France can access a cube from a workstation with a French locale setting, and see the object property values in French. However, a business user in Germany who accesses the same cube from a workstation with a German locale setting sees the same object property values in German.

The collation and language information for the client computer is stored in the form of a locale identifier (LCID). Upon connection, the client passes the LCID to the instance of Analysis Services. The instance uses the LCID to determine which set of translations to use when providing metadata for Analysis Services objects. If an Analysis Services object does not contain the specified translation, the default language is used to return the content back to the client.

[Globalization Tips and Best Practices \(Analysis Services\)](#)

Dimensions - Introduction

7/16/2019 • 3 minutes to read • [Edit Online](#)

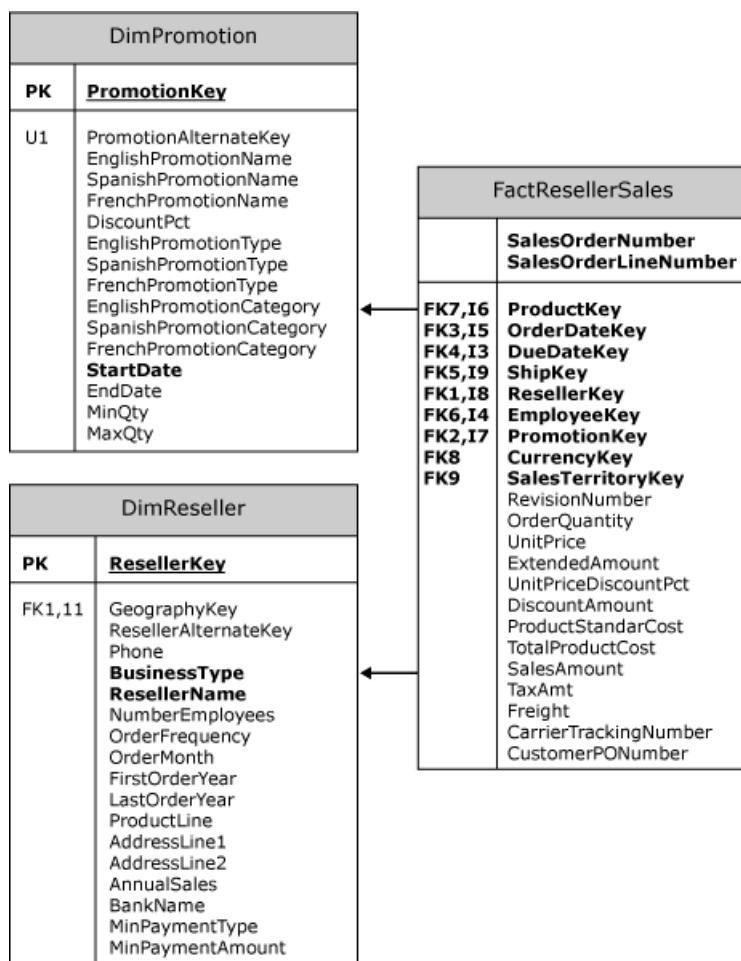

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

All Microsoft SQL Server Analysis Services dimensions are groups of attributes based on columns from tables or views in a data source view. Dimensions exist independent of a cube, can be used in multiple cubes, can be used multiple times in a single cube, and can be linked between Analysis Services instances. A dimension that exists independent of a cube is called a database dimension and an instance of a database dimension within a cube is called a cube dimension.

Dimension based on a Star Schema Design

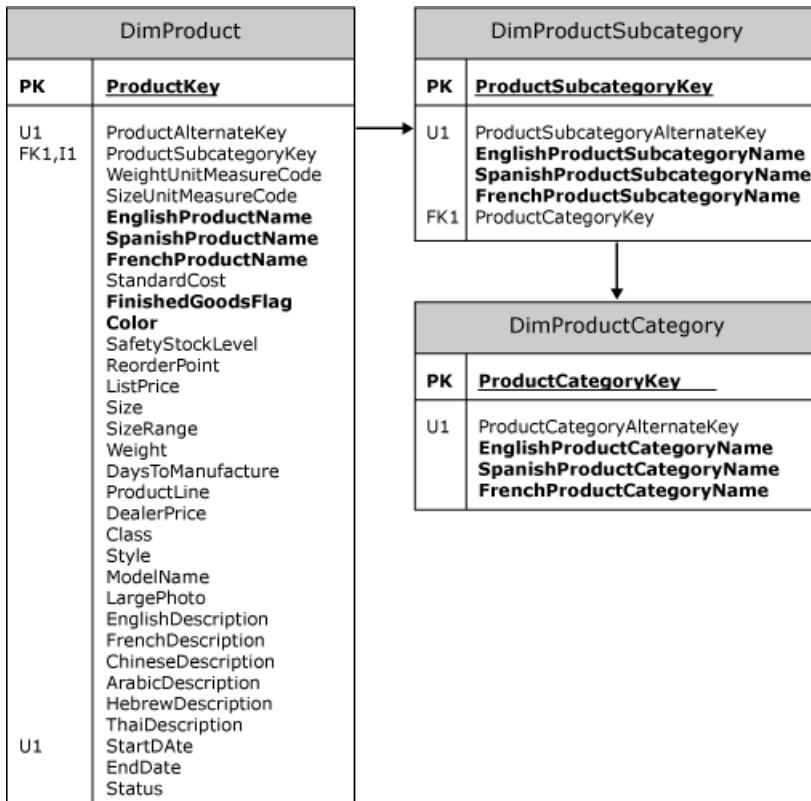

The structure of a dimension is largely driven by the structure of the underlying dimension table or tables. The simplest structure is called a star schema, where each dimension is based on a single dimension table that is directly linked to the fact table by a primary key - foreign key relationship.

The following diagram illustrates a subsection of the **AdventureWorksDW2012** sample database, in which the **FactResellerSales** fact table is related to two dimension tables, **DimReseller** and **DimPromotion**. The **ResellerKey** column in the **FactResellerSales** fact table defines a foreign key relationship to the **ResellerKey** primary key column in the **DimReseller** dimension table. Similarly, the **PromotionKey** column in the **FactResellerSales** fact table defines a foreign key relationship to the **PromotionKey** primary key column in the **DimPromotion** dimension table.

Dimension based on a Snowflake Schema Design

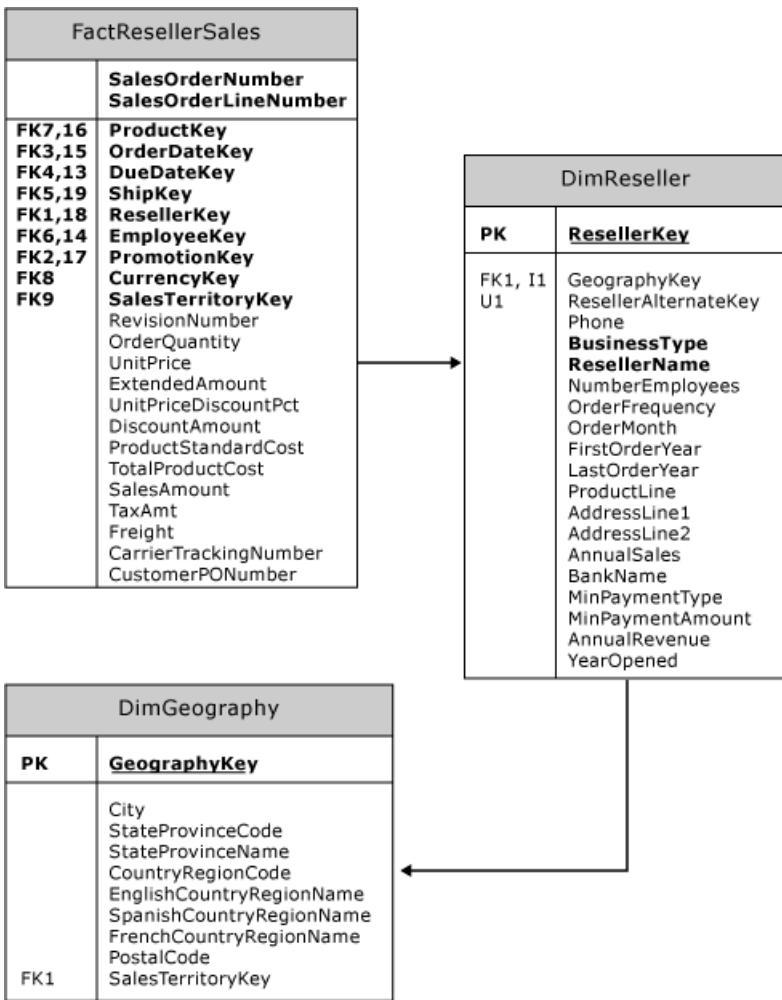

Frequently, a more complex structure is required because information from multiple tables is required to define the dimension. In this structure, called a snowflake schema, each dimension is based on attributes from columns in multiple tables linked to each other and ultimately to the fact table by primary key - foreign key relationships. For example, the following diagram illustrates the tables required to completely describe the Product dimension in the **AdventureWorksDW** sample project:

To completely describe a product, the product's category and subcategory must be included in the Product dimension. However, that information does not reside directly in the main table for the **DimProduct** dimension. A foreign key relationship from **DimProduct** to **DimProductSubcategory**, which in turn has a foreign key relationship to the **DimProductCategory** table, makes it possible to include the information for product categories and subcategories in the Product dimension.

Snowflake Schema versus Reference Relationship

Sometimes, you may have a choice between using a snowflake schema to define attributes in a dimension from multiple tables, or defining two separate dimensions and defining a reference dimension relationship between them. The following diagram illustrates such a scenario.

In the previous diagram, the **FactResellerSales** fact table does not have a foreign key relationship with the **DimGeography** dimension table. However, the **FactResellerSales** fact table does have a foreign key relationship with the **DimReseller** dimension table, which in turn has a foreign key relationship with the **DimGeography** dimension table. To define a Reseller dimension that contains geography information about each reseller, you would have to retrieve these attributes from the **DimGeography** and the **DimReseller** dimension tables. However, in Analysis Services, you can achieve the same result by creating two separate dimensions and linking them in a measure group by defining a reference dimension relationship between the two dimensions. For more information about reference dimension relationships, see [Dimension Relationships](#).

One advantage of using reference dimension relationships in this scenario is that you could create a single geography dimension and then create multiple cube dimensions based on the geography dimension, without requiring any additional storage space. For example, you could link one of the geography cube dimensions to a reseller dimension and another of the geography cube dimensions to a customer dimension. **Related topics:**[Dimension Relationships](#), [Define a Referenced Relationship](#) and [Referenced Relationship Properties](#)

Processing a Dimension

After you create a dimension, you must process the dimension before you can view the members of the attributes and hierarchies in the dimension. After the structure of a dimension is changed or the information in its underlying tables is updated, you have to process the dimension again before you can view the changes. When you process a dimension after structural changes, you must also process any cubes that include the dimension - or the cube will not be viewable.

Security

All the subordinate objects of a dimension, including hierarchies, levels, and members, are secured using roles in Analysis Services. Dimension security can be applied for all the cubes in the database that use the dimension, or

for only a specific cube. For more information about dimension security, see [Grant permissions on a dimension \(Analysis Services\)](#).

[Write-Enabled Dimensions](#)

Dimensions - Storage

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Dimensions in Microsoft SQL Server Analysis Services support two storage modes:

- Relational OLAP (ROLAP)
- Multidimensional OLAP (MOLAP)

The storage mode determines the location and form of a dimension's data. MOLAP is the default storage mode for dimensions. **Related topics:**[Partition Storage Modes and Processing](#)

MOLAP

Data for a dimension that uses MOLAP is stored in a multidimensional structure in the instance of Analysis Services. This multidimensional structure is created and populated when the dimension is processed. MOLAP dimensions provide better query performance than ROLAP dimensions.

ROLAP

Data for a dimension that uses ROLAP is actually stored in the tables used to define the dimension. The ROLAP storage mode can be used to support large dimensions without duplicating large amounts of data, but at the expense of query performance. Because the dimension relies directly on the tables in the data source view used to define the dimension, the ROLAP storage mode also supports real-time OLAP.

IMPORTANT

If a dimension uses the ROLAP storage mode and the dimension is included in a cube that uses MOLAP storage, any schema changes to its source table must be followed by immediate processing of the cube. Failure to do this may result in inconsistent results when querying the cube. **Related topic:**[Automate Analysis Services Administrative Tasks with SSIS](#).

Proactive Caching (Dimensions)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Proactive caching provides automatic MOLAP cache creation and management for OLAP objects. The cubes immediately incorporate changes that are made to the data in the database, based upon notifications received from the database. The goal of proactive caching is to provide the performance of traditional MOLAP, while retaining the immediacy and ease of management offered by ROLAP.

A simple [ProactiveCaching](#) object is composed of: timing specification, and table notification. The timing specification defines the timeframe for updating the cache after a change notification has been received. The table notification defines the notification schema between the data table and the [ProactiveCaching](#) object.

User Hierarchies - Level Properties

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The following table lists and describes the properties of a level in a user-defined hierarchy.

PROPERTY	DESCRIPTION
Description	Contains the description of the level.
HideMemberIf	Indicates whether and when a member in a level should be hidden from client applications. This property can have the following values: Never Members are never hidden. This is the default value. OnlyChildWithNoName A member is hidden when the member is the only child of its parent and the member's name is empty. OnlyChildWithParentName A member is hidden when the member is the only child of its parent and the member's name is identical to that of its parent. NoName A member is hidden when the member's name is empty. ParentName A member is hidden when the member's name is identical to that of its parent.
ID	Contains the unique identifier (ID) of the level.
Name	Contains the friendly name of the level. By default, the name of a level is the same as the name of the source attribute.
SourceAttribute	Contains the name of the source attribute on which the level is based.

User Hierarchies - Properties

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The following table describes the properties of a user-defined hierarchy.

PROPERTY	DESCRIPTION
AllMemberName	Contains the caption in the default language for the All member of the hierarchy.
AllowDuplicateNames	Determines whether duplicate names are allowed in the hierarchy. Values are True and False. Default value is True.
Description	Contains the description of the hierarchy.
DisplayFolder	Specifies the folder in which to list the hierarchy for users.
ID	Contains the unique identifier (ID) of the hierarchy.
MemberNamesUnique	Determines whether member names in the hierarchy must be unique. Values are True and False. Default value is False.
Name	Contains the name of the hierarchy.

User Hierarchies

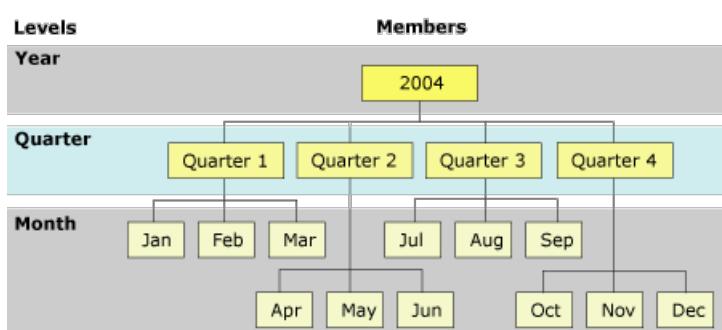

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

User-defined hierarchies are user-defined hierarchies of attributes that are used in Microsoft SQL Server Analysis Services to organize the members of a dimension into hierarchical structures and provide navigation paths in a cube. For example, the following table defines a dimension table for a time dimension. The dimension table supports three attributes, named Year, Quarter, and Month.

YEAR	QUARTER	MONTH
1999	Quarter 1	Jan
1999	Quarter 1	Feb
1999	Quarter 1	Mar
1999	Quarter 2	Apr
1999	Quarter 2	May
1999	Quarter 2	Jun
1999	Quarter 3	Jul
1999	Quarter 3	Aug
1999	Quarter 3	Sep
1999	Quarter 4	Oct
1999	Quarter 4	Nov
1999	Quarter 4	Dec

The Year, Quarter, and Month attributes are used to construct a user-defined hierarchy, named Calendar, in the time dimension. The relationship between the levels and members of the Calendar dimension (a regular dimension) is shown in the following diagram.

NOTE

Any hierarchy other than the default two-level attribute hierarchy is called a user-defined hierarchy. For more information about attribute hierarchies, see [Attributes and Attribute Hierarchies](#).

Member Structures

With the exception of parent-child hierarchies, the positions of members within the hierarchy are controlled by the order of the attributes in the hierarchy's definition. Each attribute in the hierarchy definition constitutes a level in the hierarchy. The position of a member within a level is determined by the ordering of the attribute used to create the level. The member structures of user-defined hierarchies can take one of four basic forms, depending on how the members are related to each other.

Balanced Hierarchies

In a balanced hierarchy, all branches of the hierarchy descend to the same level, and each member's logical parent is the level immediately above the member. The Product Categories hierarchy of the Product dimension in the Adventure Works DW Multidimensional 2012 sample Analysis Services database is a good example of a balanced hierarchy. Each member in the Product Name level has a parent member in the Subcategory level, which in turn has a parent member in the Category level. Also, every branch in the hierarchy has a leaf member in the Product Name level.

Unbalanced Hierarchies

In an unbalanced hierarchy, branches of the hierarchy descend to different levels. Parent-child hierarchies are unbalanced hierarchies. For example, the Organization dimension in the Adventure Works DW Multidimensional 2012 sample Analysis Services database contains a member for each employee. The CEO is the top member in the hierarchy, and the division managers and executive secretary are immediately beneath the CEO. The division managers have subordinate members but the executive secretary does not.

It may be impossible for end users to distinguish between unbalanced and ragged hierarchies. However, you employ different techniques and properties in Analysis Services to support these two types of hierarchies. For more information, see [Ragged Hierarchies](#), and [Attributes in Parent-Child Hierarchies](#).

Ragged Hierarchies

In a ragged hierarchy, the logical parent member of at least one member is not in the level immediately above the member. This can cause branches of the hierarchy to descend to different levels. For example, in a Geography dimension defined with the levels Continent, CountryRegion, and City, in that order, the member Europe appears in the top level of the hierarchy, the member France appears in the middle level, and the member Paris appears in the bottom level. France is more specific than Europe, and Paris is more specific than France. To this regular hierarchy, the following changes are made:

- The Vatican City member is added to the CountryRegion level.
- Members are added to the City level and are associated with the Vatican City member in the CountryRegion level.
- A level, named Province, is added between the CountryRegion and City levels.

The Province level is populated with members associated with other members in the CountryRegion level, and members in the City level are associated with their corresponding members in the Province level. However, because the Vatican City member in the CountryRegion level has no associated members in the Province level, members must be associated from the City level directly to the Vatican City member in the CountryRegion level. Because of the changes, the hierarchy of the dimension is now ragged. The parent of the city Vatican City is the country/region Vatican City, which is not in the level immediately above the Vatican City member in the City level. For more information, see [Ragged Hierarchies](#).

Parent-Child Hierarchies

Parent-child hierarchies for dimensions are defined by using a special attribute, called a parent attribute, to determine how members relate to each other. A parent attribute describes a *self-referencing relationship*, or *self-join*, within a dimension main table. Parent-child hierarchies are constructed from a single parent attribute. Only one level is assigned to a parent-child hierarchy, because the levels present in the hierarchy are drawn from the parent-child relationships between members associated with the parent attribute. The dimension schema of a parent-child hierarchy depends on a self-referencing relationship present on the dimension main table. For example, the following diagram illustrates the **DimOrganization** dimension main table in the Adventure Works DW Multidimensional 2012Analysis Services sample database.

DimOrganization	
PK	<u>OrganizationKey</u>
FK2	ParentOrganizationKey PercentageOfOwnership OrganizationName ParentOrganizationName
FK1	CurrencyKey

In this dimension table, the **ParentOrganizationKey** column has a foreign key relationship with the **OrganizationKey** primary key column. In other words, each record in this table can be related through a parent-child relationship with another record in the table. This kind of self-join is generally used to represent organization entity data, such as the management structure of employees in a department.

When you create a parent-child hierarchy, the columns represented by both attributes must have the same data type. Both attributes must also be in the same table. By default, any member whose parent key equals its own member key, null, 0 (zero), or a value absent from the column for member keys is assumed to be a member of the top level (excluding the (All) level).

The depth of a parent-child hierarchy can vary among its hierarchical branches. In other words, a parent-child hierarchy is considered an unbalanced hierarchy.

Unlike user-defined hierarchies, in which the number of levels in the hierarchy determines the number of levels that can be seen by end users, a parent-child hierarchy is defined with the single level of an attribute hierarchy, and the values in this single level produce the multiple levels seen by users. The number of displayed levels depends on the contents of the dimension table columns that store the member keys and the parent keys. The number of levels can change when the data in the dimension tables change. For more information, see [Parent-Child Dimensions](#), and [Attributes in Parent-Child Hierarchies](#).

Write-Enabled Dimensions

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

IMPORTANT

This feature will be removed in the next version of Microsoft SQL Server. Avoid using this feature in new development work, and plan to modify applications that currently use this feature.

The data in a dimension is generally read-only. However, for certain scenarios, you may want to write-enable a dimension. In Microsoft SQL Server Analysis Services, write-enabling a dimension enables business users to modify the contents of the dimension and see the immediate effect of changes on the hierarchies of the dimension. Any dimension that is based on a single table can be write-enabled. In a write-enabled dimension, business users and administrators can change, move, add, and delete attribute members within the dimension. These updates are referred to collectively as *dimension writeback*.

Analysis Services supports dimension writeback on all dimension attributes and any member of a dimension may be modified. For a write-enabled cube or partition, updates are stored in a writeback table separate from the cube's source tables. However, for a write-enabled dimension, updates are recorded directly in the dimension's table. Also, if the write-enabled dimension is included in a cube with multiple partitions where some or all their data sources have copies of the dimension table, only the original dimension table is updated during a writeback process.

Write-enabled dimensions and write-enabled cubes have different but complementary features. A write-enabled dimension gives business users the ability to update members, whereas a write-enabled cube gives them the ability to update cell values. Although these two features are complementary, you do not have to use both features in combination. A dimension does not have to be included in a cube for dimension writeback to occur. A write-enabled dimension can also be included in a cube that is not write-enabled. You use different procedures to write-enable dimensions and cubes, and to maintain their security.

The following restrictions apply to dimension writeback:

- When you create a new member, you must include every attribute in a dimension. You cannot insert a member without specifying a value for the key attribute of the dimension. Therefore, creating members is subject to any constraints (such as non-null key values) that are defined on the dimension table.
- Dimension writeback is supported only for star schemas. In other words, a dimension must be based on a single dimension table directly related to a fact table. After you write-enable a dimension, Analysis Services validates this requirement when you deploy to an existing Analysis Services database or when you build an Analysis Services project.

Any existing member of a writeback dimension can be modified or deleted. When a member is deleted, the deletion cascades to all child members. For example, in a Customer dimension that contains CountryRegion, Province, City, and Customer attributes, deleting a country/region would delete all provinces, cities, and customers that belong to the deleted country/region. If a country/region has only one province, deleting that province would delete the country/region also.

Members of a writeback dimension can only be moved within the same level. For example, a city could be moved to the City level in a different country/region or province, but a city cannot be moved to the Province or CountryRegion level. In a parent-child hierarchy, all members are leaf members, and therefore a member may be

moved to any level other than the **(All)** level.

If a member of a parent-child hierarchy is deleted, the member's children are moved to the member's parent. Update permissions on the relational table are required on the deleted member, but no permissions are required on the moved members. When an application moves a member in a parent-child hierarchy, the application can specify in the UPDATE operation whether descendants of the member are moved with the member or are moved to the member's parent. To recursively delete a member in a parent-child hierarchy, a user must have update permissions on the relational table for the member and all the member's descendants.

NOTE

Updates to the parent attribute in a parent-child hierarchy must not include updates to any other properties or attributes.

All changes to a dimension cause the dimension structure to be modified. Each change to a dimension is considered a single transaction, requiring incremental processing to update the dimension structure. Write-enabled dimensions have the same processing requirements as any other dimension.

NOTE

Dimension writeback is not supported by linked dimensions.

Security

The only business users who can update a write-enabled dimension are those in Analysis Services database roles that have been granted read/write permission to the dimension. For each role, you can control which members can and cannot be updated. For business users to update write-enabled dimensions, their client application must support this capability. For such users, a write-enabled dimension must be included in a cube that was processed since the dimension last changed. For more information, see [Authorizing access to objects and operations \(Analysis Services\)](#).

Users and groups included in the Administrators role can update the attribute members of a write-enabled dimension, even if the dimension is not included in a cube.

Aggregations and Aggregation Designs

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

An [AggregationDesign](#) object defines a set of aggregation definitions that can be shared across multiple partitions.

An [Aggregation](#) object represents the summarization of measure group data at certain granularity of the dimensions.

A simple [Aggregation](#) object is composed of: basic information and dimensions. Basic information includes the name of the aggregation, the ID, annotations, and a description. The dimensions are a collection of [AggregationDimension](#) objects that contain the list of granularity attributes for the dimension.

Aggregations are precalculated summaries of data from leaf cells. Aggregations improve query response time by preparing the answers before the questions are asked. For example, when a data warehouse fact table contains hundreds of thousands of rows, a query requesting the weekly sales totals for a particular product line can take a long time to answer if all the rows in the fact table have to be scanned and summed at query time to compute the answer. However, the response can be almost immediate if the summarization data to answer this query has been precalculated. This precalculation of summary data occurs during processing and is the foundation for the rapid response times of OLAP technology.

Cubes are the way that OLAP technology organizes summary data into multidimensional structures. Dimensions and their hierarchies of attributes reflect the queries that can be asked of the cube. Aggregations are stored in the multidimensional structure in cells at coordinates specified by the dimensions. For example, the question "What were the sales of product X in 1998 for the Northwest region?" involves three dimensions (Product, Time, and Geography) and one measure (Sales). The value of the cell in the cube at the specified coordinates (product X, 1998, Northwest) is the answer, a single numeric value.

Other questions may return multiple values. For example, "How much were the sales of hardware products by quarter by region for 1998?" Such queries return sets of cells from the coordinates that satisfy the specified conditions. The number of cells returned by the query depends on the number of items in the Hardware level of the Product dimension, the four quarters in 1998, and the number of regions in the Geography dimension. If all summary data has been precalculated into aggregations, the response time of the query will depend only on the time that is required to extract the specified cells. No calculation or reading of data from the fact table is required.

Although precalculation of all possible aggregations in a cube might provide the fastest possible response time for all queries, Analysis Services can easily calculate some aggregated values from other precalculated aggregations. Additionally, calculating all possible aggregations requires significant processing time and storage. Therefore, there is a tradeoff between storage requirements and the percentage of possible aggregations that are precalculated. If no aggregations are precalculated (0%), the amount of required processing time and storage space for a cube is minimized, but query response time may be slow because the data required to answer each query must be retrieved from the leaf cells and then aggregated at query time to answer each query. For example, returning a single number that answers the question asked earlier ("What were the sales of product X in 1998 for the Northwest region") might require reading thousands of rows of data, extracting the value of the column used to provide the Sales measure from each row, and then calculating the sum. Moreover, the length of time required to retrieve that data will very depending on the storage mode chosen for the data-MOLAP, HOLAP, or ROLAP.

Designing Aggregations

Microsoft SQL Server Analysis Services incorporates a sophisticated algorithm to select aggregations for precalculation so that other aggregations can be quickly computed from the precalculated values. For example, if the aggregations are precalculated for the Month level of a Time hierarchy, the calculation for a Quarter level requires only the summarization of three numbers, which can be quickly computed on demand. This technique saves processing time and reduces storage requirements, with minimal effect on query response time.

The Aggregation Design Wizard provides options for you to specify storage and percentage constraints on the algorithm to achieve a satisfactory tradeoff between query response time and storage requirements. However, the Aggregation Design Wizard's algorithm assumes that all possible queries are equally likely. The Usage-Based Optimization Wizard lets you adjust the aggregation design for a measure group by analyzing the queries that have been submitted by client applications. By using the wizard to tune a cube's aggregation you can increase responsiveness to frequent queries and decrease responsiveness to infrequent queries without significantly affecting the storage needed for the cube.

Aggregations are designed by using the wizards but are not actually calculated until the partition for which the aggregations are designed is processed. After the aggregation has been created, if the structure of a cube ever changes, or if data is added to or changed in a cube's source tables, it is usually necessary to review the cube's aggregations and process the cube again.

[Partition Storage Modes and Processing](#)

Calculations

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A calculation is a Multidimensional Expressions (MDX) expression or script that is used to define a calculated member, a named set, or a scoped assignment in a cube in Microsoft SQL Server Analysis Services. Calculations let you add objects that are defined not by the data of the cube, but by expressions that can reference other parts of the cube, other cubes, or even information outside the Analysis Services database. Calculations let you extend the capabilities of a cube, adding flexibility and power to business intelligence applications. For more information about scripting calculations, see [Introduction to MDX Scripting in Microsoft SQL Server 2005](#).

Calculated Members

A calculated member is a member whose value is calculated at run time using a Multidimensional Expressions (MDX) expression that you specify when you define the calculated member. A calculated member is available to business intelligence applications just like any other member. Calculated members do not increase the size of the cube because only the definitions are stored in the cube; values are calculated in memory as required to answer a query.

Calculated members can be defined for any dimension, including the measures dimension. Calculated members created on the Measures dimension are called calculated measures.

Although calculated members are typically based on data that already exists in the cube, you can create complex expressions by combining data with arithmetic operators, numbers, and functions. You can also use MDX functions, such as `LookupCube`, to access data in other cubes in the Analysis Services database. Analysis Services includes standardized Visual Studio function libraries, and you can use stored procedures to retrieve data from sources other than the current Analysis Services database. For more information about stored procedures, see [Defining Stored Procedures](#).

For example, suppose executives in a shipping company want to determine which types of cargo are more profitable to carry, based on profit per unit of volume. They use a Shipments cube that contains the dimensions Cargo, Fleet, and Time and the measures `Price_to_Ship`, `Cost_to_Ship`, and `Volume_in_Cubic_Meters`; however, the cube does not contain a measure for profitability. You can create a calculated member as a measure named `Profit_per_Cubic_Meter` in the cube by combining the existing measures in the following expression:

```
([Measures].[Price_to_Ship] - [Measures].[Cost_to_Ship]) /  
[Measures].[Volume_in_Cubic_Meters]
```

After you create the calculated member, the `Profit_per_Cubic_Meter` appears together with the other measures the next time that the Shipments cube is browsed.

To create calculated members, use the **Calculations** tab in Cube Designer. For more information, see [Create Calculated Members](#)

Named Sets

A named set is a CREATE SET MDX statement expression that returns a set. The MDX expression is saved as part of the definition of a cube in Microsoft SQL Server Analysis Services. A named set is created for reuse in Multidimensional Expressions (MDX) queries. A named set enables business users to simplify queries, and use a set name instead of a set expression for complex, frequently used set expressions. **Related topic:** [Create Named](#)

Script Commands

A script command is an MDX script, included as part of the definition of the cube. Script commands let you perform almost any action that is supported by MDX on a cube, such as scoping a calculation to apply to only part of the cube. In SQL Server Analysis Services, MDX scripts can apply either to the whole cube or to specific sections of the cube, at specific points throughout the execution of the script. The default script command, which is the CALCULATE statement, populates cells in the cube with aggregated data based on the default scope.

The default scope is the whole cube, but you can define a more limited scope, known as a subcube, and then apply an MDX script to only that particular cube space. The SCOPE statement defines the scope of all subsequent MDX expressions and statements in the calculation script until the scope is terminated or redefined. The THIS statement is then used to apply an MDX expression to the current scope. You can use the BACK_COLOR statement to specify a background cell color for the cells in the current scope, to help you during debugging.

For example, you can use a script command to allocate sales quotas to employees across time and sales territory based on the weighted values of sales for a prior time period.

Cube Cells (Analysis Services - Multidimensional Data)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A cube is composed of cells, organized by measure groups and dimensions. A cell represents the unique logical intersection in a cube of one member from every dimension in the cube. For example, the cube described by the following diagram contains one measure group that has two measures, organized along three dimensions named Source, Route, and Time.

The single shaded cell in this diagram is the intersection of the following members:

- The air member of the Route dimension.
- The Africa member of the Source dimension.
- The 4th quarter member of the Time dimension.
- The Packages measure.

Leaf and Nonleaf Cells

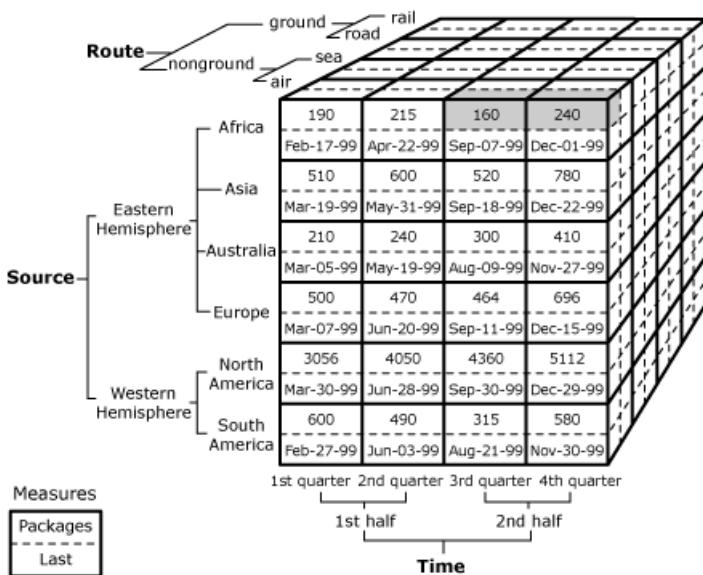

The value for a cell in a cube can be obtained in one of several ways. In the previous example, the value in the cell can be directly retrieved from the fact table of the cube, because all the members used to identify that cell are *leaf members*. A leaf member has no child members, hierarchically speaking, and typically references a single record in a dimension table. This kind of cell is referred to as a *leaf cell*.

However, a cell can also be identified by using *nonleaf members*. A nonleaf member is a member that has one or more child members. In this case, the value of the cell is typically derived from the aggregation of child members associated with the nonleaf member. For example, the intersection of the following members and dimensions refers to a cell whose value is supplied by aggregation:

- The air member of the Route dimension.
- The Africa member of the Source dimension.

- The 2nd half member of the Time dimension.
- The Packages member.

The 2nd half member of the Time dimension is a nonleaf member. Therefore, all of values associated with it must be aggregated values, as shown in the following diagram.

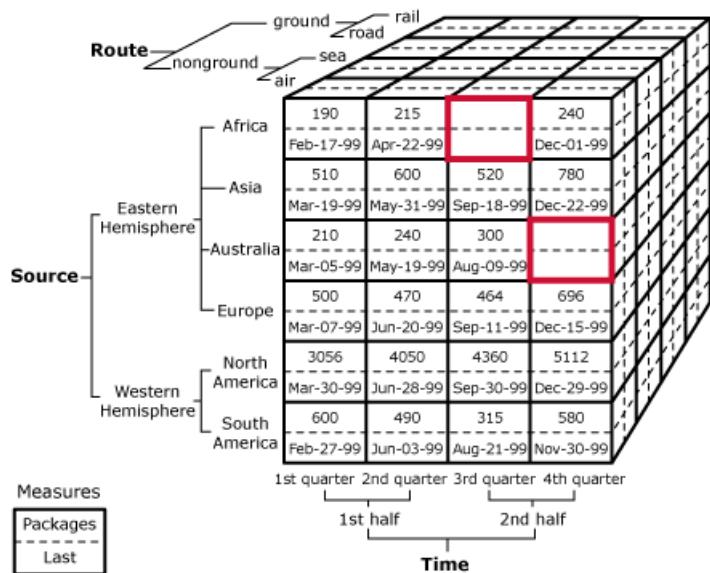

Assuming the aggregations for the 3rd quarter and 4th quarter members are summations, the value of the specified cell is 400, which is the total of all of the leaf cells shaded in the previous diagram. Because the value of the cell is derived from the aggregation of other cells, the specified cell is considered a *nonleaf cell*.

The cell values derived for members that use custom rollups and member groups, in addition to custom members, are handled similarly. However, cell values derived for calculated members are based completely on the Multidimensional Expressions (MDX) expression used to define the calculated member; in some cases, there may be no actual cell data involved. For more information, see [Custom Rollup Operators in Parent-Child Dimensions](#), [Define Custom Member Formulas](#), and [Calculations](#).

Empty Cells

It is not required that every cell in a cube contain a value; there can be intersections in a cube that have no data. These intersections, called empty cells, frequently occur in cubes because not every intersection of a dimension attribute with a measure within a cube contains a corresponding record in a fact table. The ratio of empty cells in a cube to the total number of cells in a cube is frequently referred to as the *sparsity* of a cube.

For example, the structure of the cube shown in the following diagram is similar to other examples in this topic. However, in this example, there were no air shipments to Africa for the third quarter or to Australia for the fourth quarter. There is no data in the fact table to support the intersections of those dimensions and measures; therefore the cells at those intersections are empty.

In SQL Server Analysis Services, an empty cell is a cell that has special qualities. Because empty cells can skew the results of crossjoins, counts, and so on, many MDX functions supply the ability to ignore empty cells for the purposes of calculation. For more information, see [Multidimensional Expressions \(MDX\) Reference](#), and [Key Concepts in MDX \(Analysis Services\)](#).

Security

Access to cell data is managed in Analysis Services at the role level, and can be finely controlled by using MDX expressions. For more information, see [Grant custom access to dimension data \(Analysis Services\)](#), and [Grant custom access to cell data \(Analysis Services\)](#).

Cube Objects (Analysis Services - Multidimensional Data)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Introducing Cube Objects

A simple [Cube](#) object is composed of: basic information, dimensions, and measure groups. Basic information includes the name of the cube, the default measure of the cube, the data source, the storage mode, and others.

The Dimensions collection contains the actual set of dimensions used in the cube from the database dimensions collection. All dimensions have to be defined in the dimensions collection of the database before being referenced in the cube. Private dimensions are not available in Microsoft SQL Server Analysis Services.

Measure groups are sets of measures in the cube. A measure group is a collection of measures that have a common data source view and a common set of dimensions. A measure group is the unit of process for measures; measure groups can be processed individually and then browsed.

Cube Properties - Multidimensional Model Programming

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Cubes have a number of properties that you can set to affect cube-wide behavior. These properties are summarized in the following table.

NOTE

Some properties are set automatically when the cube is created and cannot be changed.

For more information about how to set cube properties, see [Cube Designer \(Analysis Services - Multidimensional Data\)](#).

PROPERTY	DESCRIPTION
AggregationPrefix	Specifies the common prefix that is used for aggregation names.
Collation	Specifies the locale identifier (LCID) and the comparison flag, separated by an underscore: for example, Latin1_General_C1_AS.
DefaultMeasure	Contains a Multidimensional Expressions (MDX) expression that defines the default measure for the cube.
Description	Provides a description of the cube, which may be exposed in client applications.
ErrorConfiguration	Contains configurable error handling settings for handling of duplicate keys, unknown keys, error limits, action upon error detection, error log file, and null key handling.
EstimatedRows	Specifies the number of estimated rows in the cube.
ID	Contains the unique identifier (ID) of the cube.
Language	Specifies the default language identifier of the cube.
Name	Specifies the user-friendly name of the cube.
ProactiveCaching	Defines proactive cache settings for the cube.
ProcessingMode	Indicates whether indexing and aggregating should occur during or after processing. Options are regular or lazy .

PROPERTY	DESCRIPTION
ProcessingPriority	Determines the processing priority of the cube during background operations, such as lazy aggregations and indexing. The default value is 0 .
ScriptCacheProcessingMode	Indicates whether the script cache should be built during or after processing. Options are regular and lazy .
ScriptErrorHandlingMode	Determines error handling. Options are IgnoreNone or IgnoreAll
Source	Displays the data source view used for the cube.
StorageLocation	Specifies the file system storage location for the cube. If none is specified, the location is inherited from the database that contains the cube object.
StorageMode	Specifies the storage mode for the cube. Values are MOLAP , ROLAP , or HOLAP .
Visible	Determines the visibility of the cube.

NOTE

For more information about setting values for the ErrorConfiguration property when working with null values and other data integrity issues, see [Handling Data Integrity Issues in Analysis Services 2005](#).

[Proactive Caching \(Partitions\)](#)

Cube Storage (Analysis Services - Multidimensional Data)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Storage may include only the cube metadata, or may include all of the source data from the fact table as well as the aggregations defined by dimensions related to the measure group. The amount of data stored depends upon the storage mode selected and the number of aggregations. The amount of data stored directly affects query performance. Microsoft SQL Server Analysis Services uses several techniques for minimizing the space required for storage of cube data and aggregations:

- Storage options enable you to select the storage modes and locations that are most appropriate for cube data.
- A sophisticated algorithm designs efficient summary aggregations to minimize storage without sacrificing speed.
- Storage is not allocated for empty cells.

Storage is defined on a partition-by-partition basis, and at least one partition exists for each measure group in a cube. For more information, see [Partitions \(Analysis Services - Multidimensional Data\)](#), [Partition Storage Modes and Processing](#), [Measures and Measure Groups](#), and [Create Measures and Measure Groups in Multidimensional Models](#).

Partition Storage

Storage for a measure group can be divided into multiple partitions. Partitions enable you to distribute a measure group into discrete segments on a single server or across multiple servers, and to optimize storage and query performance. Each partition in a measure group can be based on a different data source and stored using different storage settings.

You specify the data source for a partition when you create it. You can also change the data source for any existing partition. A measure group can be partitioned vertically or horizontally. Each partition in a vertically partitioned measure group is based on a filtered view of a single source table. For example, if a measure group is based on a single table that contains several years of data, you could create a separate partition for each year's data. In contrast, each partition in a horizontally partitioned measure group is based on a separate table. You would use horizontal partitions if the data source stores each year's data in a separate table.

Partitions are initially created with the same storage settings as the measure group in which they are created. The storage settings determine whether the detail and aggregation data is stored in multidimensional format on the instance of Analysis Services, in relational format on the source server, or a combination of both. Storage settings also determine whether proactive caching is used to automatically process source data changes to the multidimensional data stored on the Analysis Services.

The partitions of a cube are not visible to the user. However, the choice of storage settings for different partitions may affect the immediacy of data, the amount of disk space that is used, and query performance. Partitions can be stored on multiple instances of Analysis Services. This provides a clustered approach to cube storage, and distributes workload across Analysis Services servers. For more information, see [Partition Storage Modes and Processing](#), [Remote Partitions](#), and [Partitions \(Analysis Services - Multidimensional Data\)](#).

Linked Measure Groups

It can require considerable disk space to store multiple copies of a cube on different instances of Analysis Services, but you can greatly reduce the space needed by replacing the copies of the measure group with linked measure groups. A linked measure group is based on a measure group in a cube in another Analysis Services database, on the same or a different instance of Analysis Services. A linked measure group can also be used with linked dimensions from the same source cube. The linked dimensions and measure groups use the aggregations of the source cube and have no data storage requirements of their own. Therefore, by maintaining the source measure groups and dimensions in one database, and creating linked cubes and dimensions in cubes in other databases, you can save disk space that otherwise would be used for storage. For more information, see [Linked Measure Groups](#).

Cube Translations

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

A translation is a simple mechanism to change the displayed labels and captions from one language to another. Each translation is defined as a pair of values: a string with the translated text, and a number with the language ID. Translations are available for all objects in Analysis Services. Dimensions can also have the attribute values translated. The client application is responsible for finding the language setting that the user has defined, and switch to display all captions and labels to that language. An object can have as many translations as you want.

A simple [Translation](#) object is composed of: language ID number, and translated caption. The language ID number is an **Integer** with the language ID. The translated caption is the translated text.

In Microsoft SQL Server Analysis Services, a cube translation is a language-specific representation of the name of a cube object, such as a caption or a display folder. Analysis Services also supports translations of dimension and member names.

Translations provide server support for client applications that can support multiple languages. Frequently, users from different countries view cube data. It is useful to be able to translate various elements of a cube into a different language so that these users can view and understand the cube's metadata. For example, a business user in France can access a cube from a workstation with a French locale setting, and view the object property values in French. Similarly, a business user in Germany can access the same cube from a workstation with a German locale setting and view the object property values in German.

The collation and language information for the client computer is stored in the form of a locale identifier (LCID). Upon connection, the client passes the LCID to the instance of Analysis Services. The instance uses the LCID to determine which set of translations to use when providing metadata for Analysis Services objects to each business user. If an Analysis Services object does not contain the specified translation, the default language is used to return the content back to the client.

Dimension Relationships

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Dimension usage defines the relationships between a cube dimension and the measure groups in a cube. A cube dimension is an instance of a database dimension that is used in a specific cube. A cube can, and frequently does, have cube dimensions that are not directly related to a measure group, but which might be indirectly related to the measure group through another dimension or measure group. When you add a database dimension or measure group to a cube, Microsoft SQL Server Analysis Services tries to determine dimension usage by examining relationships between the dimension tables and fact tables in the cube's data source view, and by examining the relationships between attributes in dimensions. Analysis Services automatically sets the dimension usage settings for the relationships that it can detect.

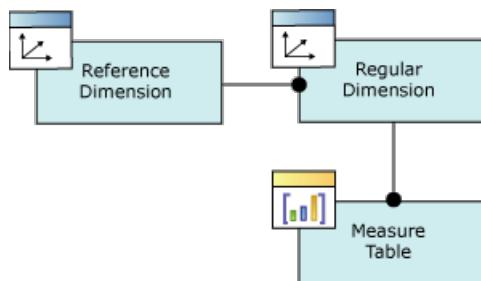

A relationship between a dimension and a measure group consists of the dimension and fact tables participating in the relationship and a granularity attribute that specifies the granularity of the dimension in the particular measure group.

Regular Dimension Relationships

A regular dimension relationship between a cube dimension and a measure group exists when the key column for the dimension is joined directly to the fact table. This direct relationship is based on a primary key-foreign key relationship in the underlying relational database, but might also be based on a logical relationship that is defined in the data source view. A regular dimension relationship represents the relationship between dimension tables and a fact table in a traditional star schema design. For more information about regular relationships, see [Define a Regular Relationship](#) and [Regular Relationship Properties](#).

Reference Dimension Relationships

A reference dimension relationship between a cube dimension and a measure group exists when the key column for the dimension is joined indirectly to the fact table through a key in another dimension table, as shown in the following illustration.

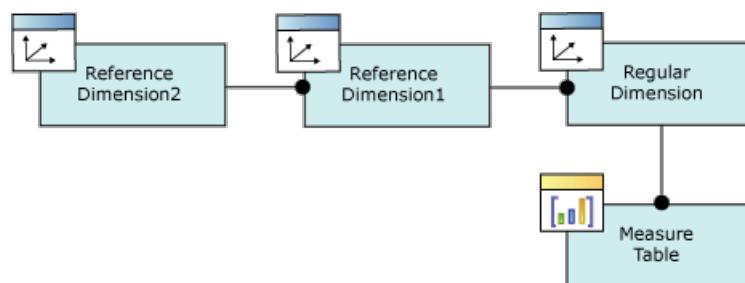

A reference dimension relationship represents the relationship between dimension tables and a fact table in a snowflake schema design. When dimension tables are connected in a snowflake schema, you can define a single dimension using columns from multiple tables, or you can define separate dimensions based on the separate dimension tables and then define a link between them using the reference dimension relationship setting. The following figure shows one fact table named **InternetSales**, and two dimension tables called **Customer** and **Geography**, in a snowflake schema.

You can create a dimension with the **Customer** table as the dimension main table and the **Geography** table included as a related table. A regular relationship is then defined between the dimension and the InternetSales measure group.

Alternatively, you can create two dimensions related to the InternetSales measure group: a dimension based on the **Customer** table, and a dimension based on the **Geography** table. You can then relate the Geography dimension to the InternetSales measure group using a reference dimension relationship using the Customer dimension. In this case, when the facts in the InternetSales measure group are dimensioned by the Geography dimension, the facts are dimensioned by customer and by geography. If the cube contained a second measure group named Reseller Sales, you would be unable to dimension the facts in the Reseller Sales measure group by Geography because no relationship would exist between Reseller Sales and Geography.

There is no limit to the number of reference dimensions that can be chained together, as shown in the following illustration.

For more information about referenced relationships, see [Define a Referenced Relationship and Referenced Relationship Properties](#).

Fact Dimension Relationships

Fact dimensions, frequently referred to as degenerate dimensions, are standard dimensions that are constructed from attribute columns in fact tables instead of from attribute columns in dimension tables. Useful dimensional data is sometimes stored in a fact table to reduce duplication. For example, the following diagram displays the **FactResellerSales** fact table, from the Adventure Works DW Multidimensional 2012 sample database.

FactResellerSales (dbo.FactResellerSales)
SalesOrderNumber
SalesOrderLineNumber
ProductKey
OrderDateKey
DueDateKey
ShipDateKey
ResellerKey
EmployeeKey
PromotionKey
CurrencyKey
SalesTerritoryKey
RevisionNumber
OrderQuantity
UnitPrice
ExtendedAmount
UnitPriceDiscountPct
DiscountAmount
ProductStandardCost
TotalProductCost
SalesAmount
TaxAmt
Freight
CarrierTrackingNumber
CustomerPONumber

The table contains attribute information not only for each line of an order issued by a reseller, but about the order itself. The attributes circled in the previous diagram identify the information in the **FactResellerSales** table that could be used as attributes in a dimension. In this case, two additional pieces of information, the carrier tracking number and the purchase order number issued by the reseller, are represented by the CarrierTrackingNumber and CustomerPONumber attribute columns. This information is interesting—for example, users would definitely be interested in seeing aggregated information, such as the total product cost, for all the orders being shipped under a single tracking number. But, without a dimension data for these two attributes cannot be organized or aggregated.

In theory, you could create a dimension table that uses the same key information as the FactResellerSales table and move the other two attribute columns, CarrierTrackingNumber and CustomerPONumber, to that dimension table. However, you would be duplicating a significant portion of data and adding unnecessary complexity to the data warehouse to represent just two attributes as a separate dimension.

NOTE

Fact dimensions are frequently used to support drillthrough actions. For more information about actions, see [Actions \(Analysis Services - Multidimensional Data\)](#).

NOTE

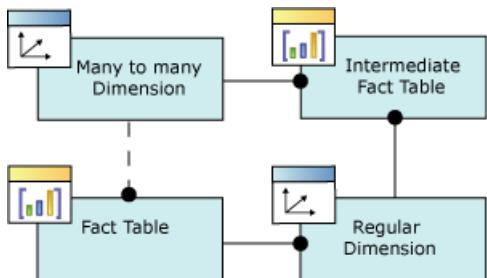

Fact dimensions must be incrementally updated after every update to the measure group that is referenced by the fact relationship. If the fact dimension is a ROLAP dimension, the Analysis Services processing engine drops any caches and incrementally processes the measure group.

For more information about fact relationships, see [Define a Fact Relationship and Fact Relationship Properties](#).

Many to Many Dimension Relationships

In most dimensions, each fact joins to one and only one dimension member, and a single dimension member can be associated with multiple facts. In relational database terminology, this is referred to as a one-to-many relationship. However, it is frequently useful to join a single fact to multiple dimension members. For example, a bank customer might have multiple accounts (checking, saving, credit card, and investment accounts), and an account can also have joint or multiple owners. The Customer dimension constructed from such relationships

would then have multiple members that relate to a single account transaction.

SQL Server Analysis Services lets you define a many-to-many relationship between a dimension and a fact table.

NOTE

To support a many-to-many dimension relationship, the data source view must have established a foreign key relationship between all the tables involved, as shown in the previous diagram. Otherwise, you will be unable to select the correct intermediate measure group when establishing the relationship in the **Dimension Usage** tab of Dimension Designer.

For more information about many-to-many relationships, see [Define a Many-to-Many Relationship and Many-to-Many Relationship Properties](#).

[Dimensions \(Analysis Services - Multidimensional Data\)](#)

Partitions - Partition Storage Modes and Processing

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The storage mode of a partition affects the query and processing performance, storage requirements, and storage locations of the partition and its parent measure group and cube. The choice of storage mode also affects processing choices.

A partition can use one of three basic storage modes:

- Multidimensional OLAP (MOLAP)
- Relational OLAP (ROLAP)
- Hybrid OLAP (HOLAP)

Microsoft SQL Server Analysis Services supports all three basic storage modes. It also supports proactive caching, which enables you to combine the characteristics of ROLAP and MOLAP storage for both immediacy of data and query performance. For more information, see [Proactive Caching \(Partitions\)](#).

MOLAP

The MOLAP storage mode causes the aggregations of the partition and a copy of its source data to be stored in a multidimensional structure in Analysis Services when the partition is processed. This MOLAP structure is highly optimized to maximize query performance. The storage location can be on the computer where the partition is defined or on another computer running Analysis Services. Because a copy of the source data resides in the multidimensional structure, queries can be resolved without accessing the partition's source data. Query response times can be decreased substantially by using aggregations. The data in the partition's MOLAP structure is only as current as the most recent processing of the partition.

As the source data changes, objects in MOLAP storage must be processed periodically to incorporate those changes and make them available to users. Processing updates the data in the MOLAP structure, either fully or incrementally. The time between one processing and the next creates a latency period during which data in OLAP objects may not match the source data. You can incrementally or fully update objects in MOLAP storage without taking the partition or cube offline. However, there are situations that may require you to take a cube offline to process certain structural changes to OLAP objects. You can minimize the downtime required to update MOLAP storage by updating and processing cubes on a staging server and using database synchronization to copy the processed objects to the production server. You can also use proactive caching to minimize latency and maximize availability while retaining much of the performance advantage of MOLAP storage. For more information, see [Proactive Caching \(Partitions\)](#), [Synchronize Analysis Services Databases](#), and [Processing a multidimensional model \(Analysis Services\)](#).

ROLAP

The ROLAP storage mode causes the aggregations of the partition to be stored in indexed views in the relational database that was specified in the partition's data source. Unlike the MOLAP storage mode, ROLAP does not cause a copy of the source data to be stored in the Analysis Services data folders. Instead, when results cannot be derived from the query cache, the indexed views in the data source is accessed to answer queries. Query response is generally slower with ROLAP storage than with the MOLAP or HOLAP storage modes. Processing time is also typically slower with ROLAP. However, ROLAP enables users to view data in real time and can save storage space when you are working with large datasets that are infrequently queried, such as purely historical

data.

NOTE

When using ROLAP, Analysis Services may return incorrect information related to the unknown member if a join is combined with a GROUP BY clause. Analysis Services eliminates relational integrity errors instead of returning the unknown member value.

If a partition uses the ROLAP storage mode and its source data is stored in SQL Server Database Engine, Analysis Services tries to create indexed views to contain aggregations of the partition. If Analysis Services cannot create indexed views, it does not create aggregation tables. Although Analysis Services handles the session requirements for creating indexed views on SQL Server Database Engine, the following conditions must be met by the ROLAP partition and the tables in its schema in order for Analysis Services to create indexed views for aggregations:

- The partition cannot contain measures that use the **Min** or **Max** aggregate functions.
- Each table in the schema of the ROLAP partition must be used only one time. For example, the schema cannot contain [dbo].[address] AS "Customer Address" and [dbo].[address] AS "SalesRep Address".
- Each table must be a table, not a view.
- All table names in the partition's schema must be qualified with the owner name, for example, [dbo].[customer].
- All tables in the partition's schema must have the same owner; for example, you cannot have a FROM clause that references the tables [tk].[customer], [john].[store], and [dave].[sales_fact_2004].
- The source columns of the partition's measures must not be nullable.
- All tables used in the view must have been created with the following options set to ON:
 - ANSI_NULLS
 - QUOTED_IDENTIFIER
- The total size of the index key, in SQL Server Database Engine, cannot exceed 900 bytes. SQL Server Database Engine will assert this condition based on the fixed length key columns when the CREATE INDEX statement is processed. However, if there are variable length columns in the index key, SQL Server Database Engine will also assert this condition for every update to the base tables. Because different aggregations have different view definitions, ROLAP processing using indexed views can succeed or fail depending on the aggregation design.
- The session creating the indexed view must have the following options set to ON: ARITHABORT, CONCAT_NULL_YIELDS_NULL, QUOTED_IDENTIFIER, ANSI_NULLS, ANSI_PADDING, and ANSI_WARNINGS. This setting can be made in SQL Server Management Studio.
- The session creating the indexed view must have the following option set to OFF: NUMERIC_ROUNDABORT. This setting can be made in SQL Server Management Studio.

HOLAP

The HOLAP storage mode combines attributes of both MOLAP and ROLAP. Like MOLAP, HOLAP causes the aggregations of the partition to be stored in a multidimensional structure in an SQL Server Analysis Services instance. HOLAP does not cause a copy of the source data to be stored. For queries that access only summary data in the aggregations of a partition, HOLAP is the equivalent of MOLAP. Queries that access source data—for example, if you want to drill down to an atomic cube cell for which there is no aggregation data—must retrieve

data from the relational database and will not be as fast as they would be if the source data were stored in the MOLAP structure. With HOLAP storage mode, users will typically experience substantial differences in query times depending upon whether the query can be resolved from cache or aggregations versus from the source data itself.

Partitions stored as HOLAP are smaller than the equivalent MOLAP partitions because they do not contain source data and respond faster than ROLAP partitions for queries involving summary data. HOLAP storage mode is generally suited for partitions in cubes that require rapid query response for summaries based on a large amount of source data. However, where users generate queries that must touch leaf level data, such as for calculating median values, MOLAP is generally a better choice.

[Synchronize Analysis Services Databases](#)

[Partitions \(Analysis Services - Multidimensional Data\)](#)

Partitions - Proactive Caching

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Proactive caching provides automatic MOLAP cache creation and management for OLAP objects. The cubes immediately incorporate changes that are made to the data in the database, based upon notifications received from the database. The goal of proactive caching is to provide the performance of traditional MOLAP, while retaining the immediacy and ease of management offered by ROLAP.

A simple [ProactiveCaching](#) object is composed of: timing specification, and table notification. The timing specification defines the timeframe for updating the cache after a change notification has been received. The table notification defines the notification schema between the data table and the [ProactiveCaching](#) object.

Multidimensional OLAP (MOLAP) storage provides the best query response, but with a penalty of some data latency. Real-time relational OLAP (ROLAP) storage lets users immediately browse the most recent changes in a data source, but at the penalty of significantly poorer performance than multidimensional OLAP (MOLAP) storage because of the absence of precalculated summaries of data and because relational storage is not optimized for OLAP-style queries. If you have applications in which your users need to see recent data and you also want the performance advantages of MOLAP storage, SQL Server Analysis Services offers the option of proactive caching to address this scenario, particularly in combination with the use of partitions. Proactive caching is set on a per partition and per dimension basis. Proactive caching options can provide a balance between the enhanced performance of MOLAP storage and the immediacy of ROLAP storage, and provide automatic partition processing when underlying data changes or on a set schedule.

Proactive Caching Configuration Options

SQL Server Analysis Services provides several proactive caching configuration options that enable you to maximize performance, minimize latency, and schedule processing. Proactive caching features simplify the process of managing data obsolescence. The proactive caching settings determine how frequently the multidimensional OLAP structure, also called the MOLAP cache, is rebuilt, whether the outdated MOLAP storage is queried while the cache is rebuilt or the underlying ROLAP data source, and whether the cache is rebuilt on a schedule or based on changes in the database.

Minimizing Latency

With proactive caching set to minimize latency, user queries against an OLAP object are made against either ROLAP storage or MOLAP storage, depending whether recent changes have occurred to the data and how proactive caching is configured. The query engine directs queries against source data in MOLAP storage until changes occur in the data source. To minimize latency, after changes occur in a data source, cached MOLAP objects can be dropped and querying switched to ROLAP storage while the MOLAP objects are rebuilt in cache. After the MOLAP objects are rebuilt and processed, queries are automatically switched to the MOLAP storage. The cache refresh can occur extremely quickly for a small partition, such as the current partition - which can be as small as the current day.

Maximizing Performance

To maximize performance while also reducing latency, caching can also be used without dropping the current MOLAP objects. Queries then continue against the MOLAP objects while data is read into and processed in a new cache. This method provides better performance but may result in queries returning old data while the new cache is being built.

[Dimension Storage](#)

[Set Partition Storage \(Analysis Services - Multidimensional\)](#)

Partitions - Remote Partitions

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The data of a remote partition is stored on a different instance of Microsoft SQL Server Analysis Services than the instance that contains the definitions (metadata) of the partition and its parent cube. A remote partition is administered on the same instance of Analysis Services where the partition and its parent cube are defined.

NOTE

To store a remote partition, the computer must have an instance of SQL Server Analysis Services installed and be running the same service pack level as the instance where the partition was defined. Remote partitions on instances of an earlier version of Analysis Services are not supported.

When remote partitions are included in a measure group, the memory and CPU utilization of the cube is distributed across all the partitions in the measure group. For example, when a remote partition is processed, either alone or as part of parent cube processing, most of the memory and CPU utilization for that partition occurs on the remote instance of Analysis Services.

NOTE

A cube that contains remote partitions can contain write-enabled dimensions; however, this may affect performance for the cube. For more information about write-enabled dimensions, see [Write-Enabled Dimensions](#).

Storage Modes for Remote Partitions

Remote partitions may use any of the storage types used by local partitions: multidimensional OLAP (MOLAP), hybrid OLAP (HOLAP), or relational OLAP (ROLAP). Remote partitions may also use proactive caching. Depending on the storage mode of a remote partition, the following data is stored on the remote instance of Analysis Services.

Storage Type	Data
MOLAP	The partition's aggregations and a copy of the partition's source data
HOLAP	The partitions aggregations
ROLAP	No partition data

If a measure group contains multiple MOLAP or HOLAP partitions stored on multiple instances of Analysis Services, the cube distributes the data in the measure group data among those instances of Analysis Services.

Merging Remote Partitions

Remote partitions can be merged only with other remote partitions that are stored on the same remote instance of Analysis Services. For more information about merging partitions, see [Merge Partitions in Analysis Services](#)

(SSAS - Multidimensional).

Archiving and Restoring Remote Partitions

Data in remote partitions can be archived or restored when the database that stores the remote partition is archived or restored. If you restore a database without restoring a remote partition, you must process the remote partition before you can use the data in the partition. For more information about archiving and restoring databases, see [Backup and Restore of Analysis Services Databases](#).

[Create and Manage a Remote Partition \(Analysis Services\)](#)

[Processing Analysis Services Objects](#)

Partitions - Write-Enabled Partitions

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The data in a cube is generally read-only. However, for certain scenarios, you may want to write-enable a partition. Write-enabled partitions are used to enable business users to explore scenarios by changing cell values and analyzing the effects of the changes on cube data. When you write-enable a partition, client applications can record changes to the data in the partition. These changes, known as writeback data, are stored in a separate table and do not overwrite any existing data in a measure group. However, they are incorporated into query results as if they are part of the cube data.

You can write-enable an entire cube or only certain partitions in the cube. Write-enabled dimensions are different but complementary. A write-enabled partition lets users update partition cells, whereas a write-enabled dimension lets users update dimension members. You can also use these two features in combination. For example, a write-enabled cube or a write-enabled partition does not have to include any write-enabled dimensions. **Related topic:**[Write-Enabled Dimensions](#).

NOTE

If you want to write-enable a cube that has a Microsoft Access database as a data source, do not use Microsoft OLE DB Provider for ODBC Drivers in the data source definitions for the cube, its partitions, or its dimensions. Instead, you can use Microsoft Jet 4.0 OLE DB Provider, or any version of the Jet Service Pack that includes Jet 4.0 OLE. For more information, see the Microsoft Knowledge Base article [How to obtain the latest service pack for the Microsoft Jet 4.0 Database Engine](#).

A cube can be write-enabled only if all its measures use the **Sum** aggregate function. Linked measure groups and local cubes cannot be write-enabled.

Writeback Storage

Any change made by the business user is stored in the writeback table as a difference from the currently displayed value. For example, if an end user changes a cell value from 90 to 100, the value **+10** is stored in the writeback table, together with the time of the change and information about the business user who made it. The net effect of accumulated changes is displayed to client applications. The original value in the cube is preserved, and an audit trail of changes is recorded in the writeback table.

Changes to leaf and nonleaf cells are handled differently. A leaf cell represents an intersection of a measure and a leaf member from every dimension referenced by the measure group. The value of a leaf cell is taken directly from the fact table, and cannot be divided further by drilling down. If a cube or any partition is write-enabled, changes can be made to a leaf cell. Changes can be made to a nonleaf cell only if the client application provides a way of distributing the changes among the leaf cells that make up the nonleaf cell. This process, called allocation, is managed through the UPDATE CUBE statement in Multidimensional Expressions (MDX). Business intelligence developers can use the UPDATE CUBE statement to include allocation functionality. For more information, see [UPDATE CUBE Statement \(MDX\)](#).

IMPORTANT

When updated cells do not overlap, the **Update Isolation Level** connection string property can be used to enhance performance for UPDATE CUBE. For more information, see [ConnectionString](#).

Regardless of whether a client application distributes changes that were made to nonleaf cells, whenever queries are evaluated, changes in the writeback table are applied to both leaf and nonleaf cells so that business users can view the effects of the changes throughout the cube.

Changes that were made by the business user are kept in a separate writeback table that you can work with as follows:

- Convert to a partition to permanently incorporate changes into the cube. This action makes the measure group read-only. You can specify a filter expression to select the changes you want to convert.
- Discard to return the partition to its original state. This action makes the partition read-only.

Security

A business user is permitted to record changes in a cube's writeback table only if the business user belongs to a role that has read/write permission to the cube's cells. For each role, you can control which cube cells can and cannot be updated. For more information, see [Grant cube or model permissions \(Analysis Services\)](#).

[Write-Enabled Dimensions](#)

[Aggregations and Aggregation Designs](#)

[Partitions \(Analysis Services - Multidimensional Data\)](#)

[Write-Enabled Dimensions](#)

Partitions (Analysis Services - Multidimensional Data)

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

A partition is a container for a portion of the measure group data. Partitions are not seen from MDX queries; all queries reflect the whole content of the measure group, regardless of how many partitions are defined for the measure group. The data content of a partition is defined by the query bindings of the partition, and by the slicing expression.

A simple [Partition](#) object is composed of: basic information, slicing definition, aggregation design, and others. Basic information includes the name of the partition, the storage mode, the processing mode, and others. The slicing definition is an MDX expression specifying a tuple or a set. The slicing definition has the same restrictions as the StrToSet MDX function. Together with the CONSTRAINED parameter, the slicing definition can use dimension, hierarchy, level and member names, keys, unique names, or other named objects in the cube, but cannot use MDX functions. The aggregation design is a collection of aggregation definitions that can be shared across multiple partitions. The default is taken from the parent cube's aggregation design.

Partitions are used by Microsoft SQL Server Analysis Services to manage and store data and aggregations for a measure group in a cube. Every measure group has at least one partition; this partition is created when the measure group is defined. When you create a new partition for a measure group, the new partition is added to the set of partitions that already exist for the measure group. The measure group reflects the combined data that is contained in all its partitions. This means that you must ensure that the data for a partition in a measure group is exclusive of the data for any other partition in the measure group to ensure that data is not reflected in the measure group more than once. The original partition for a measure group is based on a single fact table in the data source view of the cube. When there are multiple partitions for a measure group, each partition can reference a different table in either the data source view or in the underlying relational data source for the cube. More than one partition in a measure group can reference the same table, if each partition is restricted to different rows in the table.

Partitions are a powerful and flexible means of managing cubes, especially large cubes. For example, a cube that contains sales information can contain a partition for the data of each past year and also partitions for each quarter of the current year. Only the current quarter partition needs to be processed when current information is added to the cube; processing a smaller amount of data will improve processing performance by decreasing processing time. At the end of the year the four quarterly partitions can be merged into a single partition for the year and a new partition created for the first quarter of the new year. Further, this new partition creation process can be automated as part of your data warehouse loading and cube processing procedures.

Partitions are not visible to business users of the cube. However, administrators can configure, add, or drop partitions. Each partition is stored in a separate set of files. The aggregate data of each partition can be stored on the instance of Analysis Services where the partition is defined, on another instance of Analysis Services, or in the data source that is used to supply the partition's source data. Partitions allow the source data and aggregate data of a cube to be distributed across multiple hard drives and among multiple server computers. For a cube of moderate to large size, partitions can greatly improve query performance, load performance, and ease of cube maintenance.

The storage mode of each partition can be configured independently of other partitions in the measure group. Partitions can be stored by using any combination of options for source data location, storage mode, proactive caching, and aggregation design. Options for real-time OLAP and proactive caching let you balance query speed

against latency when you design a partition. Storage options can also be applied to related dimensions and to facts in a measure group. This flexibility lets you design cube storage strategies appropriate to your needs. For more information, see [Partition Storage Modes and Processing, Aggregations and Aggregation Designs](#) and [Proactive Caching \(Partitions\)](#).

Partition Structure

The structure of a partition must match the structure of its measure group, which means that the measures that define the measure group must also be defined in the partition, along with all related dimensions. Therefore, when a partition is created, it automatically inherits the same set of measures and related dimensions that were defined for the measure group.

However, each partition in a measure group can have a different fact table, and these fact tables can be from different data sources. When different partitions in a measure group have different fact tables, the tables must be sufficiently similar to maintain the structure of the measure group, which means that the processing query returns the same columns and same data types for all fact tables for all partitions.

When fact tables for different partitions are from different data sources, the source tables for any related dimensions, and also any intermediate fact tables, must also be present in all data sources and must have the same structure in all the databases. Also, all dimension table columns that are used to define attributes for cube dimensions related to the measure group must be present in all of the data sources. There is no need to define all the joins between the source table of a partition and a related dimension table if the partition source table has the identical structure as the source table for the measure group.

Columns that are not used to define measures in the measure group can be present in some fact tables but absent in others. Similarly, columns that are not used to define attributes in related dimension tables can be present in some databases but absent in others. Tables that are not used for either fact tables or related dimension tables can be present in some databases but absent in others.

Data Sources and Partition Storage

A partition is based either on a table or view in a data source, or on a table or named query in a data source view. The location where partition data is stored is defined by the data source binding. You can partition a measure group using either a single-table partition scheme, or a multi-table partition scheme:

- In a multi-table partition scheme each partition in a measure group partition is based on a separate table. This kind of partitioning is appropriate when data is separated into multiple tables. For example, some relational databases have a separate table for each month's data.
- In a single-table partition scheme a measure group is based on a single table, and each partition is based on a source system query that filters the data for the partition. For example, if a single table contains several months data, the measure group could still be partitioned by month by applying a Transact-SQL WHERE clause that returns a separate month's data for each partition.

Each partition has storage settings that determine whether the data and aggregations for the partition are stored in the local instance of Analysis Services or in a remote partition using another instance of Analysis Services. The storage settings can also specify the storage mode and whether proactive caching is used to control latency for a partition. For more information, see [Partition Storage Modes and Processing, Proactive Caching \(Partitions\)](#), and [Remote Partitions](#).

Incremental Updates

When you create and manage partitions in multiple-partition measure groups, you must take special precautions to guarantee that cube data is accurate. Although these precautions do not usually apply to single-partition measure groups, they do apply when you incrementally update partitions. When you incrementally

update a partition, a new temporary partition is created that has a structure identical to that of the source partition. The temporary partition is processed and then merged with the source partition. Therefore, you must ensure that the processing query that populates the temporary partition does not duplicate any data already present in an existing partition.

Perspectives

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

A perspective is a definition that allows users to see a cube in a simpler way. A perspective is a subset of the features of a cube. A perspective enables administrators to create views of a cube, helping users to focus on the most relevant data for them. A perspective contains subsets of all objects from a cube. A perspective cannot include elements that are not defined in the parent cube.

A simple [Perspective](#) object is composed of: basic information, dimensions, measure groups, calculations, KPIs, and actions. Basic information includes the name and the default measure of the perspective. The dimensions are a subset of the cube dimensions. The measure groups are a subset of the cube measure groups. The calculations are a subset of the cube calculations. The KPIs are a subset of the cube KPIs. The actions are a subset of the cube actions.

A cube has to be updated and processed before the perspective can be used.

Cubes can be very complex objects for users to explore in Microsoft SQL Server Analysis Services. A single cube can represent the contents of a complete data warehouse, with multiple measure groups in a cube representing multiple fact tables, and multiple dimensions based on multiple dimension tables. Such a cube can be very complex and powerful, but daunting to users who may only need to interact with a small part of the cube in order to satisfy their business intelligence and reporting requirements.

In Microsoft SQL Server Analysis Services, you can use a perspective to reduce the perceived complexity of a cube in Analysis Services. A perspective defines a viewable subset of a cube that provides focused, business-specific or application-specific viewpoints on the cube. The perspective controls the visibility of objects that are contained by a cube. The following objects can be displayed or hidden in a perspective:

- Dimensions
- Attributes
- Hierarchies
- Measure groups
- Measures
- Key Performance Indicators (KPIs)
- Calculations (calculated members, named sets, and script commands)
- Actions

For example, the **Adventure Works** cube in the Adventure Works DW Multidimensional 2012 sample Analysis Services database contains eleven measure groups and twenty-one different cube dimensions, representing sales, sales forecasting, and financial data. A client application can directly reference the complete cube, but this viewpoint may be overwhelming to a user trying to extract basic sales forecasting information. Instead, the same user can use the **Sales Targets** perspective to limit the view of the **Adventure Works** cube to only those objects relevant to sales forecasting.

Objects in a cube that are not visible to the user through a perspective can still be directly referenced and retrieved using XML for Analysis (XMLA), Multidimensional Expressions (MDX), or Data Mining Extensions (DMX) statements. Perspectives do not restrict access to objects in a cube and should not be used as such; instead,

perspectives are used to provide a better user experience while accessing a cube.

A perspective is a read-only view of the cube; objects in the cube cannot be renamed or changed by using a perspective. Similarly, the behavior or features of a cube, such as the use of visual totals, cannot be changed by using a perspective.

Security

Perspectives are not meant to be used as a security mechanism, but as a tool for providing a better user experience in business intelligence applications. All security for a particular perspective is inherited from the underlying cube. For example, perspectives cannot provide access to objects in a cube to which a user does not already have access. - Security for the cube must be resolved before access to objects in the cube can be provided through a perspective.

Logical Architecture Overview (Analysis Services - Multidimensional Data)

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

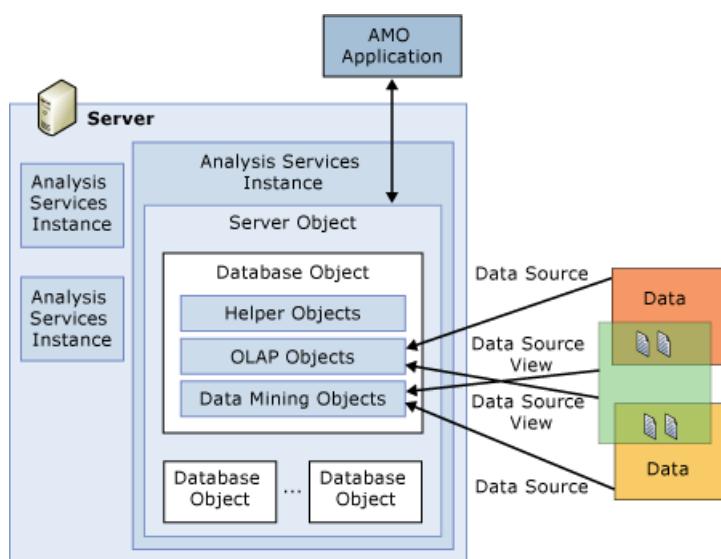

Analysis Services operates in a server deployment mode that determines the memory architecture and runtime environment used by different types of Analysis Services models. Server mode is determined during installation.

Multidimensional and Data Mining mode supports traditional OLAP and data mining. **Tabular mode** supports tabular models. **SharePoint integrated mode** refers to an instance of Analysis Services that was installed as Power Pivot for SharePoint, used for loading and querying Excel or Power Pivot data models inside a workbook.

This topic explains the basic architecture of Analysis Services when operating in Multidimensional and Data Mining mode. For more information about other modes, see [Tabular Modeling](#) and [Comparing Tabular and Multidimensional Solutions](#).

Basic Architecture

An instance of Analysis Services can contain multiple databases, and a database can have OLAP objects and data mining objects at the same time. Applications connect to a specified instance of Analysis Services and a specified database. A server computer can host multiple instances of Analysis Services. Instances of Analysis Services are named as "<ServerName>\<InstanceName>". The following illustration shows all mentioned relationships between Analysis Services objects.

Basic classes are the minimum set of objects that are required to build a cube. This minimum set of objects is a dimension, a measure group, and a partition. An aggregation is optional.

Dimensions are built from attributes and hierarchies. Hierarchies are formed by an ordered set of attributes, where each attribute of the set corresponds to a level in the hierarchy.

Cubes are built from dimensions and measure groups. The dimensions in the dimensions collection of a cube belong to the dimensions collection of the database. Measure groups are collections of measures that have the same data source view and have the same subset of dimensions from the cube. A measure group has one or more partitions to manage the physical data. A measure group can have a default aggregation design. The default aggregation design can be used by all partitions in the measure group; also, each partition can have its own

aggregation design.

Server Objects

Each instance of Analysis Services is seen as a different server object in AMO; each different instance is connected to a [Server](#) object by a different connection. Each server object contains one or more data sources, data source views, and database objects, as well as assemblies and security roles.

Dimension Objects

Each database object contains multiple dimension objects. Each dimension object contains one or more attributes, which are organized into hierarchies.

Cube Objects

Each database object contains one or more cube objects. A cube is defined by its measures and dimensions. The measures and dimensions in a cube are derived from the tables and views in the data source view on which the cube is based, or which is generated from the measure and dimension definitions.

Object Inheritance

The ASSL object model contains many repeated element groups. For example, the element group, "**Dimensions** contain **Hierarchies**," defines the dimension hierarchy of an element. Both **Cubes** and **MeasureGroups** contain the element group, "**Dimensions** contain **Hierarchies**."

Unless explicitly overridden, an element inherits the details of these repeated element groups from the higher level. For example, the **Translations** for a **CubeDimension** are the same as the **Translations** for its ancestor element, **Cube**.

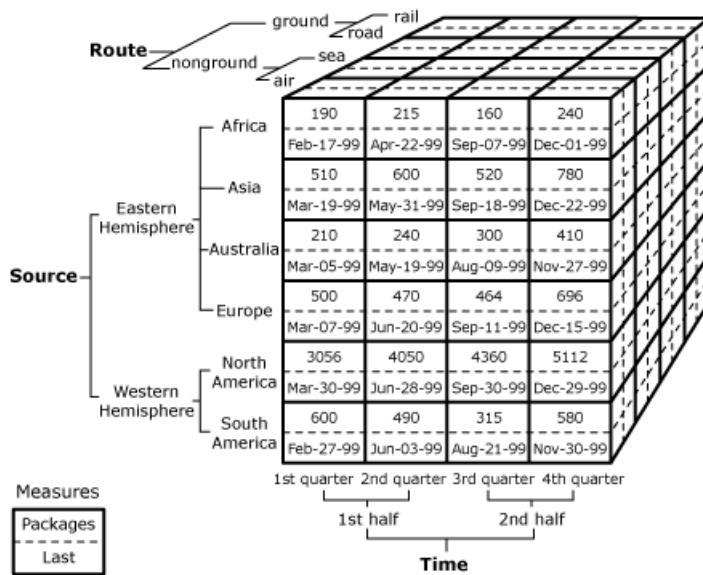

To explicitly override properties inherited from a higher-level object, an object does not need to repeat explicitly the entire structure and properties of the higher-level object. The only properties that an object needs to state explicitly are those properties that the object wants to override. For example, a **CubeDimension** may list only those **Hierarchies** that need to be disabled in the **Cube**, or for which the visibility needs to be changed, or for which some **Level** details have not been provided at the **Dimension** level.

Some properties specified on an object provide default values for the same property on a child or descendant object. For example, **Cube.StorageMode** provides the default value for **Partition.StorageMode**. For inherited default values, ASSL applies these rules for inherited default values:

- When the property for the child object is null in the XML, the property's value defaults to the inherited value. However, if you query the value from the server, the server returns the null value of the XML element.
- It is not possible to determine programmatically whether the property of a child object has been set directly on the child object or inherited.

Example

The Imports cube contains two measures, Packages and Last, and three related dimensions, Route, Source, and Time.

The smaller alphanumeric values around the cube are the members of the dimensions. Example members are ground (member of the Route dimension), Africa (member of the Source dimension), and 1st quarter (member of the Time dimension).

Measures

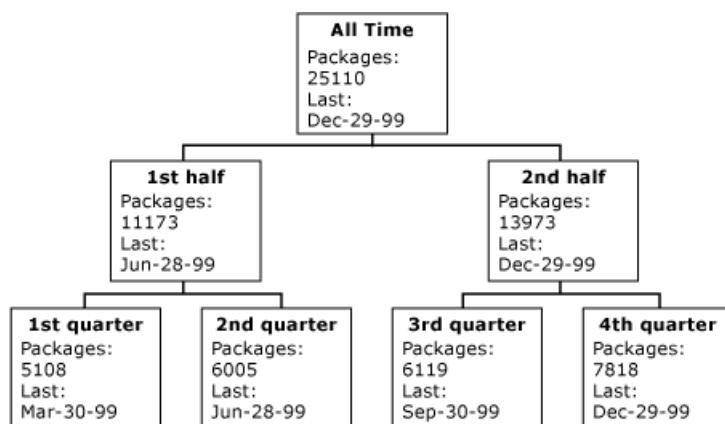

The values within the cube cells represent the two measures, Packages and Last. The Packages measure represents the number of imported packages, and the **Sum** function is used to aggregate the facts. The Last measure represents the date of receipt, and the **Max** function is used to aggregate the facts.

Dimensions

The Route dimension represents the means by which the imports reach their destination. Members of this dimension include ground, nonground, air, sea, road, or rail. The Source dimension represents the locations where the imports are produced, such as Africa or Asia. The Time dimension represents the quarters and halves of a single year.

Aggregates

Business users of a cube can determine the value of any measure for each member of every dimension, regardless of the level of the member within the dimension, because Analysis Services aggregates values at upper levels as needed. For example, the measure values in the preceding illustration can be aggregated according to a standard calendar hierarchy by using the Calendar Time hierarchy in the Time dimension as illustrated in the following diagram.

In addition to aggregating measures by using a single dimension, you can aggregate measures by using combinations of members from different dimensions. This allows business users to evaluate measures in multiple dimensions simultaneously. For example, if a business user wants to analyze quarterly imports that arrived by air from the Eastern Hemisphere and Western Hemisphere, the business user can issue a query on the cube to retrieve the following dataset.

			PACKAGES			LAST		
			All Sources	Eastern Hemisphere	Western Hemisphere	All Sources	Eastern Hemisphere	Western Hemisphere
All Time			25110	6547	18563	Dec-29-99	Dec-22-99	Dec-29-99
	1st half		11173	2977	8196	Jun-28-99	Jun-20-99	Jun-28-99
		1st quarter	5108	1452	3656	Mar-30-99	Mar-19-99	Mar-30-99
		2nd quarter	6065	1525	4540	Jun-28-99	Jun-20-99	Jun-28-99
	2nd half		13937	3570	10367	Dec-29-99	Dec-22-99	Dec-29-99
		3rd quarter	6119	1444	4675	Sep-30-99	Sep-18-99	Sep-30-99
		4th quarter	7818	2126	5692	Dec-29-99	Dec-22-99	Dec-29-99

After a cube is defined, you can create new aggregations, or you can change existing aggregations to set options such as whether aggregations are precalculated during processing or calculated at query time. **Related topic:**[Aggregations and Aggregation Designs](#).

Mapping Measures, Attributes, and Hierarchies

The measures, attributes, and hierarchies in the example cube are derived from the following columns in the cube's fact and dimension tables.

MEASURE OR ATTRIBUTE (LEVEL)	MEMBERS	SOURCE TABLE	SOURCE COLUMN	SAMPLE COLUMN VALUE
Packages measure	Not applicable	ImportsFactTable	Packages	12
Last measure	Not applicable	ImportsFactTable	Last	May-03-99
Route Category level in Route dimension	nonground,ground	RouteDimensionTable	Route_Category	Nonground
Route attribute in Route dimension	air,sea,road,rail	RouteDimensionTable	Route	Sea
Hemisphere attribute in Source dimension	Eastern Hemisphere,Western Hemisphere	SourceDimensionTable	Hemisphere	Eastern Hemisphere
Continent attribute in Source dimension	Africa,Asia,Australia,Europe,N. America,S. America	SourceDimensionTable	Continent	Europe

MEASURE OR ATTRIBUTE (LEVEL)	MEMBERS	SOURCE TABLE	SOURCE COLUMN	SAMPLE COLUMN VALUE
Half attribute in Time dimension	1st half,2nd half	TimeDimensionTable	Half	2nd half
Quarter attribute in Time dimension	1st quarter,2nd quarter,3rd quarter,4th quarter	TimeDimensionTable	Quarter	3rd quarter

Data in a single cube cell is usually derived from multiple rows in the fact table. For example, the cube cell at the intersection of the air member, the Africa member, and the 1st quarter member contains a value that is derived by aggregating the following rows in the **ImportsFactTable** fact table.

Import_ReceiptKey	RouteKey	SourceKey	TimeKey	Packages	Last
3516987	1	6	1	15	Jan-10-99
3554790	1	6	1	40	Jan-19-99
3572673	1	6	1	34	Jan-27-99
3600974	1	6	1	45	Feb-02-99
3645541	1	6	1	20	Feb-09-99
3674906	1	6	1	36	Feb-17-99

In the preceding table, each row has the same values for the **RouteKey**, **SourceKey**, and **TimeKey** columns, indicating that these rows contribute to the same cube cell.

The example shown here represents a very simple cube, in that the cube has a single measure group, and all the dimension tables are joined to the fact table in a star schema. Another common schema is a snowflake schema, in which one or more dimension tables join to another dimension table, rather than joining directly to the fact table.

Related topic:[Dimensions \(Analysis Services - Multidimensional Data\)](#).

The example shown here contains only a single fact table. When a cube has multiple fact tables, the measures from each fact table are organized into measure groups, and a measure group is related to a specific set of dimensions by defined dimension relationships. These relationships are defined by specifying the participating tables in the data source view and the granularity of the relationship. **Related topic:**[Dimension Relationships](#).

Security Roles (Analysis Services - Multidimensional Data)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Roles are used in Microsoft SQL Server Analysis Services to manage security for Analysis Services objects and data. In basic terms, a role associates the security identifiers (SIDs) of Microsoft Windows users and groups that have specific access rights and permissions defined for objects managed by an instance of Analysis Services. Two types of roles are provided in Analysis Services:

- The server role, a fixed role that provides administrator access to an instance of Analysis Services.
- Database roles, roles defined by administrators to control access to objects and data for non-administrator users.

Security in Microsoft SQL Server Analysis Services security is managed by using roles and permissions. Roles are groups of users. Users, also called members, can be added or removed from roles. Permissions for objects are specified by roles, and all members in a role can use the objects for which the role has permissions. All members in a role have equal permissions to the objects. Permissions are particular to objects. Each object has a permissions collection with the permissions granted on that object, different sets of permissions can be granted on an object. Each permission, from the permissions collection of the object, has a single role assigned to it.

Role and Role Member Objects

A role is a containing object for a collection of users (members). A Role definition establishes the membership of the users in Analysis Services. Because permissions are assigned by role, a user must be a member of a role before the user has access to any object.

A **Role** object is composed of the parameters Name, Id, and Members. Members is a collection of strings. Each member contains the user name in the form of "domain\username". Name is a string that contains the name of the role. ID is a string that contains the unique identifier of the role.

Server Role

The Analysis Services server role defines administrative access of Windows users and groups to an instance of Analysis Services. Members of this role have access to all Analysis Services databases and objects on an instance of Analysis Services, and can perform the following tasks:

- Perform server-level administrative functions using SQL Server Management Studio or Visual Studio with Analysis Services projects, including creating databases and setting server-level properties.
- Perform administrative functions programmatically with Analysis Management Objects (AMO).
- Maintain Analysis Services database roles.
- Start traces (other than for processing events, which can be performed by a database role with Process access).

Every instance of Analysis Services has a server role that defines which users can administer that instance. The name and ID of this role is Administrators, and unlike database roles, the server role cannot be deleted, nor can permissions be added or removed. In other words, a user either is or is not an administrator for an instance of Analysis Services, depending on whether he or she is included in the server role for that instance of Analysis

Services.

Database Roles

An Analysis Services database role defines user access to objects and data in an Analysis Services database. A database role is created as a separate object in an Analysis Services database, and applies only to the database in which that role is created. Windows users and groups are included in the role by an administrator, who also defines permissions within the role.

The permissions of a role may allow members to access and administer the database, in addition to the objects and data within the database. Each permission has one or more access rights associated with it, which in turn give the permission finer control over access to a particular object in the database.

Permission Objects

Permissions are associated with an object (cube, dimension, others) for a particular role. Permissions specify what operations the member of that role can perform on that object.

The [Permission](#) class is an abstract class. Therefore, you must use the derived classes to define permissions on the corresponding objects. For each object, a permission derived class is defined.

OBJECT	CLASS
Database	DatabasePermission
DataSource	DataSourcePermission
Dimension	DimensionPermission
Cube	CubePermission
MiningStructure	MiningStructurePermission
MiningModel	MiningModelPermission

Possible actions enabled by permissions are shown in the list:

ACTION	VALUES	EXPLANATION
Process	{true, false} Default=false	If true , members can process the object and any object that is contained in the object. Process permissions do not apply to mining models. MiningModel permissions are always inherited from MiningStructure .

ACTION	VALUES	EXPLANATION
ReadDefinition	<p>{None, Basic, Allowed}</p> <p>Default=None</p>	<p>Specifies whether members can read the data definition (ASSL) associated with the object.</p> <p>If Allowed, members can read the ASSL associated with the object.</p> <p>Basic and Allowed are inherited by objects that are contained in the object. Allowed overrides Basic and None.</p> <p>Allowed is required for DISCOVER_XML_METADATA on an object. Basic is required to create linked objects and local cubes.</p>
Read	<p>{None, Allowed}</p> <p>Default=None (Except for DimensionPermission, where default=Allowed)</p>	<p>Specifies whether members have read access to schema rowsets and data content.</p> <p>Allowed gives read access on a database, which lets you discover a database.</p> <p>Allowed on a cube gives read access in schema rowsets and access to cube content (unless constrained by CellPermission and CubeDimensionPermission).</p> <p>Allowed on a dimension grants that read permission on all attributes in the dimension (unless constrained by CubeDimensionPermission). Read permission is used for static inheritance to the CubeDimensionPermission only.</p> <p>None on a dimension hides the dimension and gives access to the default member only for aggregatable attributes; an error is raised if the dimension contains a non-aggregatable attribute.</p> <p>Allowed on a MiningModelPermission grants permissions to see objects in schema rowsets and to perform predict joins.</p> <p>NoteAllowed is required to read or write to any object in the database.</p>

ACTION	VALUES	EXPLANATION
Write	<p>{None, Allowed}</p> <p>Default=None</p>	<p>Specifies whether members have write access to data of the parent object.</p> <p>Access applies to Dimension, Cube, and MiningModel subclasses. It does not apply to database MiningStructure subclasses, which generates a validation error.</p> <p>Allowed on a Dimension grants write permission on all attributes in the dimension.</p> <p>Allowed on a Cube grants write permission on the cells of the cube for partitions defined as Type=writeback.</p> <p>Allowed on a MiningModel grants permission to modify model content.</p> <p>Allowed on a MiningStructure has no specific meaning in Analysis Services.</p> <p>Note: Write cannot be set to Allowed unless read is also set to Allowed</p>
Administer	<p>{true, false}</p> <p>Note: Only in Database permissions</p> <p>Default=false</p>	<p>Specifies whether members can administer a database.</p> <p>true grants members access to all objects in a database.</p> <p>A member can have Administer permissions for a specific database, but not for others.</p>

Server Objects (Analysis Services - Multidimensional Data)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Introducing Server Objects

The `Server` object represents the server and the instance of Microsoft SQL Server Analysis Services that you want to work with.

As soon as you have a connected instance of Analysis Services, you will be able to see:

- All databases that you can access, as a collection.
- All defined server properties, as a collection.
- The connection string, the connection information, and the session ID.
- The product name, edition, and version.
- The roles collections.
- The traces collection.
- The assemblies collection.

Understanding Microsoft OLAP Logical Architecture

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Microsoft SQL Server Analysis Services uses both server and client components to supply online analytical processing (OLAP) and data mining functionality for business intelligence applications:

- The server component of Analysis Services is implemented as a Microsoft Windows service. SQL Server Analysis Services supports multiple instances on the same computer, with each instance of Analysis Services implemented as a separate instance of the Windows service.
- Clients communicate with Analysis Services using the public standard XML for Analysis (XMLA), a SOAP-based protocol for issuing commands and receiving responses, exposed as a Web service. Client object models are also provided over XMLA, and can be accessed either by using a managed provider, such as ADOMD.NET, or a native OLE DB provider.
- Query commands can be issued using the following languages: SQL; Multidimensional Expressions (MDX), an industry standard query language for analysis; or Data Mining Extensions (DMX), an industry standard query language oriented toward data mining. Analysis Services Scripting Language (ASSL) can also be used to manage Analysis Services database objects.

Analysis Services also supports a local cube engine that enables applications on disconnected clients to browse locally stored multidimensional data. For more information, see [Client Architecture Requirements for Analysis Services Development](#)

Client Architecture Requirements for Analysis Services Development

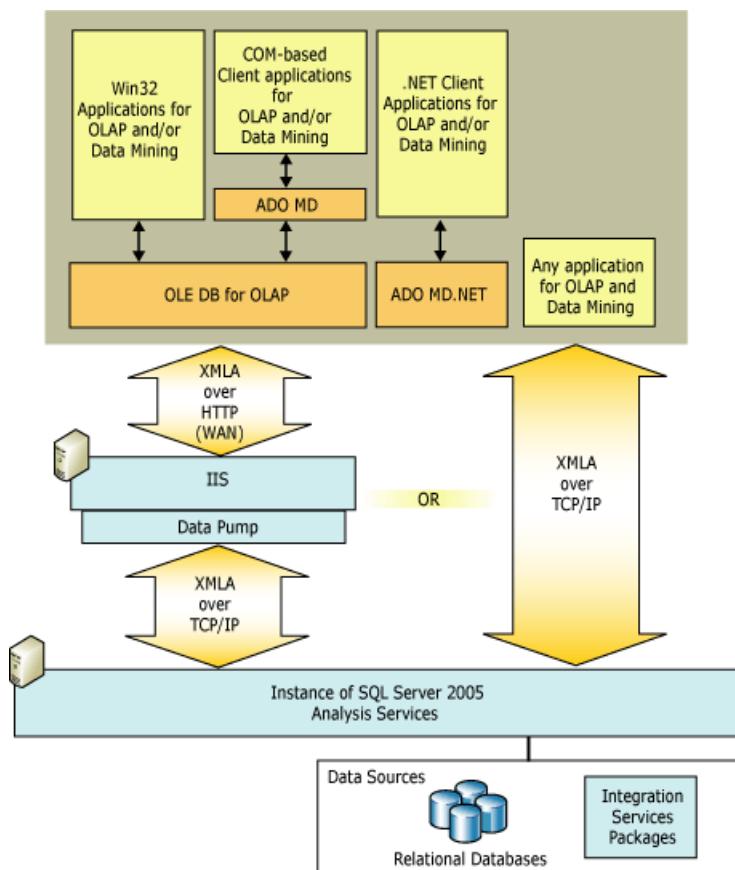

10/22/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Microsoft SQL Server Analysis Services supports a thin-client architecture. The Analysis Services calculation engine is entirely server-based, so all queries are resolved on the server. As a result, only a single round trip between the client and the server is required for each query, resulting in scalable performance as queries increase in complexity.

The native protocol for Analysis Services is XML for Analysis (XML/A). Analysis Services provides several data access interfaces for client applications, but all of these components communicate with an instance of Analysis Services using XML for Analysis.

Several different providers are provided with Analysis Services to support different programming languages. A provider communicates with an Analysis Services server by sending and receiving XML for Analysis in SOAP packets over TCP/IP or over HTTP through Internet Information Services (IIS). An HTTP connection uses a COM object instantiated by IIS, called a data pump, which acts as a conduit for Analysis Services data. The data pump does not examine the underlying data contained in the HTTP stream in any way, nor are any of the underlying data structures available to any of the code in the data library itself.

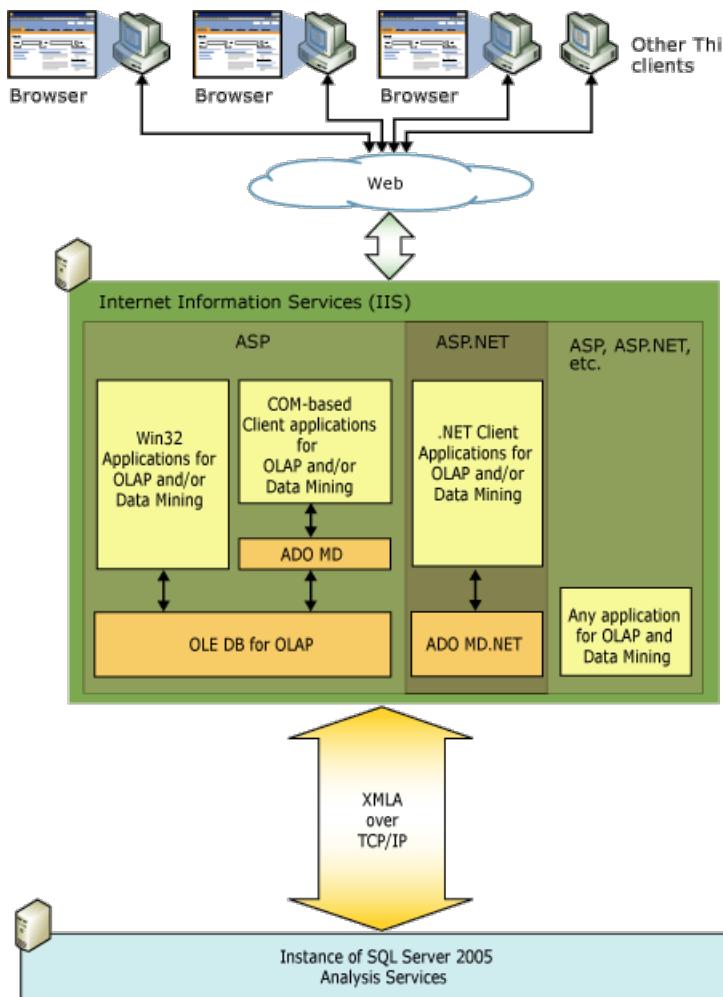

Win32 client applications can connect to an Analysis Services server using OLE DB for OLAP interfaces or the Microsoft® ActiveX® Data Objects (ADO) object model for Component Object Model (COM) automation languages, such as Microsoft Visual Basic®. Applications coded with .NET languages can connect to an Analysis Services server using ADOMD.NET.

Existing applications can communicate with Analysis Services without modification simply by using one of the Analysis Services providers.

PROGRAMMING LANGUAGE	DATA ACCESS INTERFACE
C++	OLE DB for OLAP
Visual Basic 6	ADO MD
.NET languages	ADO MD.NET
Any language that supports SOAP	XML for Analysis

Analysis Services has a Web architecture with a fully scalable middle tier for deployment by both small and large organizations. Analysis Services provides broad middle tier support for Web services. ASP applications are supported by OLE DB for OLAP and ADO MD, ASP.NET applications are supported by ADOMD.NET. The middle tier, illustrated in the following figure, is scalable to many concurrent users.

Both client and middle tier applications can communicate directly with Analysis Services without using a provider. Client and middle tier applications may send XML for Analysis in SOAP packets over TCP/IP, HTTP, or HTTPS. The client may be coded using any language that supports SOAP. Communication in this case is most easily managed by Internet Information Services (IIS) using HTTP, although a direct connection to the server using TCP/IP may also be coded. This is the thinnest possible client solution for Analysis Services.

Analysis Services in Tabular or SharePoint Mode

In SQL Server 2017, the server can be started in VertiPaq in-memory analytics engine (VertiPaq) mode for tabular

databases and for Power Pivot workbooks that have been published to a SharePoint site.

Power Pivot for Excel and Visual Studio with Analysis Services projects are the only client environments that are supported for creating and querying in-memory databases that use SharePoint or Tabular mode, respectively. The embedded Power Pivot database that you create by using the Excel and Power Pivot tools is contained within the Excel workbook, and is saved as part of the Excel .xlsx file.

However, a Power Pivot workbook can use data that is stored in a traditional cube if you import the cube data into the workbook. You can also import data from another Power Pivot workbook if it has been published to a SharePoint site.

NOTE

When you use a cube as a data source for a Power Pivot workbook, the data that you get from the cube is defined as an MDX query; however, the data is imported as a flattened snapshot. You cannot interactively work with the data or refresh the data from the cube.

For more information about using an SSAS cube as a data source, see the [Power Pivot for Excel](#).

Interfaces for Power Pivot Client

Power Pivot interacts with the VertiPaq in-memory analytics engine storage engine within the workbook by using the established interfaces and languages for Analysis Services: AMO and ADOMD.NET, and MDX and XMLA. Within the add-in, measures are defined by using a formula language similar to Excel, Data Analysis Expressions (DAX). DAX expressions are embedded within the XMLA messages that are sent to the in-process server.

Providers

Communications between Power Pivot and Excel use the MSOLAP OLEDB provider (version 11.0). Within the MSOLAP provider, there are four different modules, or transports, that can be used for sending messages between the client and server.

TCP/IP Used for normal client-server connections.

HTTP Used for HTTP connections via the SSAS data pump service, or by a call to the SharePoint Power Pivot Web Service (WS) component.

INPROC Used for connections to the in-process engine.

CHANNEL Reserved for communications with the Power Pivot System Service in the SharePoint farm.

Data Types in Analysis Services

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

For all [DataItem](#) objects, Analysis Services supports the following subset of **System.Data.OleDb.OleDbType**. To set or read the data type, use [DataItem Data Type \(ASSL\)](#).

Supported Data Types

BigInt	A 64-bit signed integer. The <i>BigInt</i> value type represents integers with values ranging from negative 9,223,372,036,854,775,808 to positive 9,223,372,036,854,775,807.
Binary	A stream of binary data of Byte type. Byte is a value type that represents unsigned integers with values that range from 0 to 255.
Boolean	Instances of this type have values of either true or false .
Currency	A <i>currency</i> value ranging from -922,337,203,685,477.5808 to +922,337,203,685,477.5807 with accuracy to a ten-thousandth of a currency unit (four decimal places).
Date	Date and time data, stored as a double. The whole portion is the number of days since December 30, 1899, and the fractional portion is a fraction of a day or time of the day.
Double	A floating-point number within the range of -1.79769313486232E +308 to 1.79769313486232E +308. A Double value stores number information up to 15 decimal digits of precision.
Integer	A 32-bit signed integer that represents signed integers with values that range from negative 2,147,483,648 through positive 2,147,483,647.
Single	A floating-point number within the range of -3.4028235E +38 through 3.4028235E +38. A Single value stores number information up to 7 decimal digits of precision.
Smallint	A 16-bit signed integer. The <i>Smallint</i> value type represents signed integers with values ranging from negative 32768 to positive 32767.
Tinyint	An 8-bit signed integer. The <i>Tinyint</i> value type represents integers with values ranging from negative 128 to positive 127.

UnsignedBigInt	A 64-bit unsigned integer. The <i>UnsignedBigInt</i> value type represents unsigned integers with values ranging from 0 to 18,446,744,073,709,551,615.
UnsignedInt	A 32-bit unsigned integer. The <i>UnsignedInt</i> value type represents unsigned integers with values ranging from 0 to 4,294,967,295.
UnsignedSmallInt	A 16-bit unsigned integer. The <i>UnsignedSmallInt</i> value type represents unsigned integers with values ranging from 0 to 65535.
UnsignedTinyInt	An 8-bit unsigned integer. The <i>UnsignedTinyInt</i> value type represents unsigned integers with values ranging from 0 to 255.
WChar	A null-terminated stream of Unicode characters. A <i>WChar</i> is a sequential collection of Unicode characters that is used to represent text.

AMO Validations on Data Types

The following table lists the extra validations that Analysis Management Objects (AMO) does for certain bindings:

OBJECT	BINDING	ALLOWED DATA TYPES
DimensionAttribute	KeyColumns	All but Binary
	NameColumn	Only WChar
	SkippedLevelsColumn	Only integer types: BigInt, Integer, SmallInt, TinyInt, UnsignedBigInt, UnsignedInt, UnsignedSmallInt, UnsignedTinyInt
	CustomRollupColumn	Only WChar
	CustomRollupPropertiesColumn	Only WChar
	UnaryOperatorColumn	Only WChar
	ValueColumn	All
AttributeTranslation	CaptionColumn	Only WChar
ScalarMiningStructureColumn	KeyColumns	All but Binary
	NameColumn	Only WChar
TableMiningStructureColumn	ForeignKeyColumns	All but Binary
MeasureGroupAttribute	KeyColumns	All but Binary

OBJECT	BINDING	ALLOWED DATA TYPES
Distinct Count Measure	Source	BigInt, Currency, Double, Integer, Single, SmallInt, TinyInt, UnsignedBigInt, UnsignedInt, UnsignedSmallInt, UnsignedTinyInt

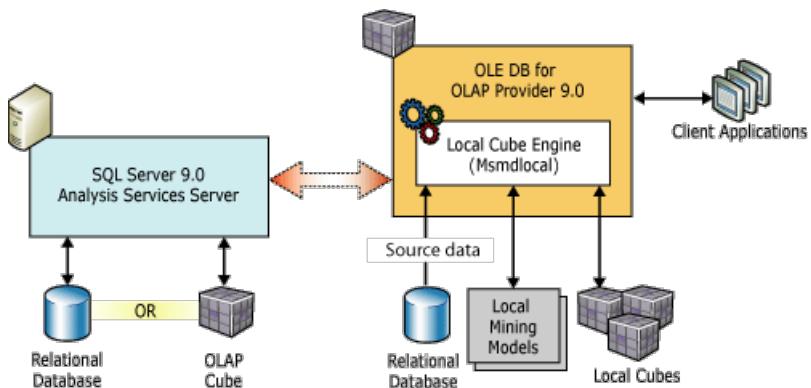

Local Cubes (Analysis Services - Multidimensional Data)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

To create, update or delete local cubes, you must write and execute either an ASSL script or an AMO program.

Local cubes and local mining models allow analysis on a client workstation while it is disconnected from the network. For example, a client application might call the OLE DB for OLAP 9.0 Provider (MSOLAP.3), which loads the local cube engine to create and query local cubes, as shown in the following illustration:

ADMOD.NET and Analysis Management Objects (AMO) also load the local cube engine when interacting with local cubes. Only a single process can access a local cube file, because the local cube engine exclusively locks a local cube file when it establishes a connection to the local cube. With a process, up to five simultaneous connections are permitted.

A .cub file may contain more than one cube or data mining model. Queries to the local cubes and data mining models are handled by the local cube engine and do not require a connection to an Analysis Services instance.

NOTE

The use of SQL Server Management Studio and Visual Studio with Analysis Services projects to manage local cubes is not supported.

Local Cubes

A local cube can be created and populated from either an existing cube in an Analysis Services instance or from a relational data source.

SOURCE FOR DATA FOR LOCAL CUBE	CREATION METHOD
Server-based cube	You can use either the CREATE GLOBAL CUBE statement or an Analysis Services Scripting Language (ASSL) script to create and populate a cube from a server-based cube. For more information, see CREATE GLOBAL CUBE Statement (MDX) or Analysis Services Scripting Language (ASSL for XMLA) .

SOURCE FOR DATA FOR LOCAL CUBE	CREATION METHOD
Relational data source	You use an ASSL script to create and populate a cube from an OLE DB relational database. To create a local cube using ASSL, you simply connect to a local cube file (*.cube) and execute the ASSL script in the same manner as executing an ASSL script against an Analysis Services instance to create a server cube. For more information, see Analysis Services Scripting Language (ASSL for XMLA) .

Use the REFRESH CUBE statement to rebuild a local cube and update its data. For more information, see [REFRESH CUBE Statement \(MDX\)](#).

Local Cubes Created from Server-based Cubes

When creating local cubes created from server-based cubes, the following considerations apply:

- Distinct count measures are not supported.
- When you add a measure, you must also include at least one dimension that is related to the measure being added. For more information about dimension relationships to measure groups, see [Dimension Relationships](#).
- When you add a parent-child hierarchy, levels and filters on a parent-child hierarchy are ignored and the entire parent-child hierarchy is included.
- Member properties are not created.
- When you include a semi-additive measure, no slices are permitted on either the Account or the Time dimension.
- Reference dimensions are always materialized.
- When you include a many-to-many dimension, the following rules apply:
 - You cannot slice the many-to-many dimension.
 - You must add a measure from the intermediary measure group.
 - You cannot slice any of the dimensions common to the two measure groups involved in the many-to-many relationship.
- Only those calculated members, named sets, and assignments that rely upon measures and dimensions added to the local cube will appear in the local cube. Invalid calculated members, named sets, and assignments will be automatically excluded.

Security

In order for a user to create a local cube from a server cube, the user must be granted **Drillthrough and Local Cube** permissions on the server cube. For more information, see [Grant cube or model permissions \(Analysis Services\)](#).

Local cubes are not secured using roles like server cubes. Anyone with file-level access to a local cube file can query cubes in it. You can use the **Encryption Password** connection property on a local cube file to set a password on the local cube file. Setting a password on a local cube file requires all future connections to the local cube file to use this password in order to query the file.

[General Properties](#)

Object Naming Rules (Analysis Services)

8/6/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

This topic describes object naming conventions, as well as the reserved words and characters that cannot be used in any object name, in code or script in Analysis Services.

Naming Conventions

Every object has a **Name** and **ID** property that must be unique within the scope of the parent collection. For example, two dimensions can have same name as long as each one resides in a different database.

Although you can specify it manually, the **ID** is typically auto-generated when the object is created. You should never change the **ID** once you have begun building a model. All object references throughout a model are based on the **ID**. Thus, changing an **ID** can easily result in model corruption.

DataSource and **DataSourceView** objects have notable exceptions to naming conventions. **DataSource** ID can be set to a single dot (.), which is not unique, as a reference to the current database. A second exception is **DataSourceView**, which adheres to the naming conventions defined for **DataSet** objects in the .NET Framework, where the **Name** is used as the identifier.

The following rules apply to **Name** and **ID** properties.

- Names are case insensitive. You cannot have a cube named "sales" and another named "Sales" in the same database.
- No leading or trailing spaces allowed in an object name, although you can embed spaces within a name. Leading and trailing spaces are implicitly trimmed. This applies to both the **Name** and **ID** of an object.
- The maximum number of characters is 100.
- There is no special requirement for the first character of an identifier. The first character may be any valid character.

Reserved Words and Characters

Reserved words are in English, and apply to object names, not Captions. If you inadvertently use a reserved word in an object name, a validation error will occur. For multidimensional and data mining models, the reserved words described below cannot be used in any object name, at any time.

For tabular models, where the database compatibility is set to 1103, validation rules have been relaxed for certain objects, out of compliance for the extended character requirements and naming conventions of certain client applications. Databases that meet these criteria are subject to less stringent validation rules. In this case, it's possible for an object name to include a restricted character and still pass validation.

Reserved Words

- AUX
- CLOCK\$
- COM1 through COM9 (COM1, COM2, COM3, and so on)
- CON

- LPT1 through LPT9 (LPT1, LPT2, LPT3, and so on)
- NUL
- PRN
- NULL is not allowed as a character in any string within the XML

Reserved Characters

The following table lists invalid characters for specific objects.

OBJECT	INVALID CHARACTERS
Server	Follow Windows server naming conventions when naming a server object. See Naming Conventions (Windows) for details.
DataSource	: / \ * ? " 0 [] {} < >
Level or Attribute	. , ; ^ : / \ * ? " & % \$! + = () {} < >
Dimension or Hierarchy	. , ; ^ : / \ * ? " & % \$! + = () {} < , >
All other objects	. , ; ^ : / \ * ? " & % \$! + = () {} < >

Exceptions: When Reserved Characters are Allowed

As noted, databases of a specific modality and compatibility level can have object names that include reserved characters. Dimension attribute, hierarchy, level, measure and KPI object names can include reserved characters, for tabular databases (1103 or higher) that allow the use of extended characters:

SERVER MODE AND DATABASE COMPATIBILITY LEVEL	RESERVED CHARACTERS ALLOWED?
MOLAP (all versions)	No
Tabular - 1050	No
Tabular - 1100	No
Tabular - 1130 and higher	Yes

Databases can have a ModelType of default. Default is equivalent to multidimensional, and thus does not support the use of reserved characters in column names.

OLAP Engine Server Components

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

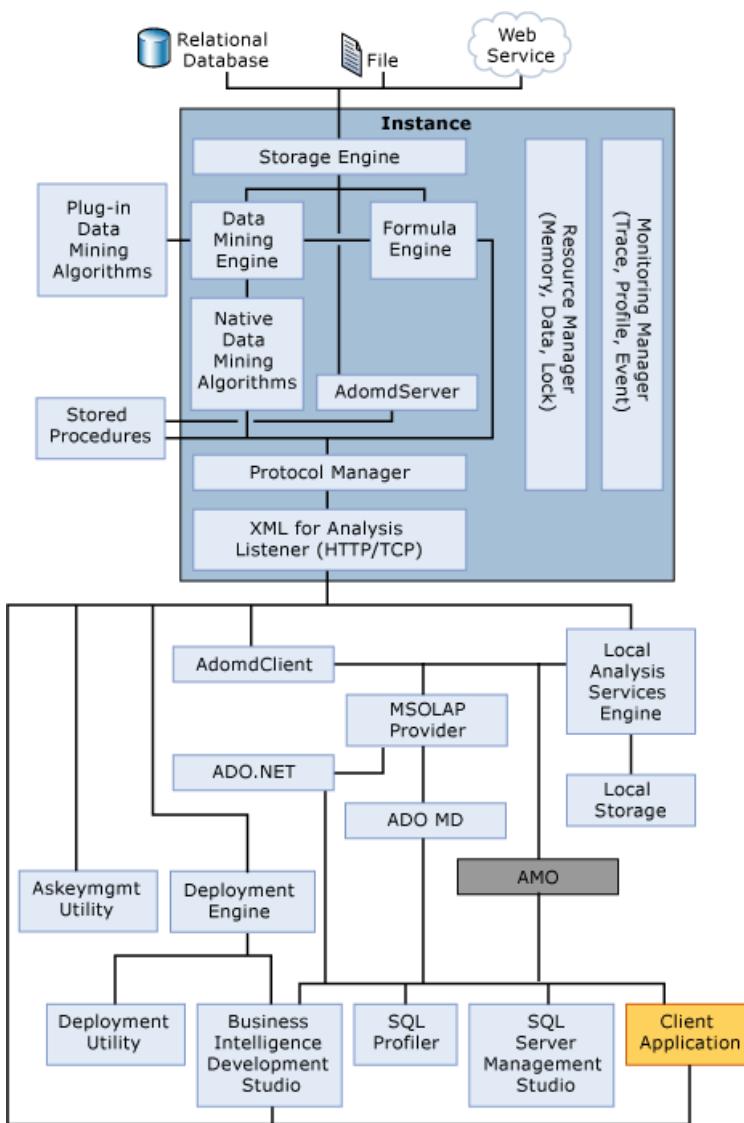

The server component of Microsoft SQL Server Analysis Services is the **msmdsrv.exe** application, which runs as a Windows service. This application consists of security components, an XML for Analysis (XMLA) listener component, a query processor component and numerous other internal components that perform the following functions:

- Parsing statements received from clients
- Managing metadata
- Handling transactions
- Processing calculations
- Storing dimension and cell data
- Creating aggregations
- Scheduling queries
- Caching objects
- Managing server resources

Architectural Diagram

An Analysis Services instance runs as a stand-alone service and communication with the service occurs through XML for Analysis (XMLA), by using either HTTP or TCP. AMO is a layer between the user application and the Analysis Services instance. This layer provides access to Analysis Services administrative objects. AMO is a class library that takes commands from a client application and converts those commands into XMLA messages for the Analysis Services instance. AMO presents Analysis Services instance objects as classes to the end user application, with method members that run commands and property members that hold the data for the Analysis Services objects.

The following illustration shows the Analysis Services components architecture, including all major elements running within the Analysis Services instance and all user components that interact with the instance. The illustration also shows that the only way to access the instance is by using the XML for Analysis (XMLA) Listener, either by using HTTP or TCP.

XMLA Listener

The XMLA listener component handles all XMLA communications between Analysis Services and its clients. The Analysis Services **Port** configuration setting in the msmdsrv.ini file can be used to specify a port on which an Analysis Services instance listens. A value of 0 in this file indicates that Analysis Services listen on the default port. Unless otherwise specified, Analysis Services uses the following default TCP ports:

PORT	DESCRIPTION
2383	Default instance of SQL Server Analysis Services.
2382	Redirector for other instances of SQL Server Analysis Services.
Dynamically assigned at server startup	Named instance of SQL Server Analysis Services.

See [Configure the Windows Firewall to Allow Analysis Services Access](#) for more details.

Extending OLAP functionality

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

As a programmer, you can extend Analysis Services by writing assemblies, personalized extensions, and stored procedures that provide functionality you want to use and repurpose in multiple database applications. Assemblies are used to extend multidimensional models functionality by adding new procedures and functions to the MDX language or by means of the personalization addin.

Stored procedures can be used to call external routines, simplifying Analysis Services database development and implementation by allowing common code to be developed once and stored in a single location. Stored procedures can be used to add business functionality to your applications that is not provided by the native functionality of MDX.

Personalizations are custom objects that you add to a cube to provide a behavior that varies by user.

Personalizations are not permanent objects in the cube, but are objects that the client application applies dynamically during the user's session. Examples include changing the currency of a monetary value depending on the person accessing the data, providing individualized KPIs, or a targeted suggestion list for regular customers who purchase online.

In This Section

[Extending OLAP through personalizations](#)

[Defining Stored Procedures](#)

Extending OLAP through personalizations

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Analysis Services provides many intrinsic functions for use with the Multidimensional Expressions (MDX) and Data Mining Extensions (DMX) languages. These functions are designed to accomplish everything from standard statistical calculations to traversing members in a hierarchy. However, as with any other complex and robust product, there is always the need to extend the functionality of such a product further.

Therefore, Analysis Services provides you with the ability to add assemblies and personalized extensions to an instance of the service, in order to complete your business needs whenever the standard functionality is not enough.

Assemblies

Assemblies enable you to extend the business functionality of MDX and DMX. You build the functionality that you want into a library, such as a dynamic link library (DLL), then add the library as an assembly to an instance of Analysis Services or to an Analysis Services database. The public methods in the library are then exposed as user-defined functions to MDX and DMX expressions, procedures, calculations, actions, and client applications.

Personalized Extensions

SQL Server Analysis Services personalization extensions are the foundation of the idea of implementing a plug-in architecture. Analysis Services personalization extensions are a simple and elegant modification to the existing managed assembly architecture and are exposed throughout the Analysis Services

[Microsoft.AnalysisServices.AdomdServer](#) object model, Multidimensional Expressions (MDX) syntax, and schema rowsets.

[Multidimensional Model Assemblies Management](#)

[Analysis Services Personalization Extensions](#)

Analysis Services Personalization Extensions

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

SQL Server Analysis Services personalization extensions are the foundation of the idea of implementing a plug-in architecture. In a plug-in architecture, you can develop new cube objects and functionality dynamically and share them easily with other developers. As such, Analysis Services personalization extensions provide the functionality that makes it possible to achieve the following:

- **Dynamic design and deployment** Immediately after you design and deploy Analysis Services personalization extensions, users have access to the objects and functionality at the start of the next user session.
- **Interface independence** Regardless of the interface that you use to create the Analysis Services personalization extensions, users can use any interface to access the objects and functionality.
- **Session context** Analysis Services personalization extensions are not permanent objects in the existing infrastructure and do not require the cube to be reprocessed. They become exposed and created for the user at the time that the user connects to the database, and remain available for the length of that user session.
- **Rapid distribution** Share Analysis Services personalization extensions with other software developers without having to go into detailed specifications about where or how to find this extended functionality.

Analysis Services personalization extensions have many uses. For example, your company has sales that involve different currencies. You create a calculated member that returns the consolidated sales in the local currency of the person who is accessing the cube. You create this member as a personalization extension. You then share this calculated member to a group of users. Once shared, those users have immediate access to the calculated member as soon as they connect to the server. They have access even if they are not using the same interface as the one that was used to create the calculated member.

Analysis Services personalization extensions are a simple and elegant modification to the existing managed assembly architecture and are exposed throughout the Analysis Services [Microsoft.AnalysisServices.AdomdServer](#) object model, Multidimensional Expressions (MDX) syntax, and schema rowsets.

Logical Architecture

The architecture for Analysis Services personalization extensions is based on the managed assembly architecture and the following four basic elements:

The [PlugInAttribute] custom attribute

When starting the service, Analysis Services loads the required assemblies and determines which classes have the [Microsoft.AnalysisServices.AdomdServer.PlugInAttribute](#) custom attribute.

NOTE

The .NET Framework defines custom attributes as a way to describe your code and affect run-time behavior. For more information, see the topic, "[Attributes Overview](#)," in the .NET Framework Developer's Guide on MSDN.

For all classes with the [Microsoft.AnalysisServices.AdomdServer.PlugInAttribute](#) custom attribute, Analysis

Services invokes their default constructors. Invoking all the constructors at startup provides a common location from which to build new objects and that is independent of any user activity.

In addition to building a small cache of information about authoring and managing personalization extensions, the class constructor typically subscribes to the [Microsoft.AnalysisServices.AdomdServer.Server.SessionOpened](#) and [Microsoft.AnalysisServices.AdomdServer.Server.SessionClosing](#) events. Failing to subscribe to these events may cause the class to be inappropriately marked for cleanup by the common language runtime (CLR) garbage collector.

Session context

For those objects that are based on personalization extensions, Analysis Services creates an execution environment during the client session and dynamically builds most of those objects in this environment. Like any other CLR assembly, this execution environment also has access to other functions and stored procedures. When the user session ends, Analysis Services removes the dynamically created objects and closes the execution environment.

Events

Object creation is triggered by the session events **On-Cube-Opened**[CubeOpened](#) and **On-Cube-Closing**[CubeClosing](#).

Communication between the client and the server occurs through specific events. These events make the client aware of the situations that lead to the client's objects being built. The client's environment is dynamically created using two sets of events: session events and cube events.

Session events are associated with the server object. When a client logs on to a server, Analysis Services creates a session and triggers the [Microsoft.AnalysisServices.AdomdServer.Server.SessionOpened](#) event. When a client ends the session on the server, Analysis Services triggers the [Microsoft.AnalysisServices.AdomdServer.Server.SessionClosing](#) event.

Cube events are associated with the connection object. Connecting to a cube triggers the [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.CubeOpened](#) event. Closing the connection to a cube, by either closing the cube or by changing to a different cube, triggers a [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.CubeClosing](#) event.

Traceability and error handling

All activity is traceable by using SQL Server Profiler. Unhandled errors are reported to the Windows event log.

All object authoring and management is independent of this architecture and is the sole responsibility of the developers of the objects.

Infrastructure Foundations

Analysis Services personalization extensions are based on existing components. The following is a summary of enhancements and improvements that provide the personalization extensions functionality.

Assemblies

The custom attribute, [Microsoft.AnalysisServices.AdomdServer.PluginAttribute](#), can be added to your custom assemblies to identify Analysis Services personalization extensions classes.

Changes to the AdomdServer Object Model

The following objects in the [Microsoft.AnalysisServices.AdomdServer](#) object model have been enhanced or added to the model.

New AdomdConnection Class

The [Microsoft.AnalysisServices.AdomdServer.AdomdConnection](#) class is new and exposes several personalization extensions through both properties and events.

Properties

- [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.SessionID*](#), a read-only string value representing the session Id of the current connection.
- [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.ClientCulture*](#), a read-only reference to the client culture associated with current session.
- [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.User*](#), a read-only reference to the identity interface representing the current user.

Events

- [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.CubeOpened](#)
- [Microsoft.AnalysisServices.AdomdServer.AdomdConnection.CubeClosing](#)

New Properties in the Context class

The [Microsoft.AnalysisServices.AdomdServer.Context](#) class has two new properties:

- [Microsoft.AnalysisServices.AdomdServer.Context.Server*](#), a read-only reference to the new server object.
- [Microsoft.AnalysisServices.AdomdServer.Context.CurrentConnection*](#), a read-only reference to the new [Microsoft.AnalysisServices.AdomdServer.AdomdConnection](#) object.

New Server class

The [Microsoft.AnalysisServices.AdomdServer.Server](#) class is new and exposes several personalization extensions through both class properties and events.

Properties

- [Microsoft.AnalysisServices.AdomdServer.Server.Name*](#), a read-only string value representing the server name.
- [Microsoft.AnalysisServices.AdomdServer.Server.Culture*](#), A read-only reference to the global culture associated with the server.

Events

- [Microsoft.AnalysisServices.AdomdServer.Server.SessionOpened](#)
- [Microsoft.AnalysisServices.AdomdServer.Server.SessionClosing](#)

AdomdCommand class

The [Microsoft.AnalysisServices.AdomdServer.AdomdCommand](#) class now supports the following MDX commands:

- [CREATE MEMBER Statement \(MDX\)](#)
- [UPDATE MEMBER Statement \(MDX\)](#)
- [DROP MEMBER Statement \(MDX\)](#)
- [CREATE SET Statement \(MDX\)](#)
- [DROP SET Statement \(MDX\)](#)
- [CREATE KPI Statement \(MDX\)](#)
- [DROP KPI Statement \(MDX\)](#)

MDX extensions and enhancements

The CREATE MEMBER command is enhanced with the **caption** property, the **display_folder** property, and the

associated_measure_group property.

The UPDATE MEMBER command is added to avoid member re-creation when an update is needed with the consequent loss of precedence in solving calculations. Updates cannot change the scope of the calculated member, move the calculated member to a different parent, or define a different **solveorder**.

The CREATE SET command is enhanced with the **caption** property, the **display_folder** property, and the new **STATIC | DYNAMIC** keyword. *Static* means that set is evaluated only at creation time. *Dynamic* means that the set is evaluated every time that the set is used in a query. The default value is **STATIC** if a keyword is omitted.

CREATE KPI and DROP KPI commands are added to the MDX syntax. KPIs can be created dynamically from any MDX script.

Schema Rowsets extensions

On MDSchema_Members *scope* column is added. Scope values are as follows:

MDMember_Scope_Global=1, MDMember_Scope_Session=2.

On MDSchema_Sets *set_evaluation_context* column is added. Set evaluation context values are as follows:
MDSet_Resolution_Static = 1, MDSet_Resolution_Dynamic = 2.

On MDSchema_Kpis scope column is added. Scope values are as follows: MDKpi_Scope_Global=1,
MDKpi_Scope_Session=2.

Accessing Query Context in Stored Procedures

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The execution context of a stored procedure is available within the code of the stored procedure as the **Context** object of the ADOMD.NET server object model. This is a read-only context and cannot be modified by the stored procedure. The following properties are available on this object.

PROPERTY	TYPE	DESCRIPTION
CurrentCube	Cube	The cube for the current query context.
CurrentDatabaseName	String	The identifier of the current database.
CurrentConnection	Connection	A reference to the connection object in the current context.
Pass	Integer	The pass number for the current context.

The **Context** object exists when the Multidimensional Expressions (MDX) object model is used in a stored procedure. It is not available when the MDX object model is used on a client. The **Context** object is not explicitly passed to or returned by the stored procedure. It is available during the execution of the stored procedure.

[Multidimensional Model Assemblies Management](#)

[Defining Stored Procedures](#)

Calling Stored Procedures

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Stored procedures can be called on the server or from client application. In either case, stored procedures always run on the server, either the context of the server or of a database. There are no special permissions required to execute a stored procedure. Once a stored procedure is added by an assembly to the server or database context, any user can execute the stored procedure as long as the role for the user permits the actions performed by the stored procedure.

Calling a stored procedure in MDX is done in the same manner as calling an intrinsic MDX function. For a stored procedure that takes no parameters, the name of the procedure and an empty pair of parentheses are used, as shown here:

```
My.StoredProcedure()
```

If the stored procedure takes one or more parameters, then the parameters are supplied, in order, separated by commas. The following example demonstrates a sample stored procedure with three parameters:

```
My.StoredProcedure("Parameter1", 2, 800)
```

Calling Stored Procedures in MDX Queries

In all MDX queries, the stored procedure must return the syntactically correct type required by an MDX expression. If a stored procedure does not return the correct type, an MDX error occurs. The following examples demonstrate stored procedures that return a set, a member, and the result of a mathematical operation.

Returning a Set

The following examples implement a stored procedure, called MySproc, that returns a set. In the first example, MySproc returns the set directly in the SELECT expression. In the second two examples, MySproc returns the set as an argument for the Crossjoin and DrilldownLevel functions.

```
SELECT MySetProcedure(a,b,c) ON 0 FROM Sales  
SELECT Crossjoin(MySetProcedure(a,b,c)) ON 0 FROM Sales  
SELECT DrilldownLevel(MySetProcedure(a,b,c)) ON 0 FROM Sales
```

Returning a Member

The following example shows a function MySproc function that returns a member:

```
SELECT Descendants(MySproc(a,b,c),3) ON 0 FROM Sales
```

Returning the Result of a Math Operation

```
SELECT Country.Members on 0, MySproc(Measures.Sales) ON 1 FROM Sales
```

Calling Stored Procedures with the Call Statement

Stored procedures can be called outside of the context of an MDX query using the MDX **Call** statement.

You can use this method to either instantiate the side effects of a stored query or for the application to get the results of a stored query. A common use of the **Call** statement would be to use Analysis Management Objects (AMO) to perform administrative functions that do not have a return result. For example, the following command calls a stored procedure:

```
Call MyStoredProcedure(a,b,c)
```

The only supported type returned from stored procedure in a **Call** statement is a rowset. The serialization for a rowset is defined by XML for Analysis. If a stored procedure in a **Call** statement returns any other type, it is ignored and not returned in XML to the calling application. For more information about XML for Analysis rowsets, see, XML for Analysis Schema Rowsets.

If a stored procedure returns a .NET rowset, Analysis Services converts the result on the server to an XML for Analysis rowset. The XML for Analysis rowset is always returned by a stored procedure in the **Call** function. If a dataset contains features that cannot be expressed in the XML for Analysis rowset, a failure results.

Procedures that return void values (for example, subroutines in Visual Basic) can also be employed with the **CALL** keyword. If, for example, you wanted to use the function `MyVoidFunction()` in an MDX statement, the following syntax would be employed:

```
CALL(MyVoidFunction)
```

[Defining Stored Procedures](#)

Creating Stored Procedures

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

All stored procedures must be associated with a common language runtime (CLR) or Component Object Model (COM) class in order to be used. The class must be installed on the server - usually in the form of a Microsoft ActiveX® dynamic link library (DLL) - and registered as an assembly on the server or in an Analysis Services database.

Stored procedures are registered on a server or on a database. Server stored procedures can be called from any query context. Database stored procedures can only be accessed if the database context is the database under which the stored procedure is defined. If functions in one assembly call functions in a different assembly, you must register both assemblies in the same context (server or database). For a server or a deployed Microsoft SQL Server Analysis Services database on a server, you can use SQL Server Management Studio to register an assembly. For an Analysis Services project, you can use Analysis Services Designer to register an assembly in the project.

IMPORTANT

COM assemblies might pose a security risk. Due to this risk and other considerations, COM assemblies were deprecated in SQL Server 2008 Analysis Services (SSAS). COM assemblies might not be supported in future releases.

Registering a Server Assembly

In Object Explorer in SQL Server Management Studio, server assemblies are listed in the **Assemblies** folder under an instance of Analysis Services. Server assemblies can contain both .NET (CLR) assemblies and COM libraries.

To create a server assembly

1. Expand the instance of Analysis Services in Object Explorer, right-click the **Assemblies** folder, and then click **New Assembly**. This displays the **Register Server Assembly** dialog box.
2. For **Type** specify the type of assembly:
 - For a managed code (CLR) DLL, specify .NET Assembly.
 - For a native code (COM) DLL, specify COM DLL.
3. For **File name**, specify the DLL containing the stored procedures.
4. For **Assembly name**, specify a name for the assembly.
5. If this is a debug build of the library that you are going to use to debug stored procedures, select the **Include debug information** check box. For more information about debugging stored procedures, see [Debugging Stored Procedures](#).
6. You can click **OK** to register the assembly immediately, or on the dialog box toolbar, you can click a command on the **Script** menu to script the registration action to a query window, a file, or the Clipboard.

After you register a server assembly, you can configure it by right-clicking the assembly in Object Explorer and then clicking **Properties**.

Registering a Database Assembly on the Server

In Object Explorer in SQL Server Management Studio, database assemblies are listed in the Assemblies folder under an Analysis Services database. Database assemblies can contain both .NET (CLR) assemblies and COM libraries.

To create a database assembly on a server

1. Expand the instance the Analysis Services database in Object Explorer, right-click the **Assemblies** folder, and then click **New Assembly**. This displays the **Register Database Assembly** dialog box.
2. For **Type** specify the type of assembly:
 - For a managed code (CLR) DLL, specify .NET Assembly.
 - For a native code (COM) DLL, specify COM DLL.
3. For **File name**, specify the DLL containing the stored procedures.
4. For **Assembly name**, specify a name for the assembly.
5. If this is a debug build of the library that you are going to use to debug stored procedures, select the **Include debug information** check box. For more information about debugging stored procedures, see [Debugging Stored Procedures](#).
6. You can click **OK** to register the assembly immediately, or on the dialog box toolbar, you can click a command on the **Script** menu to script the registration action to a query window, a file, or the Clipboard.

After you register a database assembly, you can configure it by right-clicking the assembly in Object Explorer and then clicking **Properties**.

Registering a Database Assembly in a Project

In Solution Explorer in Visual Studio with Analysis Services projects, database assemblies are listed in the Assemblies folder under an Analysis Services project. Database assemblies can contain both .NET (CLR) assemblies and COM libraries.

To create a database assembly in an Analysis Service project

1. Expand the instance the Analysis Services database in Object Explorer, right-click the **Assemblies** folder, and then click **New Assembly Reference**. This displays the **Add Reference** dialog box. The **.NET** tab of the **Add Reference** dialog box lists existing .NET (CLR) assemblies, while the **Projects** tab lists projects.
2. You can click an existing component or project and then click **Add** to add it to the Analysis Services project. To add a reference to a COM DLL, click the **Browse** tab to find the file. The **Selected projects and components** list shows the name, type, version, and location for each component that you are adding to the project.
3. When you are finished selecting components to add, click **OK** to add them to the Analysis Services project.

Script Format For an Assembly

Registering a .NET assembly is fairly simple. A .NET assembly is added to a database in binary format using the following format:

```
<Create>
  <ObjectDefinition>
    <Assembly>
      <Files>
        <File>
          <Name>filename</Name>
          <Type>filetype</Type>
          <Data>
            <Block>binarydatablock</Block>
            <Block>binarydatablock</Block>
            ...
          </Data>
        </File>
      </Files>
      <PermissionSet>PermissionSet</PermissionSet>
    </Assembly>
  <ObjectDefinition>
</Create>
```

Debugging Stored Procedures

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services stored procedures are actually CLR or COM libraries (normally DLLs) that are written in C# (or any other CLR or COM language). Therefore, debugging a stored procedure is much like debugging any other application in the Visual Studio debugging environment. You debug stored procedures in the Visual Studio development environment using the integrated debugging functions. These allow you to stop at procedure locations, inspect memory and register values, change variables, observe message traffic and get a close look at how your code works.

To debug a stored procedure

1. Open the project used to create the DLL in Visual Studio.
2. Create breakpoints in the method or function corresponding to the procedure you want to debug.
3. Use Visual Studio to create a debug build of a stored procedure DLL.
4. Deploy the DLL to the server. For more information about deploying the DLL to the server, see [Creating Stored Procedures](#).
5. You need an application that calls the stored procedure that you want to test. If you do not have one ready, you can use the MDX Query Editor in SQL Server Management Studio to create an MDX query that calls the stored procedure that you want to test.
6. In Visual Studio, attach to the Analysis Services process (Msmdsrv.exe).
 - a. From the **Debug** menu, choose **Attach to Process**.
 - b. In the **Attach to Process** dialog box, select **Show processes from all users**.
 - c. In the **Available Processes** list, in the **Process** column, click **Msmdsrv.exe**. If there is more than one instance of Analysis Services running on the server, you need to identify the process by the ID of the instance you want to use.
 - d. In the **Attach to** text box, make sure that the appropriate program type is selected. For a CLR DLL, click **Select**, then click **Debug these code types**, then click **Managed**, then click **OK**. For a COM DLL, click **Select**, then click **Debug these code types**, then click **Native**, then click **OK**.
 - e. Click **Attach**.
7. In Analysis Services, invoke the program or MDX script that calls the stored procedure. The debugger breaks when it reaches a line containing a breakpoint. You can evaluate variables in the watch window, view locals, and step through the code.

If you have problems debugging a library, make sure that the corresponding program database (PDB) file was copied to the deployment location on the server. If this file was not copied during registration or deployment, you must copy it manually to the same location as the DLL. For native code (COM DLL), the PDB file resides in the \debug subdirectory. For managed code (CLR DLL), it resides in the \WINDEBUG subdirectory.

Defining Stored Procedures

Defining Stored Procedures

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You can use stored procedures to call external routines from Microsoft SQL Server Analysis Services. You can write an external routines called by a stored procedure in any common language runtime (CLR) language, such as C, C++, C#, Visual Basic, or Visual Basic .NET. A stored procedure can be created once and called from many contexts, such as other stored procedures, calculated measures, or client applications. Stored procedures simplify Analysis Services database development and implementation by allowing common code to be developed once and stored in a single location. Stored procedures can be used to add business functionality to your applications that is not provided by the native functionality of MDX.

This section provides the information necessary to understand, design, and implement stored procedures.

TOPIC	DESCRIPTION
Designing Stored Procedures	Describes how to design assemblies for use with Analysis Services.
Creating Stored Procedures	Describes how to create assemblies for Analysis Services.
Calling Stored Procedures	Provides information on how to use assemblies in Analysis Services.
Accessing Query Context in Stored Procedures	Describes how to access scope and context information with assemblies.

Designing Stored Procedures

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Both the administrative object model Analysis Management Objects (AMO) and the client oriented object model Microsoft ActiveX® Data Objects (Multidimensional) (ADO MD) are available in stored procedures.

Stored procedures must be in scope (either the server or the database) to be visible at the Multidimensional Expressions (MDX) level to be called. However, once a stored procedure is invoked, its scope is not limited to actions under its parent. A stored procedure may make changes or modifications anywhere on the server, subject only to the security limitations of the user process that invokes it or to the limitations of the transaction in which it is operating.

Server scope procedures are available in all contexts on the server. Database scope stored procedures are visible only in the database context of the database in which they are defined.

As with any MDX function, stored procedure must be resolved before an MDX session can continue; stored procedures lock MDX sessions while executing. Unless a specific reason exists to halt an MDX session pending user interaction, then user interactions (such as dialog boxes) are discouraged.

Dependent Assemblies

All dependent assemblies must be loaded into an instance of Analysis Services to be found by the common language runtime (CLR). Analysis Services stores the dependent assemblies in the same folder as the main assembly, so the CLR automatically resolves all function references to functions in those assemblies.

Multidimensional Model Data Access (Analysis Services - Multidimensional Data)

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Use the information in this topic to learn how to access Analysis Services multidimensional data using programmatic methods, script, or client applications that include built-in support for connecting to an Analysis Services server on your network.

This topic contains the following sections:

[Client Applications](#)

[Query Languages](#)

[Programmatic Interfaces](#)

Client Applications

Although Analysis Services provides interfaces that let you build or integrate multidimensional databases programmatically, a more common approach is to use existing client applications from Microsoft and other software vendors that have built-in data access to Analysis Services data.

The following Microsoft applications support native connections to multidimensional data.

Excel

Analysis Services multidimensional data is often presented using pivot tables and pivot chart controls in an Excel workbook. PivotTables are suited to multidimensional data because the hierarchies, aggregations, and navigational constructs in the model pair well with the data summary features of a PivotTable. An Analysis Services OLE DB data provider is included in an Excel installation to make setting up data connections easier. For more information, see [Connect to or import data from SQL Server Analysis Services](#).

Reporting Services Reports

You can use Report Builder or Report Designer to create reports that consume Analysis Services databases that contain analytical data. Both Report Builder and Report Designer include an MDX query designer that you can use to type or design MDX statements that retrieve data from an available data source.

PerformancePoint Dashboards

PerformancePoint Dashboards are used to create scorecards in SharePoint that communicate business performance against predefined measures. PerformancePoint includes support for data connections to Analysis Services multidimensional data. For more information, [Create an Analysis Services data connection \(PerformancePoint Services\)](#).

SQL Server Data Tools

Model and report designers use SQL Server Data Tools to build solutions that include multidimensional models. Deploying the solution to an Analysis Services instance is what creates the database that you subsequently connect to from Excel, Reporting Services, and other business intelligence client applications.

SQL Server Data Tools is built on a Visual Studio shell and uses projects to organize and contain the model. For more information, see [Creating Multidimensional Models Using SQL Server Data Tools \(SSDT\)](#).

SQL Server Management Studio

For database administrators, SQL Server Management Studio is an integrated environment for managing your SQL Server instances, including instances of Analysis Services and multidimensional databases. For more information, see [SQL Server Management Studio](#) and [Connect to Analysis Services](#).

Query Languages

MDX is an industry standard query and calculation language used to retrieve data from OLAP databases. In Analysis Services, MDX is the query language used to retrieve data, but also supports data definition and data manipulation. MDX editors are built into SQL Server Management Studio, Reporting Services, and SQL Server Data Tools. You can use the MDX editors to create ad hoc queries or reusable script if the data operation is repeatable.

Some tools and applications, such as Excel, use MDX constructs internally to query an Analysis Services data source. You can also use MDX programmatically, by enclosing MDX statement in an XMLA Execute request.

The following links provide more information about MDX:

[Querying Multidimensional Data with MDX](#)

[Key Concepts in MDX \(Analysis Services\)](#)

[MDX Query Fundamentals \(Analysis Services\)](#)

[MDX Scripting Fundamentals \(Analysis Services\)](#)

Programmatic Interfaces

If you are building a custom application that uses multidimensional data, your approach for accessing the data will most likely fall into one of the following categories:

- **XMLA.** Use XMLA when you require compatibility with a wide variety of operating systems and protocols. XMLA offers the greatest flexibility, but often at the cost of improved performance and ease of programming.
- **Client libraries.** Use Analysis Services client libraries, such as ADOMD.NET, AMO, and OLE DB when you want to access data programmatically from client applications that run on a Microsoft Windows operating system. The client libraries wrap XMLA with an object model and optimizations that provide better performance.

ADOMD.NET and AMO client libraries are for applications written in managed code. Use OLE DB for Analysis Services if your application is written in native code.

The following table provides additional detail and links about the client libraries used for connecting Analysis Services to a custom application.

INTERFACE	DESCRIPTION
Analysis Services Management Objects (AMO)	AMO is the primary object model for administering Analysis Services instances and multidimensional databases in code. For example, SQL Server Management Studio uses AMO to support server and database administration. For more information, see Developing with Analysis Management Objects (AMO) .

INTERFACE	DESCRIPTION
ADOMD.NET	<p>ADOMD.NET is the primary object model creating and accessing multidimensional data in custom applications. You can use ADOMD.NET in a managed client application to retrieve Analysis Services information using common Microsoft .NET Framework data access interfaces. For more information, see Developing with ADOMD.NET and ADOMD.NET Client Programming.</p>
Analysis Services OLE DB Provider (MSOLAP.dll)	<p>You can use the native OLE DB provider to access Analysis Services programmatically from a non-managed API. For more information, see Analysis Services OLE DB Provider (Analysis Services - Multidimensional Data).</p>
Schema Rowsets	<p>Schema rowset tables are data structures that contain descriptive information about a multidimensional model that is deployed on the server, as well as information about current activity on the server. As a programmer, you can query schema rowset tables in client applications to examine metadata stored on, and retrieve support and monitoring information from, an Analysis Services instance. You can use schema rowsets with these programmatic interfaces: OLE DB, OLE DB for Analysis Services, OLE DB for Data Mining, or XMLA. For more information, see Analysis Services Schema Rowsets.</p> <p>The following list explains several approaches for using schema rowsets:</p> <ul style="list-style-type: none"> -Run DMV queries in SQL Server Management Studio or in custom reports to access schema rowsets using SQL syntax. For more information, see Use Dynamic Management Views (DMVs) to Monitor Analysis Services. -Write ADOMD.NET code that calls a schema rowset. -Run the XMLA Discover method directly against an Analysis Services instance to retrieve schema rowset information. For more information, see Discover Method (XMLA).
XMLA	<p>XMLA is the lowest level API available to an Analysis Services programmer, and is the common denominator that underlies all Analysis Services data access methodologies. XMLA is an industry standard, SOAP based XML protocol that supports universal data access to any standard multidimensional data source available over an HTTP connection. It uses SOAP to formulate requests and responses for multidimensional data. If your application runs on a non-Windows platform, you can use XMLA to access a multidimensional database that is running on a Windows server on your network. For more information, see Developing with XMLA in Analysis Services.</p>

INTERFACE	DESCRIPTION
Analysis Services Scripting Language (ASSL)	<p>ASSL is a descriptive term that applies to Analysis Services extensions of the XMLA protocol. Whereas the Execute and Discover methods are described by the XMLA protocol, ASSL adds the following capability:</p> <ul style="list-style-type: none">-XMLA script-XMLA object definitions-XMLA commands <p>ASSL extensions enable Analysis Services to use XMLA constructs beyond the basic provisions of the protocol, adding data definition, data manipulation, and data control support. For more information, see Developing with Analysis Services Scripting Language (ASSL).</p>

Querying Multidimensional Data with MDX

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Multidimensional Expressions (MDX) is the query language that you use to work with and retrieve multidimensional data in Microsoft Analysis Services. MDX is based on the XML for Analysis (XMLA) specification, with specific extensions for SQL Server Analysis Services. MDX utilizes expressions composed of identifiers, values, statements, functions, and operators that Analysis Services can evaluate to retrieve an object (for example a set or a member), or a scalar value (for example, a string or a number).

MDX queries and expressions in SQL Server Analysis Services are used to do the following:

- Return data to a client application from a SQL Server Analysis Services cube.
- Format query results.
- Perform cube design tasks, including the definition of calculated members, named sets, scoped assignments, and key performance indicators (KPIs).
- Perform administrative tasks, including dimension and cell security.

MDX is superficially similar in many ways to the SQL syntax that is typically used with relational databases. However, MDX is not an extension of the SQL language and is different from SQL in many ways. In order to create MDX expressions used to design or secure cubes, or to create MDX queries to return and format multidimensional data, you need to understand basic concepts in MDX and dimensional modeling, MDX syntax elements, MDX operators, MDX statements, and MDX functions.

In This Section

TOPIC	DESCRIPTION
Key Concepts in MDX (Analysis Services)	You can use Multidimensional Expressions (MDX) to query multidimensional data or to create MDX expressions for use within a cube, but first you should understand SQL Server Analysis Services dimension concepts and terminology.
MDX Query Fundamentals (Analysis Services)	Multidimensional Expressions (MDX) enables you to query multidimensional objects, such as cubes, and return multidimensional cellsets that contain the cube's data. This topic and its subtopics provide an overview of MDX queries.
MDX Scripting Fundamentals (Analysis Services)	In SQL Server Analysis Services, a Multidimensional Expressions (MDX) script is made up of one or more MDX expressions or statements that populate a cube with calculations. An MDX script defines the calculation process for a cube. An MDX script is also considered part of the cube itself. Therefore, changing an MDX script associated with a cube immediately changes the calculation process for the cube. To create MDX scripts, you can use Cube Designer in the Visual Studio with Analysis Services projects.

Key Concepts in MDX (Analysis Services)

7/16/2019 • 10 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Before you can use Multidimensional Expressions (MDX) to query multidimensional data or create MDX expressions within a cube, it helps to understand multidimensional concepts and terms.

The best place to start is with a data summarization example you already know, and then see how MDX relates to it. Here's a PivotTable created in Excel, populated with data from an Analysis Services sample cube.

The diagram shows a PivotTable with the following structure:

Reseller Sales Amount		Column Labels				Measure
Row Labels		CY 2005	CY 2006	CY 2007	CY 2008	Grand Total
Europe		\$1,698,880.94	\$5,632,816.55	\$3,538,837.31	\$10,870,534.80	
North America		\$8,065,435.31	\$22,445,548.71	\$25,722,421.91	\$11,752,320.88	\$67,985,726.81
Canada		\$1,513,359.46	\$4,822,999.20	\$5,651,305.43	\$2,390,261.51	\$14,377,925.60
United States		\$6,552,075.85	\$17,622,549.51	\$20,071,116.48	\$9,362,059.37	\$53,607,801.21
Central		\$951,240.65	\$2,625,639.72	\$3,005,591.43	\$1,323,536.38	\$7,906,008.18
Northeast		\$568,545.52	\$2,443,901.73	\$2,863,937.85	\$1,056,456.93	\$6,932,842.01
Northwest		\$1,689,790.14	\$3,471,099.54	\$4,640,535.06	\$2,633,651.25	\$12,435,076.00
Southeast		\$1,448,921.51	\$2,815,903.10	\$2,429,279.90	\$1,173,311.72	\$7,867,416.23
Southwest		\$1,893,578.02	\$6,266,005.43	\$7,131,772.25	\$3,175,103.09	\$18,466,458.79
Pacific				\$847,430.96	\$746,904.41	\$1,594,335.38
Grand Total		\$8,065,435.31	\$24,144,429.65	\$32,202,669.43	\$16,038,062.60	\$80,450,596.98

Annotations with arrows point to specific parts of the table:

- A blue arrow points to the "Dimensions and Attributes" section, which covers the rows and columns of the table.
- A red arrow points to the "Measure" section, which covers the numerical values in the cells.

Measures and Dimensions

An Analysis Services cube consists of measures, dimensions, and dimension attributes, all of which are evident in the PivotTable example.

Measures are numeric data values found in cells, aggregated as a sum, count, percentage, min, max, or average. Measure values are dynamic, calculated in real time, in response to user navigation and interaction with the PivotTable. In this example, the cells show Reseller Sales Amounts that increase or decrease based on whether you expand or collapse the axes. For any combination of Date (year, quarter, month, or date) and Sales Territory (Country group, Country, Region) you can get a Reseller Sales Amount, summed for that particular context. Other terms that are synonymous with measures are facts (in data warehouses) and calculated fields (in tabular and Excel data models).

Dimensions are on the column and row axes of a PivotTable, providing the meaning behind the measure. Dimensions are analogous to Tables in a relational data model. Common examples of a dimension include Time, Geography, Products, Customers, Employees, and so on. This example has two dimensions, Sales Territory on the rows, and Date across the top, but you could easily drag and drop other dimensions associated with Reseller Sales, such as Promotions or Products, to view sales performance along those dimensions. Your ability to explore data in interesting ways depends on the dimensions you create, and whether they are related to fact tables in your data source.

Dimension attributes are the named items within a dimension, similar to columns in a table. In this example, the Sales Territory dimension attributes consist of Country Group (Europe, North America, Pacific), Country (Canada, United States), and Region (Central, Northeast, Northwest, Southeast, Southwest).

Each attribute has a collection of data values, or members, associated with it. In our example, members of the

Country Group attribute are Europe, North America, and Pacific. **Members** refers to the actual data values that belong to an attribute.

NOTE

One aspect of data modeling is to formalize the patterns and relationships that already exist within the data itself. When working with data that falls into a natural hierarchy, as is the case with countries-regions-cities, you can formalize that relationship by creating an **attribute relationship**. An attribute relationship is a one-to-many relationship between attributes, for example a relationship between a state and a city - a state has many cities, but a city belongs to just one state. Creating attribute relationships in the model speeds up query performance, so it's a best practice to create them if the data supports it. You can create an attribute relationship in Dimension Designer in SQL Server Data Tools. See [Define Attribute Relationships](#).

Inside Excel, model metadata shows up in the PivotTable field list. Compare the PivotTable above to the field list below. Notice that the field list contains Sales Territory, Group, Country, Region (metadata), whereas the PivotTable contains just the members (data values). Knowing what the icons look like can help you easily relate the parts of a multidimensional model to a PivotTable in Excel.

The screenshot shows the 'PivotTable Fields' dialog box. At the top, there is a 'Show fields:' dropdown set to '(All)' and a 'Measure group and Measures' section. Below this, the field list is organized into categories:

- Reseller Sales** (highlighted with a red box):
 - Reseller Sales Amount
 - Reseller Standard Product Cost
 - Reseller Tax Amount
 - Reseller Total Product Cost
- KPIs**
- Account**
- Customer**
- Date** (highlighted with a red box):
 - Calendar
 - Fiscal
 - More Fields
- Sales Territory**:
 - Sales Territory (highlighted with a red box):
 - Group
 - Country
 - Region
 - More Fields

A red bracket on the right side of the dialog is labeled 'Attributes in a Hierarchy' and points to the 'Sales Territory' node under 'Dimensions'.

At the bottom, there are sections for 'FILTERS', 'ROWS', 'COLUMNS', and 'VALUES'. The 'COLUMNS' section shows 'Date.Calendar' selected, and the 'VALUES' section shows 'Reseller Sales Amount' selected.

Attribute Hierarchies

Almost without having to think about it, you know that values in a PivotTable go up or down as you expand and collapse the levels along each axis, but what makes this so? The answer lies in attribute hierarchies.

Collapse all the levels and notice the grand totals for each Country Group and Calendar Year. This value is derived from something called the **(All) member** within a hierarchy. The (All) member is the calculated value of all members in an attribute hierarchy.

- The (All) member for all Country Groups and Dates combined is \$80,450,596.98
- The (All) member for CY2008 is \$16,038,062.60
- The (All) member for Pacific is \$1,594,335.38

Aggregations like this are pre-computed and stored in advance, which is part of the secret to fast query performance of Analysis Services.

Reseller Sales Amount	Column Labels					
Row Labels	▼	+ CY 2005	+ CY 2006	+ CY 2007	+ CY 2008	Grand Total
+ Europe			\$1,698,880.94	\$5,632,816.55	\$3,538,837.31	\$10,870,534.80
+ North America		\$8,065,435.31	\$22,445,548.71	\$25,722,421.91	\$11,752,320.88	\$67,985,726.81
+ Pacific				\$847,430.96	\$746,904.41	\$1,594,335.38
Grand Total		\$8,065,435.31	\$24,144,429.65	\$32,202,669.43	\$16,038,062.60	\$80,450,596.98

Expand the hierarchy, and eventually you get to the lowest level. This is called the **leaf member**. A leaf member is a member of a hierarchy that has no children. In this example, Southwest is the leaf member.

Reseller Sales Amount	Column Labels					
Row Labels	▼	+ CY 2005	+ CY 2006	+ CY 2007	+ CY 2008	Grand Total

Southwest		\$1,893,578.02	\$6,266,005.43	\$7,131,772.25	\$3,175,103.09	\$18,466,458.79
+ Pacific				\$847,430.96	\$746,904.41	\$1,594,335.38
Grand Total		\$8,065,435.31	\$24,144,429.65	\$32,202,669.43	\$16,038,062.60	\$80,450,596.98

Anything above it is called a **parent member**. United States is the parent of Southwest.

Components of an attribute hierarchy

Together, all these concepts build towards the concept of an **attribute hierarchy**. An attribute hierarchy is a tree of attribute members containing the following levels:

- A leaf level that contains each distinct attribute member, with each member of the leaf level also known as a **leaf member**.
- Intermediate levels if the attribute hierarchy is a parent-child hierarchy (more on that later).
- An (All) member that contains the aggregated value of all the child attributes. Optionally, you can hide or turn off the (All) level when it doesn't make sense for the data. For example, although Product Code is numeric, it wouldn't make sense to sum or average or otherwise aggregate all of the Product Codes.

NOTE

BI developers often set properties on the attribute hierarchy to achieve certain behaviors in client applications, or gain certain performance benefits. For example, you would set AttributeHierarchyEnabled=False on attributes for which the (All) member doesn't make sense. Alternatively, perhaps you simply want to hide the (All) member, in which case you would set AttributeHierarchyVisible=False. See [Dimension Attribute Properties Reference](#) for more details about properties.

Navigation Hierarchies

Within the PivotTable (at least in this example), row and column axes expand to show lower levels of attributes. An expandable tree is achieved through navigation hierarchies that you create in a model. In the AdventureWorks sample model, the Sales Territory dimension has a multi-level hierarchy that begins with a Country Group, followed by Country, followed by Region.

As you can see, hierarchies are used to provide a navigation path in a PivotTable or other data summarization objects. There are two basic types: balanced and unbalanced.

Balanced Hierarchies

Q2 CY 2008

A **balanced hierarchy** is a hierarchy in which the same number of levels exists between the top level and any leaf member.

A **natural hierarchy** is one that emerges naturally from the underlying data. A common example is Country-Region-State or Year-Month-Date or Category-Subcategory-Model, where each subordinate level flows predictably from the parent.

In a multidimensional model, most hierarchies are balanced hierarchies, and many of them are also natural hierarchies.

Another related modeling term is a **user-defined hierarchy**, often used as a contrast with attribute hierarchies. It simply means a hierarchy created by the BI developer, as opposed to attribute hierarchies that are automatically generated by Analysis Services when you define an attribute.

Unbalanced Hierarchies

United Kingdom
North America
Canada
United States
Central
Northeast
Northwest
Southeast
Southwest
Pacific
Australia

A **ragged hierarchy** or **unbalanced hierarchy** is a hierarchy in which different numbers of levels exist between the top level and the leaf members. Again, it's a hierarchy created by the BI developer, but in this case there are gaps in the data.

In the AdventureWorks sample model, Sales Territory illustrates a ragged hierarchy because the United States has an additional level (Regions) that does not exist for other countries in this example.

Ragged hierarchies are a challenge to BI developers if the client application does not handle ragged hierarchies in an elegant manner. In Analysis Services model, you can build a **parent-child hierarchy** that explicitly defines a relationship among multi-level data, eliminating any ambiguity as to how one level relates to the next. See [Parent-Child Dimensions](#) for details.

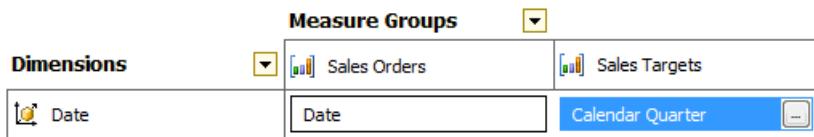

Key Attributes

Models are a collection of related objects that rely on keys and indexes to make the associations. Analysis Services models are no different. For each dimension (recall it is equivalent to a table in a relational model), there is a key attribute. The **key attribute** is used in foreign key relationships to the fact table (measure group). All non-key attributes in the dimension are linked (directly or indirectly) to the key attribute.

Often, but not always, the key attribute is also the **Granularity Attribute**. Granularity refers to the level of detail or precision within the data. Again, a common example offers the quickest path to understanding. Consider date values: For daily sales, you need date values specified to the day; for quotas, quarterly might be sufficient, but if your analytical data consists of race results from a sporting event, the grain might very well need to be milliseconds. The level of precision in your data values is the grain.

Currency is another example: a financial application might track monetary values out to many decimal places, whereas your local school's fund raiser might only need values to the nearest dollar. Understanding grain is important because you want to avoid storing unnecessary data. Trimming milliseconds from a timestamp, or pennies from a sales amount, can save storage and processing time when that level of detail is not relevant to your analysis.

To set the granularity attribute, use the Dimension Usage tab in Cube Designer in SQL Server Data Tools. In the AdventureWorks sample model, the key attribute of the Date dimension is the Date key. For Sales Orders, the granularity attribute is equivalent to the key attribute. For Sales Targets, the level of granularity is quarterly, and so the granularity attribute is set to Calendar Quarter, accordingly.

NOTE

If the granularity attribute and the key attribute are different, all non-key attributes must be linked, directly or indirectly, to the granularity attribute. Within a cube, the granularity attribute defines a dimension's granularity.

Query Scope (Cube Space)

Scope of a query refers to the boundaries within which data is being selected. It can range from the entire cube (a cube is the largest query object) to a cell.

Cube space is the product of the members of a cube's attribute hierarchies with the cube's measures.

Subcube is a subset of a cube that represents a filtered view of the cube. Subcubes can be defined with a Scope statement in the MDX calculation script, or in a subselect clause in an MDX query or as a session cube.

Cell refers to the space at the intersection of a member of the measures dimension member and a member from each attribute hierarchy in a cube.

Other Modeling Terms

This section is a collection of concepts and terms that don't fit easily into other sections, but you still need to know about.

Calculated member is a dimension member that is defined and calculated at query time. A calculated member can be defined in a user query or in the MDX calculation script and stored on the server. A calculated member corresponds to rows in the dimension table of the dimension in which it is defined.

Distinct Count is a special type of measure used for data items that should only be counted once. The AdventureWorks sample model includes distinct count measures for Internet Orders, Reseller Orders, and Sales Orders.

Measure groups are a collection of one or more measures. Mostly these are user-defined, and you use them to keep related measures together. Distinct count measures are an exception. These are always placed in a dedicated measure group that contains only the distinct measure. You can't see the measure group in the PivotTable example illustration, but it does appear in a PivotTable field list, as a named collection of measures.

Measures dimension is the dimension that contains all of the measures in a cube. It's not exposed in a multidimensional model that you build in SQL Server Data Tools, but it exists just the same. Because it contains measures, all of the members of a measures dimension are typically aggregated (generally by sum or by count).

Database Dimensions and Cube Dimensions. Within a model, you can define standalone dimensions that are then included in any number of cubes in the same model. When you add a dimension to a cube, it's called a cube dimension. By itself within a project, as a standalone item in Object Explorer, it's called a database dimension. Why make the distinction? Because you can set properties on them independently. In product documentation, you'll see both terms used, so it's worthwhile to understand what they mean.

Next Steps

Now that you have a grasp of important concepts and terminology, you can continue on to these additional topics that further explain fundamental concepts in Analysis Services:

- [The Basic MDX Query \(MDX\)](#)
- [The Basic MDX Script \(MDX\)](#)
- [Multidimensional Modeling \(Adventure Works Tutorial\)](#)

Autoexists

7/16/2019 • 8 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The concept of *autoexists* limits the cube space to those cells that actually exist in the cube in contraposition to those that might exist as a result of creating all possible combinations of attribute hierarchy members from the same hierarchy. This is because members of one attribute hierarchy cannot exist with members of another attribute hierarchy in the same dimension. When two or more attribute hierarchies of the same dimension are used in a SELECT statement, Analysis Services evaluates the attributes' expressions to make sure that the members of those attributes are properly confined to meet the criteria of all other attributes.

For example, suppose you are working with attributes from the Geography dimension. If you have one expression that returns all members from the City attribute and another expression that confines members from the Country attribute to all countries in Europe, then this will result in the City members being confined to only those cities that belong to countries in Europe. This is because of the autoexists characteristic of Analysis Services. Autoexists only applies to attributes from the same dimension because it tries to prevent the dimension records excluded in one attribute expression from being included by the other attribute expressions. Autoexists can also be understood as the resulting intersection of the different attributes expressions over the dimension rows.

Cell Existence

The following cells always exist:

- The (All) member, of every hierarchy, when crossed with members of other hierarchies in the same dimension.
- Calculated members when crossed with their non-calculated siblings, or with the parents or descendants of their non-calculated siblings.

Providing Non-existing cells

A non-existing cell is a cell provided by the system as a response to a query or calculation that requests a cell that does not exist in the cube. For example, if you have a cube that has a City attribute hierarchy and a Country attribute hierarchy that belong to the Geography dimension, and an Internet Sales Amount measure, the space of this cube only includes those members that exist with each other. For example, if the City attribute hierarchy includes the cities New York, London, Paris, Tokyo, and Melbourne; and the Country attribute hierarchy includes the countries United States, United Kingdom, France, Japan, and Australia; then the space of the cube does not include the space (cell) at the intersection of Paris and United States.

When querying cells that do not exist, non-existing cells return nulls; that is, they cannot contain calculations and you cannot define a calculation that writes to this space. For example, the following statement includes cells that do not exist.

```
SELECT [Customer].[Gender].[Gender].Members ON COLUMNS,  
{[Customer].[Customer].[Aaron A. Allen]  
,[Customer].[Customer].[Abigail Clark]} ON ROWS  
FROM [Adventure Works]  
WHERE Measures.[Internet Sales Amount]
```

NOTE

This query uses the [Members \(Set\) \(MDX\)](#) function to return the set of members of the Gender attribute hierarchy on the column axis, and crosses this set with the specified set of members from the Customer attribute hierarchy on the row axis.

When you execute the previous query, the cell at the intersection of Aaron A. Allen and Female displays a null. Similarly, the cell at the intersection of Abigail Clark and Male displays a null. These cells do not exist and cannot contain a value, but cells that do not exist can appear in the result returned by a query.

When you use the [Crossjoin \(MDX\)](#) function to return the cross-product of attribute hierarchy members from attribute hierarchies in the same dimension, auto-exists limits those tuples being returned to the set of tuples that actually exist, rather than returning a full Cartesian product. For example, run and then examine the results from the execution of the following query.

```
SELECT CROSSJOIN
(
    {[Customer].[Country].[United States]},
    [Customer].[State-Province].Members
) ON 0
FROM [Adventure Works]
WHERE Measures.[Internet Sales Amount]
```

NOTE

Notice that 0 is used to designate the column axis, which is shorthand for axis(0) - which is the column axis.

The previous query only returns cells for members from each attribute hierarchy in the query that exist with each other. The previous query can also be written using the new * variant of the [* \(Crossjoin\) \(MDX\)](#) function.

```
SELECT
    [Customer].[Country].[United States] *
    [Customer].[State-Province].Members
ON 0
FROM [Adventure Works]
WHERE Measures.[Internet Sales Amount]
```

The previous query could also be written in the following manner:

```
SELECT [Customer].[State-Province].Members
ON 0
FROM [Adventure Works]
WHERE (Measures.[Internet Sales Amount],
    [Customer].[Country].[United States])
```

The cells values returned will be identical, although the metadata in the result set will be different. For example, with the previous query, the Country hierarchy was moved to the slicer axis (in the WHERE clause) and therefore does not appear explicitly in the result set.

Each of these three previous queries demonstrates the effect of the auto-exists behavior in SQL Server Analysis Services.

Deep and Shallow Autoexists

Autoexists can be applied to the expressions as Deep or Shallow. **Deep Autoexists** means that all expressions will

be evaluated to meet the deepest possible space after applying the slicer expressions, the sub select expressions in the axis, and so on. **Shallow Autoexists** means that external expressions are evaluated before the current expression and those results are passed to the current expression. The default setting is deep autoexists.

The following scenario and samples will help to illustrate the different types of Autoexistss. In the following examples two sets will be created: one as a calculated expression and the other as a constant expression.

```
//Obtain the Top 10 best reseller selling products by Name

with member [Measures].[PCT Discount] AS '[Measures].[Discount Amount]/[Measures].[Reseller Sales Amount]',  
FORMAT_STRING = 'Percent'

set Top10SellingProducts as 'topcount([Product].[Model Name].children, 10, [Measures].[Reseller Sales Amount])'

set Preferred10Products as '  
 {[Product].[Model Name].&[Mountain-200],  
 [Product].[Model Name].&[Road-250],  
 [Product].[Model Name].&[Mountain-100],  
 [Product].[Model Name].&[Road-650],  
 [Product].[Model Name].&[Touring-1000],  
 [Product].[Model Name].&[Road-550-W],  
 [Product].[Model Name].&[Road-350-W],  
 [Product].[Model Name].&[HL Mountain Frame],  
 [Product].[Model Name].&[Road-150],  
 [Product].[Model Name].&[Touring-3000]  
'  
  
select {[Measures].[Reseller Sales Amount], [Measures].[Discount Amount], [Measures].[PCT Discount]} on 0,  
Top10SellingProducts on 1  
from [Adventure Works]
```

The obtained result set is:

	Reseller Sales Amount	Discount Amount	PCT Discount
Mountain-200	\$14,356,699.36	\$19,012.71	0.13%
Road-250	\$9,377,457.68	\$4,032.47	0.04%
Mountain-100	\$8,568,958.27	\$139,393.27	1.63%
Road-650	\$7,442,141.81	\$39,698.30	0.53%
Touring-1000	\$6,723,794.29	\$166,144.17	2.47%
Road-550-W	\$3,668,383.88	\$1,901.97	0.05%

Road-350-W	\$3,665,932.31	\$20,946.50	0.57%
HL Mountain Frame	\$3,365,069.27	\$174.11	0.01%
Road-150	\$2,363,805.16	\$0.00	0.00%
Touring-3000	\$2,046,508.26	\$79,582.15	3.89%

The obtained set of products seems to be the same as Preferred10Products; so, verifying the Preferred10Products set:

```
with member [Measures].[PCT Discount] AS '[Measures].[Discount Amount]/[Measures].[Reseller Sales Amount]',  
FORMAT_STRING = 'Percent'
```

```
set Top10SellingProducts as 'topcount([Product].[Model Name].children, 10, [Measures].[Reseller Sales Amount])'
```

```
set Preferred10Products as '
```

```
{[Product].[Model Name].&[Mountain-200],
```

```
[Product].[Model Name].&[Road-250],
```

```
[Product].[Model Name].&[Mountain-100],
```

```
[Product].[Model Name].&[Road-650],
```

```
[Product].[Model Name].&[Touring-1000],
```

```
[Product].[Model Name].&[Road-550-W],
```

```
[Product].[Model Name].&[Road-350-W],
```

```
[Product].[Model Name].&[HL Mountain Frame],
```

```
[Product].[Model Name].&[Road-150],
```

```
[Product].[Model Name].&[Touring-3000]
```

```
}'
```

```
select {[Measures].[Reseller Sales Amount], [Measures].[Discount Amount], [Measures].[PCT Discount]} on 0,
```

```
Preferred10Products on 1
```

```
from [Adventure Works]
```

As per the following results, both sets (Top10SellingProducts, Preferred10Products) are the same

	Reseller Sales Amount	Discount Amount	PCT Discount
Mountain-200	\$14,356,699.36	\$19,012.71	0.13%
Road-250	\$9,377,457.68	\$4,032.47	0.04%
Mountain-100	\$8,568,958.27	\$139,393.27	1.63%
Road-650	\$7,442,141.81	\$39,698.30	0.53%

Touring-1000	\$6,723,794.29	\$166,144.17	2.47%
Road-550-W	\$3,668,383.88	\$1,901.97	0.05%
Road-350-W	\$3,665,932.31	\$20,946.50	0.57%
HL Mountain Frame	\$3,365,069.27	\$174.11	0.01%
Road-150	\$2,363,805.16	\$0.00	0.00%
Touring-3000	\$2,046,508.26	\$79,582.15	3.89%

The following example will illustrate the concept of deep Autoexists. In the example we are filtering Top10SellingProducts by [Product].[Product Line] attribute for those in [Mountain] group. Note that both attributes (slicer and axis) belong to the same dimension, [Product].

```
with member [Measures].[PCT Discount] AS '[Measures].[Discount Amount]/[Measures].[Reseller Sales Amount]',  
FORMAT_STRING = 'Percent'  
  
set Top10SellingProducts as 'topcount([Product].[Model Name].children, 10, [Measures].[Reseller Sales Amount])'  
  
// Preferred10Products set removed for clarity  
  
select {[Measures].[Reseller Sales Amount], [Measures].[Discount Amount], [Measures].[PCT Discount]} on 0,  
Top10SellingProducts on 1  
  
from [Adventure Works]  
  
where [Product].[Product Line].[Mountain]
```

Produces the following result set:

	Reseller Sales Amount	Discount Amount	PCT Discount
Mountain-200	\$14,356,699.36	\$19,012.71	0.13%
Mountain-100	\$8,568,958.27	\$139,393.27	1.63%
HL Mountain Frame	\$3,365,069.27	\$174.11	0.01%
Mountain-300	\$1,907,249.38	\$876.95	0.05%
Mountain-500	\$1,067,327.31	\$17,266.09	1.62%
Mountain-400-W	\$592,450.05	\$303.49	0.05%
LL Mountain Frame	\$521,864.42	\$252.41	0.05%
ML Mountain Frame-W	\$482,953.16	\$206.95	0.04%
ML Mountain Frame	\$343,785.29	\$161.82	0.05%

Women's Mountain Shorts	\$260,304.09	\$6,675.56	2.56%
--------------------------------	---------------------	-------------------	--------------

In the above result set we have seven newcomers to the list of Top10SellingProducts and Mountain-200, Mountain-100, and HL Mountain Frame have moved to the top of the list. In the previous result set those three values were interspersed.

This is called Deep Autoexists, because the Top10SellingProducts set is evaluated to meet the slicing conditions of the query. Deep Autoexists means that all expressions will be evaluated to meet the deepest possible space after applying the slicer expressions, the sub select expressions in the axis, and so on.

However, one might want to be able to do the analysis over the Top10SellingProducts as equivalent to Preferred10Products, as in the following example:

```
with member [Measures].[PCT Discount] AS '[Measures].[Discount Amount]/[Measures].[Reseller Sales Amount]',  
FORMAT_STRING = 'Percent'
```

```
set Top10SellingProducts as 'topcount([Product].[Model Name].children, 10, [Measures].[Reseller Sales Amount])'
```

```
set Preferred10Products as '
```

```
{[Product].[Model Name].&[Mountain-200],
```

```
[Product].[Model Name].&[Road-250],
```

```
[Product].[Model Name].&[Mountain-100],
```

```
[Product].[Model Name].&[Road-650],
```

```
[Product].[Model Name].&[Touring-1000],
```

```
[Product].[Model Name].&[Road-550-W],
```

```
[Product].[Model Name].&[Road-350-W],
```

```
[Product].[Model Name].&[HL Mountain Frame],
```

```
[Product].[Model Name].&[Road-150],
```

```
[Product].[Model Name].&[Touring-3000]
```

```
}
```

```
select {[Measures].[Reseller Sales Amount], [Measures].[Discount Amount], [Measures].[PCT Discount]} on 0,
```

```
Preferred10Products on 1
```

```
from [Adventure Works]
```

```
where [Product].[Product Line].[Mountain]
```

Produces the following result set:

	Reseller Sales Amount	Discount Amount	PCT Discount
Mountain-200	\$14,356,699.36	\$19,012.71	0.13%
Mountain-100	\$8,568,958.27	\$139,393.27	1.63%

HL Mountain Frame	\$3,365,069.27	\$174.11	0.01%
--------------------------	-----------------------	-----------------	--------------

In the above results, the slicing gives a result that contains only those products from Preferred10Products that are part of the [Mountain] group in [Product].[Product Line]; as expected, because Preferred10Products is a constant expression.

This result set is also understood as Shallow Autoexists. This is because the expression is evaluated before the slicing clause. In the previous example, the expression was a constant expression for illustration purposes in order to introduce the concept.

Autoexists behavior can be modified at the session level using the **Autoexists** connection string property. The following example begins by opening a new session and adding the *Autoexists=3* property to the connection string. You must open a new connection in order to do the example. Once the connection is established with the Autoexist setting it will remain in effect until that connection is finished.

```
with member [Measures].[PCT Discount] AS '[Measures].[Discount Amount]/[Measures].[Reseller Sales Amount]',  
FORMAT_STRING = 'Percent'  
  
set Top10SellingProducts as 'topcount([Product].[Model Name].children, 10, [Measures].[Reseller Sales Amount])'  
  
//Preferred10Products set removed for clarity  
  
select {[Measures].[Reseller Sales Amount], [Measures].[Discount Amount], [Measures].[PCT Discount]} on 0,  
Top10SellingProducts on 1  
  
from [Adventure Works]  
  
where [Product].[Product Line].[Mountain]
```

The following result set now shows the shallow behavior of Autoexists.

	Reseller Sales Amount	Discount Amount	PCT Discount
Mountain-200	\$14,356,699.36	\$19,012.71	0.13%
Mountain-100	\$8,568,958.27	\$139,393.27	1.63%
HL Mountain Frame	\$3,365,069.27	\$174.11	0.01%

Autoexists behavior can be modified by using the AUTOEXISTS=[1|2|3] parameter in the connection string; see [Supported XMLA Properties \(XMLA\)](#) and [ConnectionString](#) for parameter usage.

Calculation Context

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The calculation context is the known subspace of the cube where an expression is evaluated and all coordinates are either explicitly known or can be derived from the expression.

Determining the calculation context

Every set, member, tuple, or numeric function executes in the context of the entire MDX expression or statement. When an argument, such as a tuple, is passed to a function, only some of the coordinates in the cube space are explicitly provided. The other coordinates are obtained based on the current calculation context.

The calculation context for unspecified cell coordinates and attribute members is determined in the following order:

1. The FROM clause (if applicable) - this clause can either specify an entire cube or can specify a subcube in the form of a SELECT statement.
2. The WHERE clause (if applicable) - this clause, which is also known as the *slicer axis*, on which you specify a set, tuple, or member that restricts the members returned on the column and row axis by a query.
Conceptually, the default member of every attribute hierarchy that is not explicitly specified on column or row axis is part of the slicer axis.

NOTE

When cell coordinates for a particular attribute are specified on both the slicer axis and on another axis, the coordinates specified in the function may take precedence in determining the members of the set on the axis. The [Filter \(MDX\)](#) and [Order \(MDX\)](#) functions are examples of such functions - you can filter or order a result by attribute members that are excluded from the calculation context by the WHERE clause, or by a SELECT statement in the FROM clause.

3. The named sets and calculated members defined in the query or expression.
4. The tuples and sets specified on the row and column axes, utilizing the default member for attributes that do not appear on the row, column, or slicer axis.
5. The cube or subcube cells on each axis, eliminating empty tuples on the axis and applying the HAVING clause.
6. For more information, see [Establishing Cube Context in a Query \(MDX\)](#).

In the following query, the calculation context for the row axis is restricted by the Country attribute member and the Calendar Year attribute member that are specified in the WHERE clause.

```
SELECT Customer.City.City.Members ON 0
FROM [Adventure Works]
WHERE (Customer.Country.France, [Date].[Calendar].[Calendar Year].[CY 2004],
      Measures.[Internet Sales Amount])
```

However, if you modify this query by specifying the **FILTER** function on the row axis, and utilize a Calendar Year attribute hierarchy member in the **FILTER** function, then the attribute member from the Calendar Year attribute hierarchy that is used to provide the calculation context for the members of the set on the column axis can be

modified.

```
SELECT FILTER
(
    Customer.City.City.Members,
    ([Date].[Calendar].[Calendar Year].[CY 2003],
     Measures.[Internet Order Quantity]) > 75
) ON 0
FROM [Adventure Works]
WHERE (Customer.Country.France,
       [Date].[Calendar].[Calendar Year].[CY 2004],
       Measures.[Internet Sales Amount])
```

In the previous query, the calculation context for the cells in the tuples that appear on the column axis is filtered by the CY 2003 member of the Calendar Year attribute hierarchy, even though the nominal calculation context for the Calendar Year attribute hierarchy is CY 2004. Furthermore, it is filtered by the Internet Order Quantity measure. However, once the members of the set on the column axis is set, the calculation context for the values for the members that appear on the axis is again determined by the WHERE clause.

IMPORTANT

To increase query performance, you should eliminate members and tuples as early in the resolution process as possible. In this manner, complex query time calculations on the final set of members operate on the fewest cells possible.

Calculated Members in Subselects and Subcubes

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A calculated member is a dimension member whose value is calculated from an expression at run time, and can be used in subselects and subcubes to more precisely define the cubespace of a query.

Enabling calculated members in the subspace

The **SubQueries** connection string property in [ConnectionString](#) or the **DBPROPMSMDSUBQUERIES** property in [Supported XMLA Properties \(XMLA\)](#) defines the behavior or allowance of calculated members or calculated sets on subselects or subcubes. In the context of this document, subselect refers to subselects and subcubes unless otherwise stated.

The SubQueries property allows the following values.

Value	Description
0	Calculated members are not allowed in subselects or subcubes. An error is raised when evaluating the subselect or subcube if a calculated member is referenced.
1	Calculated members are allowed in subselects or subcubes but no ascendant members are introduced in the returning subspace.
2	Calculated members are allowed in subselects or subcubes and ascendant members are introduced in the returning subspace. Also, mixed granularity is allowed in the selection of calculated members.

Using values of 1 or 2 in the SubQueries property allows calculated members to be used to filter the returning subspace of subselects.

An example will help clarify the concept; first a calculated member must be created and then a subselect query issued to show the above mentioned behavior.

The following sample creates a calculated member that adds [Seattle Metro] as a city to the [Geography].[Geography] hierarchy under Washington state.

To run the example, the connection string must contain the SubQueries property with a value of 1 and all MDX statements must be run in the same session.

IMPORTANT

If you're using Management Studio to test the queries, click the Options button on Connection Manager to access the additional connection string properties pane, where you can enter subqueries=1 or 2 to allow calculated members in the subspace.

First issue the following MDX expression:

```
CREATE MEMBER [Adventure Works].[Geography].[Geography].[State-Province].&[WA]&[US].[Seattle Metro Agg]
AS AGGREGATE(
{
    [Geography].[Geography].[City].&[Bellevue]&[WA]
    , [Geography].[Geography].[City].&[Issaquah]&[WA]
    , [Geography].[Geography].[City].&[Redmond]&[WA]
    , [Geography].[Geography].[City].&[Seattle]&[WA]
}
)
```

Then issue the following MDX query to see calculated members allowed in subselects.

```
Select [Date].[Calendar Year].members on 0,
       [Geography].[Geography].allmembers on 1
  from (Select {[Geography].[Geography].[State-Province].&[WA]&[US].[Seattle Metro Agg]}) on 0 from [Adventure
  Works])
 Where [Measures].[Reseller Sales Amount]
```

The obtained results are:

	All Periods	CY 2011	CY 2012	CY 2013	CY 2014
Seattle Metro Agg	\$2,383,545.69	\$291,248.93	\$763,557.02	\$915,832.36	\$412,907.37

As said before, the ascendants of [Seattle Metro] do not exist in the returned subspace, when SubQueries=1, hence [Geography].[Geography].allmembers only contains the calculated member.

If the example is run using SubQueries=2, in the connection string, the obtained results are:

	All Periods	CY 2001	CY 2002	CY 2003	CY 2004
All Geographies	(null)	(null)	(null)	(null)	(null)
United States	(null)	(null)	(null)	(null)	(null)
Washington	(null)	(null)	(null)	(null)	(null)
Seattle Metro Agg	\$2,383,545.69	\$291,248.93	\$763,557.02	\$915,832.36	\$412,907.37

As said before, when using SubQueries=2, the ascendants of [Seattle Metro] exist in the returned subspace but no values exist for those members because there is no regular members to provide for the aggregations. Therefore, NULL values are provided for all ascendant members of the calculated member in this example.

To understand the above behavior, it helps to understand that calculated members do not contribute to the aggregations of their parents as regular members do; the former implies that filtering by calculated members alone will lead to empty ascendants because there are no regular members to contribute to the aggregated values of the resulting subspace. If you add regular members to the filtering expression then the aggregated values will come from those regular members. Continuing with the above example, if the cities of Portland, in Oregon, and the city

of Spokane, in Washington, are added to the same axis where the calculated member appears; as shown in the next MDX expression:

```
Select [Date].[Calendar Year].members on 0,
       [Geography].[Geography].allmembers on 1
  from (Select {
      [Seattle Metro Agg]
    , [Geography].[Geography].[City].&[Portland]&[OR]
    , [Geography].[Geography].[City].&[Spokane]&[WA]
  } on 0 from [Adventure Works]
)
Where [Measures].[Reseller Sales Amount]
```

The following results are obtained.

	All Periods	CY 2001	CY 2002	CY 2003	CY 2004
All Geographies	\$235,171.62	\$419.46	\$4,996.25	\$131,788.82	\$97,967.09
United States	\$235,171.62	\$419.46	\$4,996.25	\$131,788.82	\$97,967.09
Oregon	\$30,968.25	\$419.46	\$4,996.25	\$17,442.97	\$8,109.56
Portland	\$30,968.25	\$419.46	\$4,996.25	\$17,442.97	\$8,109.56
97205	\$30,968.25	\$419.46	\$4,996.25	\$17,442.97	\$8,109.56
Washington	\$204,203.37	(null)	(null)	\$114,345.85	\$89,857.52
Spokane	\$204,203.37	(null)	(null)	\$114,345.85	\$89,857.52
99202	\$204,203.37	(null)	(null)	\$114,345.85	\$89,857.52
Seattle Metro Agg	\$2,383,545.69	\$291,248.93	\$763,557.02	\$915,832.36	\$412,907.37

In the above results the aggregated values for [All Geographies], [United States], [Oregon] and [Washington] come from aggregating over the descendants of &[Portland]&[OR] and &[Spokane]&[WA]. Nothing comes from the calculated member.

Remarks

Only global or session calculated members are allowed in the subselect or subcube expressions. Having query calculated members in the MDX expression will raise an error when the subselect or subcube expression is evaluated.

Cube Space

7/16/2019 • 5 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Cube space is the product of the members of a cube's attribute hierarchies with the cube's measures. Therefore, the cube space is determined by the combinatorial product of all attribute hierarchy members in the cube and the cube's measures and defines the maximum size of the cube. It is important to note that this space includes all possible combinations of attribute hierarchy members; even combinations that might be deemed as impossible in the real world i.e. combinations where the city is Paris and the countries are England or Spain or Japan or India or elsewhere.

Autoexists and cube space

The concept of *autoexists* limits this cube space to those cells that actually exist. Members of an attribute hierarchy in a dimension may not exist with members of another attribute hierarchy in the same dimension.

For example, if you have a cube that has a City attribute hierarchy, a Country attribute hierarchy, and an Internet Sales Amount measure, the space of this cube only includes those members that exist with each other. For example, if the City attribute hierarchy includes the cities New York, London, Paris, Tokyo, and Melbourne; and the Country attribute hierarchy includes the countries United States, United Kingdom, France, Japan, and Australia; then the space of the cube does not include the space (cell) at the intersection of Paris and United States.

When querying cells that do not exist, non-existing cells return nulls; that is, they cannot contain calculations and you cannot define a calculation that writes to this space. For example, the following statement includes cells that do not exist.

```
SELECT [Customer].[Gender].[Gender].Members ON COLUMNS,  
{[Customer].[Customer].[Aaron A. Allen]  
,[Customer].[Customer].[Abigail Clark]} ON ROWS  
FROM [Adventure Works]  
WHERE Measures.[Internet Sales Amount]
```

NOTE

This query uses the [Members \(Set\) \(MDX\)](#) function to return the set of members of the Gender attribute hierarchy on the column axis, and crosses this set with the specified set of members from the Customer attribute hierarchy on the row axis.

When you execute the previous query, the cell at the intersection of Aaron A. Allen and Female displays a null. Similarly, the cell at the intersection of Abigail Clark and Male displays a null. These cells do not exist and cannot contain a value, but cells that do not exist can appear in the result returned by a query.

When you use the [Crossjoin \(MDX\)](#) function to return the cross-product of attribute hierarchy members from attribute hierarchies in the same dimension, auto-exists limits those tuples being returned to the set of tuples that actually exist, rather than returning a full Cartesian product. For example, run and then examine the results from the execution of the following query.

```

SELECT CROSSJOIN
(
    {[Customer].[Country].[United States]},
    [Customer].[State-Province].Members
) ON 0
FROM [Adventure Works]
WHERE Measures.[Internet Sales Amount]

```

NOTE

Notice that 0 is used to designate the column axis, which is shorthand for axis(0) - which is the column axis.

The previous query only returns cells for members from each attribute hierarchy in the query that exist with each other. The previous query can also be written using the new * variant of the [*\(Crossjoin\) \(MDX\)](#) function.

```

SELECT
    [Customer].[Country].[United States] *
    [Customer].[State-Province].Members
ON 0
FROM [Adventure Works]
WHERE Measures.[Internet Sales Amount]

```

The previous query could also be written in the following manner:

```

SELECT [Customer].[State-Province].Members
ON 0
FROM [Adventure Works]
WHERE (Measures.[Internet Sales Amount],
    [Customer].[Country].[United States])

```

The cells values returned will be identical, although the metadata in the result set will be different. For example, with the previous query, the Country hierarchy was moved to the slicer axis (in the WHERE clause) and therefore does not appear explicitly in the result set.

Each of these three previous queries demonstrates the effect of the auto-exists behavior in SQL Server Analysis Services.

User-Defined Hierarchies and Cube Space

The previous examples in this topic define positions in cube space by using attribute hierarchies. However, you can also define a position in cube space by using user-defined hierarchies that have been defined based on attribute hierarchies in a dimension. A user-defined hierarchy is a hierarchy of attribute hierarchies designed to facilitate browsing of cube data by users.

For example, the **CROSSJOIN** query in the previous section could also have been written as follows:

```

SELECT CROSSJOIN
(
    {[Customer].[Country].[United States]},
    [Customer].[Customer Geography].[State-Province].Members
)
ON 0
FROM [Adventure Works]
WHERE Measures.[Internet Sales Amount]

```

In the previous query, the Customer Geography user-defined hierarchy within the Customer dimension is used to

define the position in cube space that was previously defined by using an attribute hierarchy. The identical position in cube space can be defined by using either attribute hierarchies or user-defined hierarchies.

Attribute Relationships and Cube Space

Defining attribute relationships between related attributes improves query performance (by facilitating the creation of appropriate aggregations) and affects the member of a related attribute hierarchy that appears with an attribute hierarchy member. For example, when you define a tuple that includes a member from the City attribute hierarchy and the tuple does not explicitly define the Country attribute hierarchy member, you might expect that the default Country attribute hierarchy member would be the related member of the Country attribute hierarchy. However, this is only true if an attribute relationship is defined between the City attribute hierarchy and the Country attribute hierarchy.

The following example returns the member of a related attribute hierarchy that is not included explicitly in the query.

```
WITH MEMBER Measures.x AS  
    Customer.Country.CurrentMember.Name  
SELECT Measures.x ON 0,  
Customer.City.Members ON 1  
FROM [Adventure Works]
```

NOTE

Notice that the **WITH** keyword is used with the [CurrentMember \(MDX\)](#) and [Name \(MDX\)](#) functions to create a calculated member for use in the query. For more information, see [The Basic MDX Query \(MDX\)](#).

In the previous query, the name of the member of the Country attribute hierarchy that is associated with each member of the State attribute hierarchy is returned. The expected Country member appears (because an attribute relationship is defined between the City and Country attributes). However, if no attribute relationship were defined between attribute hierarchies in the same dimension, the (All) member would be returned, as illustrated in the following query.

```
WITH MEMBER Measures.x AS  
    Customer.Education.CurrentMember.Name  
SELECT Measures.x ON 0,  
Customer.City.Members ON 1  
FROM [Adventure Works]
```

In the previous query, the (All) member ("All Customers") is returned, because there is no relationship between Education and City. Therefore, the (All) member of the Education attribute hierarchy would be the default member of the Education attribute hierarchy used in any tuple involving the City attribute hierarchy where an Education member is not explicitly provided.

Subselects in Queries

7/16/2019 • 10 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Subselect expressions are nested SELECT expressions that are used to restrict the space of the cube from where the outer external SELECT is being evaluated. Subselects allow you to define a new space over which all calculations are evaluated.

Subselects by example

Let's begin with an example of how subselects can help to produce the results we want to show. Assume that you are requested to produce a table that shows the sales behavior, over years, for the top 10 products.

The result should look like the following table:

	Sum of Years	Year 1	...
Sum of Top 10 Products			
Product A			
...			

To do something like the above one could write the following MDX expression:

```
SELECT [Date].[Calendar Year].MEMBERS on 0
    , TOPCOUNT( [Product].[Product].MEMBERS
        , 10
        , [Measures].[Sales Amount]
    ) ON 1
FROM [Adventure Works]
```

That returns the following results:

	All Periods	CY 2005	CY 20062	CY 2007	CY 2008
All Products	\$80,450,596.98	\$8,065,435.31	\$24,144,429.65	\$32,202,669.43	\$16,038,062.60
Mountain-200 Black, 38	\$1,634,647.94	(null)	(null)	\$894,207.97	\$740,439.97
Mountain-200 Black, 42	\$1,285,524.65	(null)	(null)	\$722,137.65	\$563,387.00
Mountain-200 Silver, 38	\$1,181,945.82	(null)	(null)	\$634,600.78	\$547,345.03

Mountain-200 Black, 46	\$995,927.43	(null)	(null)	\$514,995.76	\$480,931.68
Mountain-200 Silver, 42	\$1,005,111.77	(null)	(null)	\$529,543.29	\$475,568.49
Mountain-200 Silver, 46	\$975,932.56	(null)	(null)	\$526,759.30	\$449,173.26
Road-150 Red, 56	\$792,228.98	\$382,159.24	\$410,069.74	(null)	(null)
Mountain-200 Black, 38	\$1,471,078.72	(null)	\$789,958.49	\$681,120.23	(null)
Road-350-W Yellow, 48	\$1,380,253.88	(null)	(null)	\$744,988.37	\$635,265.50

Which is very close to what we are looking for; except that the query returned 9 not 10 products and the All Products total reflects the sum of all products not the sum of the returned Top 9 (in this case). Another attempt to solve the problem is presented in the following MDX query:

```
SELECT [Date].[Calendar Year].MEMBERS on 0
    , TOPCOUNT( [Product].[Product].CHILDREN, 10, [Measures].[Sales Amount]) ON 1
FROM [Adventure Works]
```

That returns the following results:

	All Periods	CY 2005	CY 2006	CY 2007	CY 2008
Mountain-200 Black, 38	\$1,634,647.94	(null)	(null)	\$894,207.97	\$740,439.97
Mountain-200 Black, 42	\$1,285,524.65	(null)	(null)	\$722,137.65	\$563,387.00
Mountain-200 Silver, 38	\$1,181,945.82	(null)	(null)	\$634,600.78	\$547,345.03
Mountain-200 Black, 46	\$995,927.43	(null)	(null)	\$514,995.76	\$480,931.68
Mountain-200 Silver, 42	\$1,005,111.77	(null)	(null)	\$529,543.29	\$475,568.49
Mountain-200 Silver, 46	\$975,932.56	(null)	(null)	\$526,759.30	\$449,173.26
Road-150 Red, 56	\$792,228.98	\$382,159.24	\$410,069.74	(null)	(null)

Mountain-200 Black, 38	\$1,471,078.72	(null)	\$789,958.49	\$681,120.23	(null)
Road-350-W Yellow, 48	\$1,380,253.88	(null)	(null)	\$744,988.37	\$635,265.50
Road-150 Red, 62	\$566,797.97	\$234,018.86	\$332,779.11	(null)	(null)

That was very close to the desired result because it only missed the sum of the products. At this point one can start tweaking the above MDX expression to add the missing line; however, that task could prove to be a cumbersome one.

Another approach to solve the problem, would be to start thinking in terms of redefining the cube space over which the MDX expression is resolved. What if the 'new' cube contains only data from the Top 10 products? That cube then will have the All member adjusted to the Top 10 products only and now a simple query would resolve our needs.

The following MDX expression uses a subselect statement to redefine the cube space to the Top 10 products and produce the desired results:

```

SELECT [Date].[Calendar Year].MEMBERS on 0
    , [Product].[Product].MEMBERS on 1
  FROM (SELECT TOPCOUNT( [Product].[Product].CHILDREN
        , 10
        , [Measures].[Sales Amount]
      ) ON 0
    FROM [Adventure Works]
  )
 WHERE [Measures].[Sales Amount]
  
```

The above expression returns the following results:

	All Periods	CY 2005	CY 2006	CY 2007	CY 2008
All Products	\$19,997,183.30	\$1,696,815.63	\$2,816,611.28	\$7,930,797.72	\$7,552,958.66
Mountain-200 Silver, 38	\$2,160,981.60	(null)	(null)	\$1,024,359.10	\$1,136,622.49
Mountain-200 Silver, 42	\$1,914,547.85	(null)	(null)	\$903,061.68	\$1,011,486.18
Mountain-200 Silver, 46	\$1,906,248.55	(null)	(null)	\$877,077.79	\$1,029,170.76
Mountain-200 Black, 38	\$1,811,229.02	(null)	\$896,511.60	\$914,717.43	(null)
Mountain-200 Black, 38	\$2,589,363.78	(null)	(null)	\$1,261,406.37	\$1,327,957.41

Mountain-200 Black, 42	\$2,265,485.38	(null)	(null)	\$1,126,055.89	\$1,139,429.49
Mountain-200 Black, 46	\$1,957,528.24	(null)	(null)	\$946,453.88	\$1,011,074.37
Road-150 Red, 62	\$1,769,096.69	\$828,011.68	\$941,085.01	(null)	(null)
Road-150 Red, 56	\$1,847,818.63	\$868,803.96	\$979,014.67	(null)	(null)
Road-350-W Yellow, 48	\$1,774,883.56	(null)	(null)	\$877,665.59	\$897,217.96

The results above are exactly what we were looking for.

Let's review what exactly did the subselect do for us. The subselect returned for us a new cube that contained all other dimensions from product as they are; but, in the product dimension it filtered all members to match the top 10 products that we were interested in. It was as if we had removed all data that did not meet the Top 10 criteria and had rebuilt the cube. The other important concept to understand in this example is the fact that the Top 10 products were calculated over the All member of all the other dimensions in the cube; the former is true because no other filtering restrictions were imposed in the subselect.

Subselects can be as complex as one would like; the following example will illustrate how to produce a similar table as the mentioned above but filtered on France on the Sales Territory dimension and on Internet for the Sales Channel dimension.

```

SELECT [Date].[Calendar Year].MEMBERS on 0
    , [Product].[Product].MEMBERS on 1
    FROM (SELECT TOPCOUNT( [Product].[Product].CHILDREN
        , 10
        , [Measures].[Sales Amount]
        ) ON 0
        , [Sales Territory].[Sales Territory].[Region].[France] on 1
        , [Sales Channel].[Sales Channel].[Internet] on 2
    FROM [Adventure Works]
    )
    WHERE [Measures].[Sales Amount]

```

Produced the following results:

	All Periods	CY 2005	CY 2006	CY 2007	CY 2008
All Products	\$748,682.49	\$32,204.43	\$73,125.18	\$269,506.56	\$373,846.32
Mountain-200 Silver, 38	\$90,479.61	(null)	(null)	\$41,759.82	\$48,719.79
Mountain-200 Silver, 42	\$97,439.58	(null)	(null)	\$39,439.83	\$57,999.75

Mountain-200 Silver, 46	\$102,079.56	(null)	(null)	\$27,839.88	\$74,239.68
Mountain-200 Black, 38	\$26,638.28	(null)	\$12,294.59	\$14,343.69	(null)
Mountain-200 Black, 38	\$96,389.58	(null)	(null)	\$41,309.82	\$55,079.76
Mountain-200 Black, 42	\$80,324.65	(null)	(null)	\$43,604.81	\$36,719.84
Mountain-200 Black, 46	\$107,864.53	(null)	(null)	\$45,899.80	\$61,964.73
Road-150 Red, 62	\$46,517.51	\$14,313.08	\$32,204.43	(null)	(null)
Road-150 Red, 56	\$46,517.51	\$17,891.35	\$28,626.16	(null)	(null)
Road-350-W Yellow, 48	\$54,431.68	(null)	(null)	\$15,308.91	\$39,122.77

The above results are the Top 10 products sold in France through the Internet channel.

Subselect statement

The BNF for the Subselect is:

```
[WITH [<calc-clause> ...]]
SELECT [<axis-spec> [, <axis-spec> ...]]
FROM [<identifier> | (< sub-select-statement >)]
[WHERE <slicer>]
[[CELL] PROPERTIES <cellprop> [, <cellprop> ...]]

< sub-select-statement > :=
  SELECT [<axis-spec> [, <axis-spec> ...]]
  FROM [<identifier> | (< sub-select-statement >)]
  [WHERE <slicer>]
```

The subselect is another Select statement where the axis specifications and the slicer specification filter the space of the cube over which the outer select is evaluated.

When a member is specified in one of the axis or slicer clause then that member with its descendants and descendants are included in the sub cube space for the subselect; all non mentioned sibling members, in the axis or slicer clause, and their descendants are filtered from the subspace. This way, the space of the outer select has been limited to the existing members in the axis clause or slicer clause, with their descendants as mentioned before.

Because the All member of all non mentioned dimensions in axis or slicer clauses belongs to the space of the select; then, all descendants to the All member on those dimensions are, also, part of the subselect space.

The All member, in all dimensions, in the subcube space, is re-evaluated to reflect the impact of the constraints of the new space.

The following example will show what has been said above; the first MDX expression helps to display the unfiltered values in the cube, the second MDX illustrates the effect of filtering in the Subselect clause:

```
SELECT { [Customer].[Customer Geography].[All Customers]
    , [Customer].[Customer Geography].[Country].&[United States]
    , [Customer].[Customer Geography].[State-Province].&[OR]&[US]
    , [Customer].[Customer Geography].[City].&[Portland]&[OR]
    , [Customer].[Customer Geography].[State-Province].&[WA]&[US]
    , [Customer].[Customer Geography].[City].&[Seattle]&[WA]
} ON 1
, {[Measures].[Internet Sales Amount], [Measures].[Reseller Sales Amount]} ON 0
FROM [Adventure Works]
```

Returns the following values:

	Internet Sales Amount	Reseller Sales Amount
All Customers	\$29,358,677.22	\$80,450,596.98
United States	\$9,389,789.51	\$80,450,596.98
Oregon	\$1,170,991.54	\$80,450,596.98
Portland	\$110,649.54	\$80,450,596.98
Washington	\$2,467,248.34	\$80,450,596.98
Seattle	\$75,164.86	\$80,450,596.98

In the above example Seattle is a child of Washington, Portland is a child of Oregon, Oregon and Washington are children of United States and United States is a child of [Customer Geography].[All Customers]. All of the shown members in this example have other siblings that contribute to the parent aggregate value; i.e. Spokane, Tacoma and Everett are sibling cities of Seattle and they all contribute to Washington Internet Sales Amount. Reseller Sales Amount value is independent of Customer Geography attribute; hence the All value is displayed in the results. The next MDX expression illustrates the filtering effect of the subselect clause:

```
SELECT { [Customer].[Customer Geography].[All Customers]
    , [Customer].[Customer Geography].[Country].&[United States]
    , [Customer].[Customer Geography].[State-Province].&[OR]&[US]
    , [Customer].[Customer Geography].[City].&[Portland]&[OR]
    , [Customer].[Customer Geography].[State-Province].&[WA]&[US]
    , [Customer].[Customer Geography].[City].&[Seattle]&[WA]
} ON 1
, {[Measures].[Internet Sales Amount], [Measures].[Reseller Sales Amount]} ON 0
FROM ( SELECT [Customer].[State-Province].&[WA]&[US] ON 0
        FROM [Adventure Works]
    )
```

Returns the following values:

	Internet Sales Amount	Reseller Sales Amount
All Customers	\$2,467,248.34	\$80,450,596.98

United States	\$2,467,248.34	\$80,450,596.98
Washington	\$2,467,248.34	\$80,450,596.98
Seattle	\$75,164.86	\$80,450,596.98

The results above show that only ascendants and descendants of Washington State are part of the subspace where the outer select statement was evaluated; Oregon and Portland have been removed from the subcube because Oregon and all the other sibling states were not mentioned in the subselect when Washington was mentioned.

The All member was adjusted to reflect the filtering on Washington; not only was adjusted in the [Customer Geography] dimension but in all other dimensions that crossed with [Customer Geography]. All dimensions that do not cross with [Customer Geography] remain in the subcube unaltered.

The following two MDX statements illustrate how the All member in other dimensions is adjusted to meet the filtering effect of the subselect. The first query displays the unaltered results and the second shows the impact of the filtering:

```

SELECT { [Customer].[Customer Geography].[All Customers]
    , [Customer].[Customer Geography].[Country].&[United States]
    , [Customer].[Customer Geography].[State-Province].&[OR]&[US]
    , [Customer].[Customer Geography].[City].&[Portland]&[OR]
    , [Customer].[Customer Geography].[State-Province].&[WA]&[US]
    , [Customer].[Customer Geography].[City].&[Seattle]&[WA]
} ON 1
    , [Product].[Product Line].MEMBERS ON 0
FROM [Adventure Works]
WHERE [Measures].[Internet Sales Amount]

```

	All Products	Accessory	Components	Mountain	Road	Touring
All Customers	\$29,358,677.22	\$604,053.30	(null)	\$10,251,183.52	\$14,624,108.58	\$3,879,331.82
United States	\$9,389,789.51	\$217,168.79	(null)	\$3,547,956.78	\$4,322,438.41	\$1,302,225.54
Oregon	\$1,170,991.54	\$30,513.17	(null)	\$443,607.98	\$565,372.10	\$131,498.29
Portland	\$110,649.54	\$2,834.17	(null)	\$47,099.91	\$53,917.17	\$6,798.29
Washington	\$2,467,248.34	\$62,662.92	(null)	\$945,219.38	\$1,155,880.07	\$303,485.97
Seattle	\$75,164.86	\$2,695.74	(null)	\$19,914.53	\$44,820.06	\$7,734.54

```

SELECT { [Customer].[Customer Geography].[All Customers]
    , [Customer].[Customer Geography].[Country]&[United States]
    , [Customer].[Customer Geography].[State-Province]&[OR]&[US]
    , [Customer].[Customer Geography].[City]&[Portland]&[OR]
    , [Customer].[Customer Geography].[State-Province]&[WA]&[US]
    , [Customer].[Customer Geography].[City]&[Seattle]&[WA]
} ON 1
    , [Product].[Product Line].MEMBERS ON 0
FROM ( SELECT [Customer].[State-Province]&[WA]&[US] ON 0
        FROM [Adventure Works]
    )
WHERE [Measures].[Internet Sales Amount]

```

	All Products	Accessory	Components	Mountain	Road	Touring
All Customers	\$2,467,248.34	\$62,662.92	(null)	\$945,219.38	\$1,155,880.07	\$303,485.97
United States	\$2,467,248.34	\$62,662.92	(null)	\$945,219.38	\$1,155,880.07	\$303,485.97
Washington	\$2,467,248.34	\$62,662.92	(null)	\$945,219.38	\$1,155,880.07	\$303,485.97
Seattle	\$75,164.86	\$2,695.74	(null)	\$19,914.53	\$44,820.06	\$7,734.54

The above results show that All Products values have been adjusted to only values from Washington State, as expected.

Subselects can be nested with no limit to how deep you can nest subselects, except available memory. The inner most subselect defines the starting subspace over which filtering is applied and passed onto the next outer select. An important thing to notice is the fact that nesting is not a commutative operation; so the order in which the nesting is set my produce different results. The following examples should show the difference when choosing a nesting order.

```

SELECT [Sales Territory].[Sales Territory Region].MEMBERS on 0
    , [Product].[Product].MEMBERS on 1
    FROM (SELECT TOPCOUNT( [Product].[Product].CHILDREN, 5, [Measures].[Sales Amount]) ON 0
            FROM (SELECT TOPCOUNT( [Sales Territory].[Sales Territory Region].CHILDREN, 5, [Measures].[Sales
Amount]) ON 0
                    FROM [Adventure Works]
                )
            )
        WHERE [Measures].[Sales Amount]

```

Returned the following results.

	All Sales Territories	Australia	Canada	Central	Northwest	Southwest
All Products	\$7,591,495.49	\$1,281,059.99	\$1,547,298.12	\$600,205.79	\$1,924,763.50	\$2,238,168.08
Mountain-200 Silver, 38	\$1,449,576.15	\$248,702.93	\$275,052.45	\$141,103.65	\$349,487.01	\$435,230.12

Mountain-200 Black, 38	\$1,722,896.50	\$218,024.05	\$418,726.43	\$123,929.46	\$486,694.63	\$475,521.93
Mountain-200 Black, 42	\$1,573,655.14	\$239,137.96	\$319,921.61	\$130,102.75	\$420,445.84	\$464,046.98
Mountain-200 Black, 46	\$1,420,500.58	\$192,320.16	\$230,875.99	\$117,044.49	\$424,813.66	\$455,446.27
Road-150 Red, 56	\$1,424,867.11	\$382,874.89	\$302,721.64	\$88,025.44	\$243,322.36	\$407,922.78

```

SELECT [Sales Territory].[Sales Territory Region].MEMBERS on 0
    , [Product].[Product].MEMBERS on 1
    FROM (SELECT TOPCOUNT( [Sales Territory].[Sales Territory Region].CHILDREN, 5, [Measures].[Sales Amount]) ON 0
        FROM (SELECT TOPCOUNT( [Product].[Product].CHILDREN, 5, [Measures].[Sales Amount]) ON 0
            FROM [Adventure Works]
        )
    )
    WHERE [Measures].[Sales Amount]

```

Returned the following results.

	All Sales Territories	Australia	Canada	Northwest	Southwest	United Kingdom
All Products	\$7,938,218.56	\$1,096,312.24	\$1,474,255.49	\$2,042,674.72	\$2,238,099.55	\$1,086,876.56
Mountain-200 Silver, 38	\$1,520,958.53	\$248,702.93	\$275,052.45	\$349,487.01	\$435,230.12	\$212,486.03
Mountain-200 Silver, 42	\$1,392,237.14	\$198,127.15	\$229,679.01	\$361,233.58	\$407,854.24	\$195,343.16
Mountain-200 Black, 38	\$1,861,703.23	\$218,024.05	\$418,726.43	\$486,694.63	\$475,521.93	\$262,736.19
Mountain-200 Black, 42	\$1,702,427.25	\$239,137.96	\$319,921.61	\$420,445.84	\$464,046.98	\$258,874.87
Mountain-200 Black, 46	\$1,460,892.41	\$192,320.16	\$230,875.99	\$424,813.66	\$455,446.27	\$157,436.31

As you can see there are differences in the results between both sets. The first query answered the question of which are the best selling products in the top 5 selling regions, the second query answered the question of where are the largest sales of the top 5 selling products.

Remarks

Subselects have the following restrictions and limitations:

- The WHERE clause does not filter the subspace.
- The WHERE clause changes the default member in the sub cube only.

- The NON EMPTY clause is not allowed in an axis clause; use a [NonEmpty \(MDX\)](#) function expression instead.
- The HAVING clause is not allowed in an axis clause; use a [Filter \(MDX\)](#) function expression instead.
- By default calculated members are not allowed in subselects; however, this restriction can be changed, in a per session basis, by assigning a value to the **SubQueries** connection string property in [ConnectionString](#) or **DBPROP_MSMD_SUBQUERIES** property in [Supported XMLA Properties \(XMLA\)](#). See [Calculated Members in Subselects and Subcubes](#) for a detailed explanation of the behavior of calculated members depending on the values of **SubQueries** or **DBPROP_MSMD_SUBQUERIES**.

Tuples

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A tuple uniquely identifies a slice of data from a cube. The tuple is formed by a combination of dimension members, as long as there are no two or more members that belong to the same hierarchy.

Implicit or default attribute members in a tuple

When defining a tuple in an MDX query or expression, you do not need to explicitly include the attribute member from every attribute hierarchy. If a member from an attribute hierarchy is not explicitly included in a query or an expression, the default member for that attribute hierarchy is the attribute member implicitly included in the tuple. Unless otherwise explicitly defined in a cube, the default member for every attribute hierarchy is the (All) member, if an (All) member exists. If an (All) member does not exist within an attribute hierarchy, the default member is a member of the attribute hierarchy's top level. The default measure is the first measure specified in the cube, unless a default measure is explicitly defined. For more information, see [Define a Default Member](#) and [DefaultMember \(MDX\)](#).

For example, the following tuple identifies a single cell in the Adventure Works database by explicitly defining only a single member of the Measures dimension.

```
(Measures.[Reseller Sales Amount])
```

The previous example uniquely identifies the cell consisting of the Reseller Sales Amount member from the Measures dimension and the default member from every attribute hierarchy in the cube. The default member is the (All) member for every attribute hierarchy other than the Destination Currency attribute hierarchy. The default member for the Destination Currency hierarchy is the US Dollar member (this default member is defined in the MDX script for the Adventure Works cube).

IMPORTANT

The member of an attribute hierarchy in a tuple is also affected by relationships that are defined between attributes within a dimension.

The following query returns the value for the cell referenced by the tuple specified in the previous example, (\$80,450.596.98).

```
SELECT  
Measures.[Reseller Sales Amount] ON COLUMNS  
FROM [Adventure Works]
```

NOTE

When you specify an axis for a set (in this case composed of a single tuple) in a query, you must begin by specifying a set for the column axis before specifying a set for the row axis. The column axis can also be referred to as *axis(0)* or simply *0*. For more information about MDX queries, see [The Basic MDX Query \(MDX\)](#).

You can use a tuple in a query to return the value in the cell that is referenced by the tuple, as in the previous example. Or you can use a tuple in an expression to explicitly refer to the members specified in the tuple. The query or the expression can utilize functions that either return or consume tuples. A tuple can be used to either refer to the value of the cell that the tuple specifies, or to specify a combination of members when utilized in a function.

Tuple dimensionality

The *dimensionality* of a tuple refers to the sequence or order of the members in the tuple. Since the implicit members always occur in the same order, dimensionality is most often thought of in terms of the explicitly defined members of the tuple. The ordering of the members of the tuple is important when you define a set of tuples. The following example includes two members in a tuple on the column axis.

```
SELECT  
([Measures].[Reseller Sales Amount],[Date].[Calendar Year].[CY 2004]) ON COLUMNS  
FROM [Adventure Works]
```

NOTE

When you explicitly specify a member in a tuple from more than one dimension, you must include the entire tuple in parentheses. When only specifying a single member in a tuple, parentheses are optional.

The tuple in the query in the previous example specifies the return of the cube cell at the intersection of the Reseller Sales Amount Measure of the Measures dimension and the CY 2004 member of the Calendar Year attribute hierarchy in the Date dimension.

NOTE

An attribute member can be referred by either its member name or its member key. In the previous example, you could replace the reference to [CY 2004] with &[2004].

Visual Totals and Non Visual Totals

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Visual Totals are totals at the end of a column or row that add up all of the items visible in the column or row. This is the default behavior for most tables when displayed. However, there are times when the user wants to display only certain columns in a table but keep the totals for the entire row, including those that are not displayed. These are called **Non Visual Totals**, because the total comes from both the visible and non-visible values.

The following scenario demonstrates the behavior of Non Visual totals. The first step shows the default behavior of Visual Totals.

The following example is a query of [Adventure Works] to obtain [Reseller Sales Amount] figures in a table where the product categories are the columns and the reseller business types are the rows. Note that totals are given for both products and resellers when the following SELECT statement is issued:

```
select [Category].members on 0,  
[Business Type].members on 1  
from [Adventure Works]  
where [Measures].[Reseller Sales Amount]
```

Produces the following results:

	All Products	Accessories	Bikes	Clothing	Components
All Resellers	\$80,450,596.98	\$571,297.93	\$66,302,381.56	\$1,777,840.84	\$11,799,076.66
Specialty Bike Shop	\$6,756,166.18	\$65,125.48	\$6,080,117.73	\$252,933.91	\$357,989.07
Value Added Reseller	\$34,967,517.33	\$175,002.81	\$30,892,354.33	\$592,385.71	\$3,307,774.48
Warehouse	\$38,726,913.48	\$331,169.64	\$29,329,909.50	\$932,521.23	\$8,133,313.11

Non-Visual on rows and columns

To produce a table with data only for the Accessories and Clothing products, the Value Added Reseller and Warehouse resellers, yet keeping the overall totals could be written as follows using NON VISUAL:

```
select [Category].members on 0,  
[Business Type].members on 1  
from NON VISUAL (Select {[Category].Accessories, [Category].Clothing} on 0,  
{[Business Type].[Value Added Reseller], [Business Type].[Warehouse]} on 1  
from [Adventure Works])
```

```
where [Measures].[Reseller Sales Amount]
```

Produces the following results:

	All Products	Accessories	Clothing
All Resellers	\$80,450,596.98	\$571,297.93	\$1,777,840.84
Value Added Reseller	\$34,967,517.33	\$175,002.81	\$592,385.71
Warehouse	\$38,726,913.48	\$331,169.64	\$932,521.23

Non-Visual on rows

To produce a table that visually totals the columns but for row totals brings the true total of all [Category], the following query should be issued:

```
select [Category].members on 0,  
[Business Type].members on 1  
  
from NON VISUAL (Select {[Category].Accessories, [Category].Clothing} on 0  
  
from ( Select {[Business Type].[Value Added Reseller], [Business Type].[Warehouse]} on 0  
  
from [Adventure Works])  
)  
  
where [Measures].[Reseller Sales Amount]
```

Note how NON VISUAL is only applied to [Category].

The above query produces the following results:

	All Products	Accessories	Clothing
All Resellers	\$73,694,430.80	\$506,172.45	\$1,524,906.93
Value Added Reseller	\$34,967,517.33	\$175,002.81	\$592,385.71
Warehouse	\$38,726,913.48	\$331,169.64	\$932,521.23

When compared with the previous results, you can observe that the [All Resellers] row now adds up to the displayed values for [Value Added Reseller] and [Warehouse] but that the [All Products] column shows the total value for all products, including those not displayed.

Working with Members, Tuples, and Sets (MDX)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

MDX provides numerous functions that return one or more members, tuples, or sets; or that act upon a member, tuple, or set.

Member Functions

MDX provides several functions for retrieving members from other MDX entities, such as from dimensions, levels, sets, or tuples. For example, the [FirstChild](#) function is a function that acts upon a member and returns a member.

To obtain the first child member of the Time dimension, you can explicitly state the member, as in the following example.

```
SELECT [Date].[Calendar Year].[CY 2001] on 0  
FROM [Adventure Works]
```

You can also use the [FirstChild](#) function to return the same member, as in the following example.

```
SELECT [Date].[Calendar Year].FirstChild on 0  
FROM [Adventure Works]
```

For more information about MDX member functions, see [MDX Function Reference \(MDX\)](#).

Tuple Functions

MDX provides several functions that return tuples, and they can be used anywhere that a tuple is accepted. For example, the [Item \(Tuple\) \(MDX\)](#) function can be used to extract the first tuple from set, which is very useful when you know that a set is composed of a single tuple and you want to supply that tuple to a function that requires a tuple.

The following example returns the first tuple from within the set of tuples on the column axis.

```
SELECT {  
    ([Measures].[Reseller Sales Amount]  
     ,[Date].[Calendar Year].[CY 2003]  
    )  
    , ([Measures].[Reseller Sales Amount]  
     ,[Date].[Calendar Year].[CY 2004]  
    )  
}.Item(0)  
ON COLUMNS  
FROM [Adventure Works]
```

For more information about tuple functions, see [MDX Function Reference \(MDX\)](#).

Set Functions

MDX provides several functions that return sets. Explicitly typing tuples and enclosing them in braces is not the only way to retrieve a set. For more information about the members function to return a set, see [Key Concepts in MDX \(Analysis Services\)](#). There are many additional set functions.

The colon operator lets you use the natural order of members to create a set. For example, the set shown in the following example contains tuples for the 1st through the 4th quarter of calendar year 2002.

```
SELECT
  {[Calendar Quarter].[Q1 CY 2002]:[Calendar Quarter].[Q4 CY 2002]}
ON 0
FROM [Adventure Works]
```

If you do not use the colon operator to create the set, you can create the same set of members by specifying the tuples in the following example.

```
SELECT {
  [Calendar Quarter].[Q1 CY 2002],
  [Calendar Quarter].[Q2 CY 2002],
  [Calendar Quarter].[Q3 CY 2002],
  [Calendar Quarter].[Q4 CY 2002]
} ON 0
FROM [Adventure Works]
```

The colon operator is an inclusive function. The members on both sides of the colon operator are included in the resulting set.

For more information about set functions, see [MDX Function Reference \(MDX\)](#).

Array Functions

An array function acts upon a set and returns an array. For more information about array functions, see [MDX Function Reference \(MDX\)](#).

Hierarchy Functions

A hierarchy function returns a hierarchy by acting upon a member, level, hierarchy, or string. For more information about hierarchy functions, see [MDX Function Reference \(MDX\)](#).

Level Functions

A level function returns a level by acting upon a member, level, or string. For more information about level functions, see [MDX Function Reference \(MDX\)](#).

Logical Functions

A logical function acts upon a MDX expression to return information about the tuples, members, or sets in the expression. For example, the [IsEmpty \(MDX\)](#) function evaluates whether an expression has returned an empty cell value. For more information about logical functions, see [MDX Function Reference \(MDX\)](#).

Numeric Functions

A numeric function acts upon a MDX expression to return a scalar value. For example, the [Aggregate \(MDX\)](#) function returns a scalar value calculated by aggregating measures over the tuples in a specified set. For more information about numeric functions, see [MDX Function Reference \(MDX\)](#).

String Functions

A string function acts upon a MDX expression to return a string. For example, the [UniqueName \(MDX\)](#) function returns a string value containing the unique name of a dimension, hierarchy, level, or member. For more information about string functions, see [MDX Function Reference \(MDX\)](#).

MDX Query Fundamentals (Analysis Services)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Multidimensional Expressions (MDX) lets you query multidimensional objects, such as cubes, and return multidimensional cellsets that contain the cube's data. This topic and its subtopics provide an overview of MDX queries.

The following topics describe MDX queries and the cellsets they produce, and provide more detailed information about basic MDX syntax.

In This Section

TOPIC	DESCRIPTION
The Basic MDX Query (MDX)	Provides basic syntax information for the MDX SELECT statement.
Restricting the Query with Query and Slicer Axis (MDX)	Describes what query and slicer axes are and how to specify them.
Establishing Cube Context in a Query (MDX)	Provides a description of the purpose of the FROM clause in an MDX SELECT statement.
Building Named Sets in MDX (MDX)	Describes the purpose of named sets in MDX, and the techniques needed to create and use them in MDX queries.
Building Calculated Members in MDX (MDX)	Provides information about calculated members in MDX, including the techniques needed to create and use them in MDX expressions.
Building Cell Calculations in MDX (MDX)	Details the process of creating and using calculated cells.
Creating and Using Property Values (MDX)	Details the process of creating and using dimension, level, member, and cell properties.
Manipulating Data (MDX)	Describes the basics behind manipulating data using drillthrough and rollup, and also describes pass order and solve order in MDX.
Modifying Data (MDX)	Describes how to use writebacks to temporarily or permanently change multidimensional data.
Using Variables and Parameters (MDX)	Describes how to use variables and parameters within MDX queries.

MDX Query - The Basic Query

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The basic Multidimensional Expressions (MDX) query is the SELECT statement—the most frequently used query in MDX. By understanding how an MDX SELECT statement must specify a result set, what the syntax of the SELECT statement is, and how to create a simple query using the SELECT statement, you will have a solid understanding of how to use MDX to query multidimensional data.

Specifying a Result Set

In MDX, the SELECT statement specifies a result set that contains a subset of multidimensional data that has been returned from a cube. To specify a result set, an MDX query must contain the following information:

- The number of axes that you want the result set to contain. You can specify up to 128 axes in an MDX query.
- The set of members or tuples to include on each axis of the MDX query.
- The name of the cube that sets the context of the MDX query.
- The set of members or tuples to include on the slicer axis. For more information about slicer and query axes, see [Restricting the Query with Query and Slicer Axes \(MDX\)](#).

To identify the query axes, the cube that will be queried, and the slicer axis, the MDX SELECT statement uses the following clauses:

- A SELECT clause that determines the query axes of an MDX SELECT statement. For more information about the construction of query axes in a SELECT clause, see [Specifying the Contents of a Query Axis \(MDX\)](#).
- A FROM clause that determines which cube will be queried. For more information about the FROM clause, see [SELECT Statement \(MDX\)](#).
- An optional WHERE clause that determines which members or tuples to use on the slicer axis to restrict the data returned. For more information about the construction of a slicer axis in a WHERE clause, see [Specifying the Contents of a Slicer Axis \(MDX\)](#).

NOTE

For more detailed information about the various clauses of the SELECT statement, see [SELECT Statement \(MDX\)](#).

SELECT Statement Syntax

The following syntax shows a basic SELECT statement that includes the use of the SELECT, FROM, and WHERE clauses:

```
[ WITH <SELECT WITH clause> [ , <SELECT WITH clause> ... ] ]
  SELECT [ * | ( <SELECT query axis clause>
    [ , <SELECT query axis clause> ... ] ) ]
  FROM <SELECT subcube clause>
  [ <SELECT slicer axis clause> ]
  [ <SELECT cell property list clause> ]
```

The MDX SELECT statement supports optional syntax, such as the WITH keyword, the use of MDX functions to create calculated members for inclusion in an axis or slicer axis, and the ability to return the values of specific cell properties as part of the query. For more information about the MDX SELECT statement, see [SELECT Statement \(MDX\)](#).

Comparing the Syntax of the MDX SELECT Statement to SQL

The syntax format for the MDX SELECT statement is similar to that of SQL syntax. However, there are several fundamental differences:

- MDX syntax distinguishes sets by surrounding tuples or members with braces (the { and } characters.) For more information about member, tuple, and set syntax, see [Working with Members, Tuples, and Sets \(MDX\)](#).
- MDX queries can have 0, 1, 2 or up to 128 query axes in the SELECT statement. Each axis behaves in exactly the same way, unlike SQL where there are significant differences between how the rows and the columns of a query behave.
- As with an SQL query, the FROM clause names the source of the data for the MDX query. However, the MDX FROM clause is restricted to a single cube. Information from other cubes can be retrieved on a value-by-value basis by using the LookupCube function.
- The WHERE clause describes the slicer axis in an MDX query. It acts as something like an invisible, extra axis in the query, slicing the values that appear in the cells in the result set; unlike the SQL WHERE clause it does not directly affect what appears on the rows axis of the query. The functionality of the SQL WHERE clause is available through other MDX functions such as the FILTER function.

SELECT Statement Example

The following example shows a basic MDX query that uses the SELECT statement. This query returns a result set that contains the 2002 and 2003 sales and tax amounts for the Southwest sales territories.

```
SELECT
  { [Measures].[Sales Amount],
    [Measures].[Tax Amount] } ON COLUMNS,
  { [Date].[Fiscal].[Fiscal Year].&[2002],
    [Date].[Fiscal].[Fiscal Year].&[2003] } ON ROWS
FROM [Adventure Works]
WHERE ( [Sales Territory].[Southwest] )
```

In this example, the query defines the following result set information:

- The SELECT clause sets the query axes as the Sales Amount and Tax Amount members of the Measures dimension, and the 2002 and 2003 members of the Date dimension.
- The FROM clause indicates that the data source is the Adventure Works cube.
- The WHERE clause defines the slicer axis as the Southwest member of the Sales Territory dimension.

Notice that the query example also uses the COLUMNS and ROWS axis aliases. The ordinal positions for these axes could also have been used. The following example shows how the MDX query could have been written to

use the ordinal position of each axis:

```
SELECT
{ [Measures].[Sales Amount],
  [Measures].[Tax Amount] } ON 0,
{ [Date].[Fiscal].[Fiscal Year].&[2002],
  [Date].[Fiscal].[Fiscal Year].&[2003] } ON 1
FROM [Adventure Works]
WHERE ( [Sales Territory].[Southwest] )
```

For more detailed examples, see [Specifying the Contents of a Query Axis \(MDX\)](#) and [Specifying the Contents of a Slicer Axis \(MDX\)](#).

[SELECT Statement \(MDX\)](#)

MDX Query - EXISTING Keyword

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Forces a specified set to be evaluated within the current context.

Syntax

```
Existing Set_Expression
```

Arguments

Set_Expression

A valid Multidimensional Expressions (MDX) set expression.

Remarks

By default, sets are evaluated within the context of the cube that contains the members of the set. The **Existing** keyword forces a specified set to be evaluated within the current context instead.

Example

The following example returns the count of the resellers whose sales have declined over the previous time period, based on user-selected State-Province member values evaluated using the **Aggregate** function. The **Hierarchize (MDX)** and **DrilldownLevel (MDX)** functions are used to return values for declining sales for product categories in the Product dimension. The **Existing** keyword forces the set in the **Filter** function to be evaluated in the current context - that is, for the Washington and Oregon members of the State-Province attribute hierarchy.

```

WITH MEMBER Measures.[Declining Reseller Sales] AS
  Count
    (Filter
      (Existing
        (Reseller.Reseller.Reseller)
        , [Measures].[Reseller Sales Amount] <
          ([Measures].[Reseller Sales Amount]
            ,[Date].Calendar.PrevMember
          )
        )
      )
    )
MEMBER [Geography].[State-Province].x AS
  Aggregate
    ( {[Geography].[State-Province].&[WA]&[US]
      , [Geography].[State-Province].&[OR]&[US] }
    )
SELECT NON EMPTY HIERARCHIZE
  (AddCalculatedMembers
    (
      {DrillDownLevel
        ({[Product].[All Products]}
        )
      }
    )
  ) DIMENSION PROPERTIES PARENT_UNIQUE_NAME ON COLUMNS
FROM [Adventure Works]
WHERE
  ( [Geography].[State-Province].x
    , [Date].[Calendar].[Calendar Quarter].&[2003]&[4]
    ,[Measures].[Declining Reseller Sales]
  )

```

MDX Query and Slicer Axes - Restricting the Query

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

When formulating a Multidimensional Expressions (MDX) SELECT statement, an application typically examines a cube and divides the set of hierarchies into two subsets:

- **Query axes**-the set of hierarchies from which data is retrieved for multiple members. For more information about query axes, see [Specifying the Contents of a Query Axis \(MDX\)](#).
- **Slicer axis**-the set of hierarchies from which data is retrieved for a single member. For more information about the slicer axis, see [Specifying the Contents of a Slicer Axis \(MDX\)](#).

Because query and slicer axes can be constructed from multiple hierarchies of the cube to be queried, these terms are used to differentiate the hierarchies used by the cube that is to be queried from the hierarchies created in the cube returned by an MDX query.

To see a simple example using query and slicer axes, see [Using Query and Slicer Axes in a Simple Example \(MDX\)](#).

MDX Query and Slicer Axes - Specify the Contents of a Query Axis

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Query axes specify the edges of a cellset returned by a Multidimensional Expressions (MDX) SELECT statement. Specifying the edges of a cellset lets you restrict the returned data that is visible to the client.

To specify query axes, you use the `<SELECT query axis clause>` to assign a set to a particular query axis. Each `<SELECT query axis clause>` value defines one query axis. The number of axes in the dataset is equal to the number of `<SELECT query axis clause>` values in the SELECT statement.

Query Axis Syntax

The following syntax shows the syntax for the `<SELECT query axis clause>`:

```
<SELECT query axis clause> ::=  
    [ NON EMPTY ] Set_Expression [ <SELECT dimension property list clause> ] [<HAVING clause>]  
    ON {  
        Integer_Expression |  
        AXIS( Integer_Expression ) |  
        {COLUMNS | ROWS | PAGES | SECTIONS | CHAPTERS}  
    }
```

Each query axis has a number: zero (0) for the x-axis, 1 for the y-axis, 2 for the z-axis, and so on. In the syntax for the `<SELECT query axis clause>`, the `Integer_Expression` value specifies the axis number. An MDX query can support up to 128 specified axes, but very few MDX queries will use more than 5 axes. For the first 5 axes, the aliases COLUMNS, ROWS, PAGES, SECTIONS, and CHAPTERS can instead be used.

An MDX query cannot skip query axes. That is, a query that includes one or more query axes must not exclude lower-numbered or intermediate axes. For example, a query cannot have a ROWS axis without a COLUMNS axis, or have COLUMNS and PAGES axes without a ROWS axis.

However, you can specify a SELECT clause without any axes (that is, an empty SELECT clause). In this case, all dimensions are slicer dimensions, and the MDX query selects one cell.

In the query axis syntax previously shown, each `Set_Expression` value specifies the set that defines the contents of the query axis. For more information about sets, see [Working with Members, Tuples, and Sets \(MDX\)](#).

Examples

The following simple SELECT statement returns the measure Internet Sales Amount on the Columns axis, and uses the MDX MEMBERS function to return all the members from the Calendar hierarchy on the Date dimension on the Rows axis:

```

SELECT {[Measures].[Internet Sales Amount]} ON COLUMNS,
 {[Date].[Calendar].MEMBERS} ON ROWS
 FROM [Adventure Works]

```

The two following queries return exactly the same results but demonstrate the use of axis numbers rather than aliases:

```

SELECT {[Measures].[Internet Sales Amount]} ON 0,
 {[Date].[Calendar].MEMBERS} ON 1
 FROM [Adventure Works]

```

```

SELECT {[Measures].[Internet Sales Amount]} ON AXIS(0),
 {[Date].[Calendar].MEMBERS} ON AXIS(1)
 FROM [Adventure Works]

```

The NON EMPTY keyword, used before the set definition, is an easy way to remove all empty tuples from an axis. For example, in the examples we've seen so far there is no data in the cube from August 2004 onwards. To remove all rows from the cellset that have no data in any column, simply add NON EMPTY before the set on the Rows axis definition as follows:

```

SELECT {[Measures].[Internet Sales Amount]} ON COLUMNS,
 NON EMPTY
 {[Date].[Calendar].MEMBERS} ON ROWS
 FROM [Adventure Works]

```

NON EMPTY can be used on all axes in a query. Compare the results of the following two queries, the first of which does not use NON EMPTY and the second of which does on both axes:

```

SELECT {[Measures].[Internet Sales Amount]}
 * [Promotion].[Promotion].[Promotion].MEMBERS
 ON COLUMNS,
 {[Date].[Calendar].[Calendar Year].MEMBERS} ON ROWS
 FROM [Adventure Works]
 WHERE([Product].[Subcategory].&[19])

```

```

SELECT NON EMPTY {[Measures].[Internet Sales Amount]}
 * [Promotion].[Promotion].[Promotion].MEMBERS
 ON COLUMNS,
 NON EMPTY
 {[Date].[Calendar].[Calendar Year].MEMBERS} ON ROWS
 FROM [Adventure Works]
 WHERE([Product].[Subcategory].&[19])

```

The HAVING clause can be used to filter the contents of an axis based on a specific criteria; it is less flexible than other methods that can achieve the same results, such as the FILTER function, but it is simpler to use. Here is an example that returns only those dates where Internet Sales Amount is greater than \$15,000:

```
SELECT {[Measures].[Internet Sales Amount]}  
ON COLUMNS,  
NON EMPTY  
{[Date].[Calendar].[Date].MEMBERS}  
HAVING [Measures].[Internet Sales Amount]>15000  
ON ROWS  
FROM [Adventure Works]
```

[Specifying the Contents of a Slicer Axis \(MDX\)](#)

MDX Query and Slicer Axes - Specify the Contents of a Slicer Axis

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The slicer axis filters the data returned by the Multidimensional Expressions (MDX) SELECT statement, restricting the returned data so that only data intersecting with the specified members will be returned. It can be thought of as an invisible extra axis in a query. The slicer axis is defined in the WHERE clause of the SELECT statement in MDX.

Slicer Axis Syntax

To explicitly specify a slicer axis, you use the `<SELECT slicer axis clause>` in MDX, as described in the following syntax:

```
<SELECT slicer axis clause> ::= WHERE Set_Expression
```

In the slicer axis syntax shown, `Set_Expression` can take either a tuple expression, which is treated as a set for the purposes of evaluating the clause, or a set expression. If a set expression is specified, MDX will try to evaluate the set, aggregating the result cells in every tuple along the set. In other words, MDX will try to use the [Aggregate](#) function on the set, aggregating each measure by its associated aggregation function. Also, if the set expression cannot be expressed as a crossjoin of attribute hierarchy members, MDX treats cells that fall outside of the set expression for the slicer as null for evaluation purposes.

IMPORTANT

Unlike the WHERE clause in SQL, the WHERE clause of an MDX SELECT statement never directly filters what is returned on the Rows axis of a query. To filter what appears on the Rows or Columns axis of a query, you can use a variety of MDX functions, for example FILTER, NONEMPTY and TOPCOUNT.

Implicit Slicer Axis

If a member from a hierarchy within the cube is not explicitly included in a query axis, the default member from that hierarchy is implicitly included in the slicer axis. For more information about default members, see [Define a Default Member](#).

Examples

The following query does not include a WHERE clause, and returns the value of the Internet Sales Amount measure for all Calendar Years:

```
SELECT {[Measures].[Internet Sales Amount]} ON COLUMNS,  
[Date].[Calendar Year].MEMBERS ON ROWS  
FROM [Adventure Works]
```

Adding a WHERE clause, as follows:

```
SELECT {[Measures].[Internet Sales Amount]} ON COLUMNS,  
[Date].[Calendar Year].MEMBERS ON ROWS  
FROM [Adventure Works]  
WHERE([Customer].[Customer Geography].[Country].&[United States])
```

does not change what is returned on Rows or Columns in the query; it changes the values returned for each cell. In this example, the query is sliced so that it returns the value of Internet Sales Amount for all Calendar Years but only for Customers who live in the United States. Multiple members from different hierarchies can be added to the WHERE clause. The following query shows the value of Internet Sales Amount for all Calendar Years for Customers who live in the United States and who bought Products in the Category Bikes:

```
SELECT {[Measures].[Internet Sales Amount]} ON COLUMNS,  
[Date].[Calendar Year].MEMBERS ON ROWS  
FROM [Adventure Works]  
WHERE([Customer].[Customer Geography].[Country].&[United States], [Product].[Category].&[1])
```

If you want to use multiple members from the same hierarchy, you need to include a set in the WHERE clause. For example, the following query shows the value of Internet Sales Amount for all Calendar Years for Customers who bought Products in the Category Bikes and live in either the United States or the United Kingdom:

```
SELECT {[Measures].[Internet Sales Amount]} ON COLUMNS,  
[Date].[Calendar Year].MEMBERS ON ROWS  
FROM [Adventure Works]  
WHERE(  
{[Customer].[Customer Geography].[Country].&[United States]  
, [Customer].[Customer Geography].[Country].&[United Kingdom]}  
, [Product].[Category].&[1])
```

As mentioned above, using a set in the WHERE clause will implicitly aggregate values for all members in the set. In this case, the query shows aggregated values for the United States and the United Kingdom in each cell.

MDX Query and Slicer Axes - Using Axes in a Simple Example

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The simple example presented in this topic illustrates the basics of specifying and using query and slicer axes.

The Cube

A cube, named TestCube, has two simple dimensions named Route and Time. Each dimension has only one user hierarchy, named Route and Time respectively. Because the measures of the cube are part of the Measures dimension, this cube has three dimensions in all.

The Query

The query is to provide a matrix in which the Packages measure can be compared across routes and times.

In the following MDX query example, the Route and Time hierarchies are the query axes, and the Measures dimension is the slicer axis. The **Members** function indicates that MDX will use the members of the hierarchy or level to construct a set. The use of the **Members** function means that you do not have to explicitly state each member of a specific hierarchy or level in an MDX query.

```
SELECT
  { Route.nonground.Members } ON COLUMNS,
  { Time.[1st half].Members } ON ROWS
FROM TestCube
WHERE ( [Measures].[Packages] )
```

The Results

The result is a grid that identifies the value of the Packages measure at each intersection of the COLUMNS and ROWS axis dimensions. The following table shows how this grid would look.

	AIR	SEA
1st quarter	60	50
2nd quarter	45	45

[Specifying the Contents of a Slicer Axis \(MDX\)](#)

Establishing Cube Context in a Query (MDX)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Every MDX query runs within a specified cube context. This context defines the members that are evaluated by the expressions within the query.

In the SELECT statement, the FROM clause determines the cube context. This context can be the whole cube or just a subcube from that cube. Having specified cube context through the FROM clause, you can use additional functions to expand or restrict that context.

NOTE

The SCOPE and CALCULATE statements also let you manage cube context from within an MDX script. For more information, see [MDX Scripting Fundamentals \(Analysis Services\)](#).

FROM Clause Syntax

The following syntax describes the FROM clause:

```
<SELECT subcube clause> ::=  
    Cube_Identifier |  
    (SELECT [  
        * |  
        ( <SELECT query axis clause> [ , <SELECT query axis clause> ... ] ) ]  
    FROM <SELECT subcube clause> <SELECT slicer axis clause> )
```

In this syntax, notice that it is the `<SELECT subcube clause>` clause that describes the cube or subcube on which the SELECT statement is executed.

A simple example of a FROM clause would be one that runs against the entire Adventure Works sample cube. Such a FROM clause would have the following format:

```
FROM [Adventure Works]
```

For more information about the FROM clause in the MDX SELECT statement, see [SELECT Statement \(MDX\)](#).

Refining the Context

Although the FROM clause specifies the cube context as within a single cube, this does not have to limit you from working with data from more than one cube at a time.

You can use the MDX [LookupCube](#) function to retrieve data from cubes outside the cube context. Additionally, functions such as the [Filter](#) function, are available that allow temporary restriction of the context while evaluating the query.

See Also

[MDX Query Fundamentals \(Analysis Services\)](#)

Building Subcubes in MDX (MDX)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A subcube is a subset of a cube or representing a filtered view of the underlying data. By limiting the cube to a subcube, you can improve query performance.

To define a subcube, you use the **CREATE SUBCUBE** statement, as described in this topic.

CREATE SUBCUBE Syntax

Use the following syntax to create a subcube:

```
CREATE SUBCUBE Subcube_Identifier AS Subcube_Expression
```

The CREATE SUBCUBE syntax is fairly simple. The *Subcube_Identifier* parameter identifies the cube on which the subcube will be based. The *Subcube_Expression* parameter selects the part of the cube that will become the subcube.

After you create a subcube, that subcube becomes the context for all MDX queries until either the session closes or you run the **DROP SUBCUBE** statement.

What a Subcube Contains

Although the CREATE SUBCUBE statement is fairly simple to use, the statement itself does not explicitly show all the members that become part of a subcube. In defining a subcube, the following rules apply:

- If you include the **(All)** member of a hierarchy, you include every member of that hierarchy.
- If you include any member, you include that member's ascendants and descendants.
- If you include every member from a level, you include all members from the hierarchy. Members from other hierarchies will be excluded if those members do not exist with members from the level (for example, an unbalanced hierarchy such as a city that does not contain customers).
- A subcube will always contain every **(All)** member from the cube.

Additionally, aggregate values within the subcube are visually totaled. For example, a subcube contains `USA`, `WA`, and `OR`. The aggregate value for `USA` will be the sum of `{WA,OR}` because `WA` and `OR` are the only states defined by the subcube. All other states will be ignored.

Also, explicit references to cells outside the subcube return cell values that are evaluated in the context of the whole cube. For example, you create a subcube that is limited to the current year. You then use the **ParallelPeriod** function to compare the current year to the previous year. The difference in values will be returned even though the previous year's value lies outside the subcube.

Finally, if the original context is not overwritten, set functions evaluated in a subselect are evaluated in the context of the subselect. If the context is overwritten, set functions are evaluated in the context of the whole cube.

CREATE SUBCUBE Example

The following example creates a subcube that restricts the Budget cube to only accounts 4200 and 4300:

```
CREATE SUBCUBE Budget AS SELECT {[Account].[Account].&[4200], [Account].[Account].&[4300] } ON 0 FROM Budget
```

Having created a subcube for the session, any subsequent queries will be against the subcube, not the whole cube. For example, you run the following query. This query will only return members from accounts 4200 and 4300.

```
SELECT [Account].[Account].Members ON 0, Measures.Members ON 1 FROM Budget
```

[Establishing Cube Context in a Query \(MDX\)](#)
[MDX Query Fundamentals \(Analysis Services\)](#)

MDX Named Sets - Building Named Sets

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A set expression can be a lengthy and complex declaration, and therefore be difficult to follow or understand. Or, a set expression may be used so frequently that repeatedly defining the set becomes burdensome. To help make working with a lengthy, complex or commonly used expression easier, Multidimensional Expressions (MDX) lets you such an expression as a *named set*.

Basically, a named set is a set expression to which an alias has been assigned. A named set can incorporate any members or functions that can ordinarily be incorporated into a set. Because MDX treats the named set alias as a set expression, you can use that alias anywhere a set expression is accepted.

You can define a named set to have one of the following contexts:

- **Query-scoped** To create a named set that is defined as part of an MDX query, and therefore whose scope is limited to the query, you use the WITH keyword. You can then use the named set within an MDX SELECT statement. Using this approach, the named set created by using the WITH keyword can be changed without disturbing the SELECT statement.

For more information about how to use the WITH keyword to create named sets, see [Creating Query-Spaced Named Sets \(MDX\)](#).

- **Session-scoped** To create a named set whose scope is wider than the context of the query, that is, whose scope is the lifetime of the MDX session, you use the CREATE SET statement. A named set defined by using the CREATE SET statement is available to all MDX queries in that session. The CREATE SET statement makes sense, for example, in a client application that consistently reuses a set in a variety of queries.

For more information about how to use the CREATE SET statement to create named sets in a session, see [Creating Session-Spaced Named Sets \(MDX\)](#).

See Also

[SELECT Statement \(MDX\)](#)

[CREATE SET Statement \(MDX\)](#)

[MDX Query Fundamentals \(Analysis Services\)](#)

MDX Named Sets - Creating Query-Scoped Named Sets

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If a named set is only required for a single Multidimensional Expressions (MDX) query, you can define that named set by using the WITH keyword. A named set that is created by using the WITH keyword no longer exists after the query has finished running.

As discussed in this topic, the syntax of the WITH keyword is quite flexible, even accommodating the use of functions to define the named set.

NOTE

For more information about named sets, see [Building Named Sets in MDX \(MDX\)](#).

WITH Keyword Syntax

Use the following syntax to add the WITH keyword to a MDX SELECT statement:

```
[ WITH <SELECT WITH clause> [ , <SELECT WITH clause> ... ] ]
SELECT [ * | ( <SELECT query axis clause> [ , <SELECT query axis clause> ... ] ) ]
FROM <SELECT subcube clause>
[ <SELECT slicer axis clause> ]
[ <SELECT cell property list clause> ]

<SELECT WITH clause> ::=
( SET Set_Identifier AS 'Set_Expression')
```

In the syntax for the WITH keyword, the `Set_Identifier` parameter contains the alias for the named set. The `Set_Expression` parameter contains the set expression to which the named set alias refers.

WITH Keyword Example

The following MDX query examines the unit sales of the various Chardonnay and Chablis wines in **FoodMart 2000**, the sample database for Microsoft SQL Server 2000 Analysis Services. This query, although fairly simple in terms of the result set, is lengthy and unwieldy when you have to maintain such a query.

```

SELECT
  {[Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Good].[Good Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Pearl].[Pearl Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Portsmouth].[Portsmouth
Chardonnay], [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Top Measure].
[Top Measure Chardonnay], [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].
[Walrus].[Walrus Chardonnay], [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].
[Good].[Good Chablis Wine], [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].
[Pearl].[Pearl Chablis Wine], [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].
[Portsmouth].[Portsmouth Chablis Wine], [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and
Wine].[Wine].[Top Measure].[Top Measure Chablis Wine], [Product].[All Products].[Drink].[Alcoholic
Beverages].[Beer and Wine].[Wine].[Walrus].[Walrus Chablis Wine]} ON COLUMNS,
  {Measures.[Unit Sales]} ON ROWS
FROM Sales

```

To make the previous MDX query easier to maintain, you can create a named set for the query by using the WITH keyword. The following code shows how to use the WITH keyword to create a named set, `[ChardonnayChablis]`, and how the named set makes the SELECT statement shorter and easier to maintain.

```

WITH SET [ChardonnayChablis] AS
  {[Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Good].[Good Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Pearl].[Pearl Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Portsmouth].[Portsmouth
Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Top Measure].[Top Measure
Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Walrus].[Walrus Chardonnay],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Good].[Good Chablis Wine],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Pearl].[Pearl Chablis Wine],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Portsmouth].[Portsmouth
Chablis Wine],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Top Measure].[Top Measure
Chablis Wine],
  [Product].[All Products].[Drink].[Alcoholic Beverages].[Beer and Wine].[Wine].[Walrus].[Walrus Chablis
Wine]}

SELECT
  [ChardonnayChablis] ON COLUMNS,
  {Measures.[Unit Sales]} ON ROWS
FROM Sales

```

Using Functions Together with the WITH Keyword

Although you can explicitly define each member of a named set, this approach can produce a lengthy statement. To make the creation and maintenance of a named set easier, you can use MDX functions to define the members.

For example, the following MDX query example uses the `Filter`, `CurrentMember`, and `Name` MDX functions and the `InStr` VBA function to create the `[ChardonnayChablis]` named set. This version of the `[ChardonnayChablis]` named set is the same as the explicitly defined version shown previously in this topic.

```

WITH SET [ChardonnayChablis] AS
  'Filter([Product].Members, (InStr(1, [Product].CurrentMember.Name, "chardonnay") <> 0) OR (InStr(1,
[Product].CurrentMember.Name, "chablis") <> 0))'

SELECT
  [ChardonnayChablis] ON COLUMNS,
  {Measures.[Unit Sales]} ON ROWS
FROM Sales

```

[Creating Session-Scope Named Sets \(MDX\)](#)

MDX Named Sets - Creating Session-Scoped Named Sets

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

To create a named set that is available throughout a Multidimensional Expressions (MDX) session, you use the [CREATE SET](#) statement. A named set that is created by using the CREATE SET statement will not be removed until after the MDX session closes.

As discussed in this topic, the syntax of the WITH keyword is straightforward and easy to use.

NOTE

For more information about named sets, see [Building Named Sets in MDX \(MDX\)](#).

CREATE SET Syntax

Use the following syntax for the CREATE SET statement:

```
CREATE SESSION SET [CURRENTCUBE. | <cube name>.]<Set Identifier> AS <Set Expression>
```

In the CREATE SET syntax, the `<cube name>` parameter contains the name of the cube that contains the members for the named set. If the `<cube name>` parameter is not specified, the current cube will be used as the cube that contains the member for the named set. Also, the `<Set Identifier>` parameter contains the alias for the named set, and the `<Set Expression>` parameter contains the set expression to which the named set alias will refer.

CREATE SET Example

The following example uses the CREATE SET statement to create the `SetCities_2_3` named set based on the Store cube. The members of the `SetCities_2_3` named set are the stores within City 2 and City 3.

```
create Session set [Store].[SetCities_2_3] as
{[Data Stores].[ByLocation].[State].&[CA].&[City 02],
[Data Stores].[ByLocation].[State].&[NH].&[City 03]}
```

By using the CREATE SET statement to define the `SetCities_2_3` named set, this named set remains available for the length of the current MDX session. The following example is a valid query that would return City 2 and City 3 members, and that could be run anytime after you create the `SetCities_2_3` named set and before the session closes.

```
select SetCities_2_3 on 0 from [Store]
```

MDX Calculated Members - Building Calculated Members

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Multidimensional Expressions (MDX), a calculated member is a member that is resolved by calculating an MDX expression to return a value. This innocuous definition covers an incredible amount of ground. The ability to construct and use calculated members in an MDX query provides a great deal of manipulation capability for multidimensional data.

You can create calculated members at any point within a hierarchy. You can also create calculated members that depend not only on existing members in a cube, but also on other calculated members defined in the same MDX expression.

You can define a calculated member to have one of the following contexts:

- **Query-scoped** To create a calculated member that is defined as part of an MDX query, and therefore whose scope is limited to the query, you use the WITH keyword. You can then use the calculated member within an MDX SELECT statement. Using this approach, the calculated member created by using the WITH keyword can be changed without disturbing the SELECT statement.

For more information about how to use the WITH keyword to create calculated members, see [Creating Query-Scoped Calculated Members \(MDX\)](#).

- **Session-scoped** To create a calculated member whose scope is wider than the context of the query, that is, whose scope is the lifetime of the MDX session, you use the CREATE MEMBER statement. A calculated member defined by using the CREATE MEMBER statement is available to all MDX queries in that session. The CREATE MEMBER statement makes sense, for example, in a client application that consistently reuses the same set in a variety of queries.

For more information about how to use the CREATE MEMBER statement to create calculated members in a session, see [Creating Session-Scope Calculated Members \(MDX\)](#).

MDX Calculated Members - Query-Scoped Calculated Members

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If a calculated member is only required for a single Multidimensional Expressions (MDX) query, you can define that calculated member by using the WITH keyword. A calculated member that is created by using the WITH keyword no longer exists after the query has finished running.

As discussed in this topic, the syntax of the WITH keyword is quite flexible, even allowing a calculated member to be based on another calculated member.

NOTE

For more information about calculated members, see [Building Calculated Members in MDX \(MDX\)](#).

WITH Keyword Syntax

Use the following syntax to add the WITH keyword to an MDX SELECT statement:

```
[ WITH <SELECT WITH clause> [ , <SELECT WITH clause> ... ] ] SELECT [ * | ( <SELECT query axis clause> [ , <SELECT query axis clause> ... ] ) ]FROM <SELECT subcube clause> [ <SELECT slicer axis clause> ][ <SELECT cell property list clause> ]
<SELECT WITH clause> ::=

( [ CALCULATED ] MEMBER <CREATE MEMBER body clause> ) | <CREATE MEMBER body clause> ::= Member_Identifier AS
'MDX_Expression'

[ <CREATE MEMBER property clause> [ , <CREATE MEMBER property clause> ... ] ]
<CREATE MEMBER property clause> ::=
( MemberProperty_Identifier = Scalar_Expression )
```

In the syntax for the WITH keyword, the `Member_Identifier` value is the fully qualified name of the calculated member. This fully qualified name includes the dimension or level to which the calculated member is associated. The `MDX_Expression` value returns the value of the calculated member after the expression value has been evaluated. The values of intrinsic cell properties for a calculated member can be optionally specified by supplying the name of the cell property in the `MemberProperty_Identifier` value and the value of the cell property in the `Scalar_Expression` value.

WITH Keyword Examples

The following MDX query defines a calculated member, `[Measures].[Special Discount]`, calculating a special discount based on the original discount amount.

```

WITH
  MEMBER [Measures].[Special Discount] AS
    [Measures].[Discount Amount] * 1.5
SELECT
  [Measures].[Special Discount] ON COLUMNS,
  NON EMPTY [Product].[Product].MEMBERS ON Rows
FROM [Adventure Works]
WHERE [Product].[Category].[Bikes]

```

You can also create calculated members at any point within a hierarchy. For example, the following MDX query defines the `[BigSeller]` calculated member for a hypothetical Sales cube. This calculated member determines whether a specified store has at least 100.00 in unit sales for beer and wine. However, the query creates the `[BigSeller]` calculated member not as a child member of the `[Product]` dimension, but instead as a child member of the `[Beer and Wine]` member.

```

WITH
  MEMBER [Product].[Beer and Wine].[BigSeller] AS
    IIF([Product].[Beer and Wine] > 100, "Yes", "No")
SELECT
  {[Product].[BigSeller]} ON COLUMNS,
  Store.[Store Name].Members ON ROWS
FROM Sales

```

Calculated members do not have to depend only on existing members in a cube. Calculated member can also be based on other calculated members defined in the same MDX expression. For example, the following MDX query uses the value created in the first calculated member, `[Measures].[Special Discount]`, to generate the value of the second calculated member, `[Measures].[Special Discounted Amount]`.

```

WITH
  MEMBER [Measures].[Special Discount] AS
    [Measures].[Discount Percentage] * 1.5,
    FORMAT_STRING = 'Percent'

  MEMBER [Measures].[Special Discounted Amount] AS
    [Measures].[Reseller Average Unit Price] * [Measures].[Special Discount],
    FORMAT_STRING = 'Currency'

SELECT
  {[Measures].[Special Discount], [Measures].[Special Discounted Amount]} ON COLUMNS,
  NON EMPTY [Product].[Product].MEMBERS ON Rows
FROM [Adventure Works]
WHERE [Product].[Category].[Bikes]

```

[Creating Session-Scoped Calculated Members \(MDX\)](#)

MDX Calculated Members - Session-Scoped Calculated Members

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

To create a calculated member that is available throughout a Multidimensional Expressions (MDX) session, you use the [CREATE MEMBER](#) statement. A calculated member that is created by using the CREATE MEMBER statement will not be removed until after the MDX session closes.

As discussed in this topic, the syntax of the CREATE MEMBER statement is straightforward and easy to use.

NOTE

For more information about calculated members, see [Building Calculated Members in MDX \(MDX\)](#).

CREATE MEMBER Syntax

Use the following syntax to add the CREATE MEMBER statement to the MDX statement:

```
CREATE [SESSION] MEMBER [<cube-name>.]<fully-qualified-member-name> AS <expression> [,<property-definition-list>]
<cube name> ::= CURRENTCUBE | <Cube Name>
<property-definition-list> ::= <property-definition>
    | <property-definition>, <property-definition-list>
<property-definition> ::= <property-identifier> = <property-value>
<property-identifier> ::= VISIBLE | SOLVEORDER | SOLVE_ORDER | FORMAT_STRING | NON_EMPTY_BEHAVIOR <ole db
member properties>
```

In the syntax for the CREATE MEMBER statement, the `<fully-qualified-member-name>` value is the fully qualified name of the calculated member. The fully qualified name includes the dimension or level to which the calculated member is associated. The `<expression>` value returns the value of the calculated member after the expression value has been evaluated.

CREATE MEMBER Example

The following example uses the CREATE MEMBER statement to create the `LastFourStores` calculated member. This calculated member returns the sum of units sold for the last four stores, and will be available throughout the whole session of the cube.

```
Create Session Member [Store].[Measures].LastFourStores as
sum(([Stores].[ByLocation].Lag(3) :
[Stores].[ByLocation].NextMember), [Measures].[Units Sold])
```

MDX Cell Calculations - Build Cell Calculations

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Multidimensional Expressions (MDX) provides you with a number of tools for generating calculated values, such as calculated members, custom rollups, and custom members. However, using these features to affect a specific set of cells, or a single cell for that matter, would be difficult.

To generate calculated values specifically for cells, you need to use the calculated cells feature in MDX. Calculated cells let you define a specific slice of cells, called a *calculation subcube*, and apply a formula to each and every cell within the calculation subcube, subject to an optional condition that can be applied to each cell.

Calculated cells also offer complex functionality, such as goal-seeking formulas, as used in KPIs, or speculative analysis formulas. This level of functionality comes from the pass order feature in Microsoft SQL Server Analysis Services that allows recursive passes to be made with calculated cells, with calculation formulas applied at specific passes in the pass order. For more information on pass order, see [Understanding Pass Order and Solve Order \(MDX\)](#).

In terms of creation scope, calculated cells are similar to both named sets and calculated members in that calculated cells can be temporarily created for the lifetime of either a session or a single query, or made globally available as part of a cube:

- **Query-scoped** To create a calculated cell that is defined as part of an MDX query, and therefore whose scope is limited to the query, you use the **WITH** keyword. You can then use the calculated cell within an MDX SELECT statement. Using this approach, the calculated cell created by using the **WITH** keyword can be changed without disturbing the SELECT statement.

For more information about how to use the **WITH** keyword to create calculated members, see [Creating Query-Scope Cell Calculations \(MDX\)](#).

- **Session-scoped** To create a calculated member whose scope is wider than the context of the query, that is, whose scope is the lifetime of the MDX session, you use either the CREATE CELL CALCULATION or ALTER CUBE statement.

For more information about how to use either the CREATE CELL CALCULATION or ALTER CUBE statement to create calculated cells in a session, see [Creating Session-Scope Calculated Cells](#)

MDX Cell Calculations - Query-Scoped Cell Calculations

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You use the **WITH** keyword in Multidimensional Expressions (MDX) to describe calculated cells within the context of a query. The **WITH** keyword has the following syntax:

```
WITH CELL CALCULATION Cube_Name.CellCalc_Identifier String_Expression
```

The `CellCalc_Identifier` value is the name of the calculated cells. The `String_Expression` value contains a list of orthogonal, single-dimensional MDX set expressions. Each of these set expressions must resolve to one of the categories listed in the following table.

CATEGORY	DESCRIPTION
Empty set	An MDX set expression that resolves into an empty set. In this case, the scope of the calculated cell is the whole cube.
Single member set	An MDX set expression that resolves into a single member.
Set of level members	An MDX set expression that resolves into the members of a single level. An example of such a set expression is the <code>Level_Expression.Members</code> MDX function. To include calculated members, use the <code>Level_Expression.AllMembers</code> MDX function. For more information, see AllMembers (MDX) .
Set of descendants	An MDX set expression that resolves into the descendants of a specified member. An example of such a set expression is the <code>Descendants(Member_Expression, Level_Expression, Desc_Flag)</code> MDX function. For more information, see Descendants (MDX) .

If the `String_Expression` argument does not describe a dimension, MDX assumes that all members are included for the purposes of constructing the calculation subcube. Therefore, if the `String_Expression` argument is NULL, the calculated cells definition applies to the whole cube.

The `MDX_Expression` argument contains an MDX expression that evaluates to a cell value for all the cells defined in the `String_Expression` argument.

Additional Considerations

MDX processes the calculation condition, specified by the **CONDITION** property, only once. This single processing provides increased performance for the evaluation of multiple calculated cells definitions, especially with overlapping calculated cells across cube passes.

When this single processing occurs depends on the creation scope of the calculated cells definition:

- If created at global scope, as part of a cube, MDX process the calculation condition when the cube is processed. If cells are modified in the cube in any way, and the cells are included in the calculation subcube

of a calculated cells definition, the calculation condition may not be accurate until the cube is reprocessed. Cell modification can occur from writebacks, for example. The calculation condition is reprocessed when the cube is reprocessed.

- If created at session scope, MDX processes the calculation condition when the statement is issued during the session. As with calculated cells definitions created globally, if the cells are modified, the calculation condition may not be accurate for the calculated cells definition.
- If created at query scope, MDX processes the calculation condition when the query runs. The cell modification issue applies here, also, although data latency issues are minimal because of the low processing time of MDX query execution.

On the other hand, MDX processes the calculation formula whenever an MDX query is issued against the cube involving cells included in the calculated cells definition. This processing occurs regardless of the creation scope.

[CREATE CELL CALCULATION Statement \(MDX\)](#)

MDX Cell Calculations - Session-Scoped Calculated Cells

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

IMPORTANT

This syntax has been deprecated. You should use MDX assignments instead. For more information on assignments, see [The Basic MDX Script \(MDX\)](#).

To create calculated cells that are available to all queries in the same session, you can use either the [CREATE CELL CALCULATION](#) statement or the [ALTER CUBE](#) statement. Both statements have the same result.

CREATE CELL CALCULATION Syntax

IMPORTANT

This syntax has been deprecated. You should use MDX assignments instead. For more information on assignments, see [The Basic MDX Script \(MDX\)](#).

Use the following syntax to use the CREATE CELL CALCULATION statement to define a session-scoped calculated cell:

```
CREATE CELL CALCULATION Cube_Expression.<CREATE CELL CALCULATION body clause>

<CREATE CELL CALCULATION body clause> ::=CellCalc_Identifier FOR String_Expression AS 'MDX_Expression'
[ <CREATE CELL CALCULATION property clause> [ , <CREATE CELL CALCULATION property clause> ... ] ]

<CREATE CELL CALCULATION property clause> ::=
( CONDITION = 'Logical_Expression' ) |
( DISABLED = { TRUE | FALSE } ) |
( DESCRIPTION =String_Expression ) |
( CALCULATION_PASS_NUMBER = Integer_Expression ) |
( CALCULATION_PASS_DEPTH = Integer_Expression ) |
( SOLVE_ORDER = Integer_Expression ) |
( FORMAT_STRING = String_Expression ) |
( CellProperty_Identifier = Scalar_Expression )
```

ALTER CUBE Syntax

IMPORTANT

This syntax has been deprecated. You should use MDX assignments instead. For more information on assignments, see [The Basic MDX Script \(MDX\)](#).

Use the following syntax to use the ALTER CUBE statement to define a session-scoped calculated cell:

```

ALTER CUBE Cube_Identifier CREATE CELL CALCULATION
FOR String_Expression AS 'MDX_Expression'
[ <CREATE CELL CALCULATION property clause> [ , <CREATE CELL CALCULATION property clause> ... ] ]

<CREATE CELL CALCULATION property clause> ::=
( CONDITION = 'Logical_Expression' ) |
( DISABLED = { TRUE | FALSE } ) |
( DESCRIPTION =String_Expression ) |
( CALCULATION_PASS_NUMBER = Integer_Expression ) |
( CALCULATION_PASS_DEPTH = Integer_Expression ) |
( SOLVE_ORDER = Integer_Expression ) |
( FORMAT_STRING = String_Expression ) |
( CellProperty_Identifier = Scalar_Expression )

```

The `String_Expression` value contains a list of orthogonal, single-dimensional MDX set expressions, each of which must resolve to one of the categories of sets that are listed in the following table.

CATEGORY	DESCRIPTION
Empty set	An MDX set expression that resolves into an empty set. In this case, the scope of the calculated cell is the whole cube.
Single member set	An MDX set expression that resolves into a single member.
Set of level members	An MDX set expression that resolves into the members of a single level. An example of this is the Level_Expression.Members MDX function. To include calculated members, use the Level_Expression.AllMembers MDX function. For more information, see AllMembers (MDX) .
Set of descendants	An MDX set expression that resolves into the descendants of a specified member. An example of this is the Descendants(Member_Expression, Level_Expression, Desc_Flag) MDX function. For more information, see Descendants (MDX) .

See Also

[Building Cell Calculations in MDX \(MDX\)](#)

MDX Building Measures

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Multidimensional Expressions (MDX), a measure is a named DAX expression that is resolved by calculating the expression to return a value in a Tabular Model. This innocuous definition covers an incredible amount of ground. The ability to construct and use measures in an MDX query provides a great deal of manipulation capability for tabular data.

WARNING

Measures can only be defined in tabular models; if your database is set in multidimensional mode, creating a measure will generate an error

To create a measure that is defined as part of an MDX query, and therefore whose scope is limited to the query, you use the WITH keyword. You can then use the measure within an MDX SELECT statement. Using this approach, the calculated member created by using the WITH keyword can be changed without disturbing the SELECT statement. However, in MDX you reference the measure in a different way than when in DAX expressions; to reference the measure you name it as a member of the [Measures] dimension, see the following MDX example:

```
with measure 'Sales Territory'[Total Sales Amount] = SUM('Internet Sales'[Sales Amount]) + SUM('Reseller Sales'[Sales Amount])
select measures.[Total Sales Amount] on columns
    ,NON EMPTY [Date].[Calendar Year].children on rows
from [Model]
```

It will return the following data when executed:

	TOTAL SALES AMOUNT
2001	11331808.96
2002	30674773.18
2003	41993729.72
2004	25808962.34

[CREATE MEMBER Statement \(MDX\)](#)

[MDX Function Reference \(MDX\)](#)

[SELECT Statement \(MDX\)](#)

MDX Member Properties

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Member properties cover the basic information about each member in each tuple. This basic information includes the member name, parent level, the number of children, and so on. Member properties are available for all members at a given level. In terms of organization, member properties are treated as dimensionally organized data, stored on a single dimension.

NOTE

In MicrosoftSQL Server, member properties are known as attribute relationships. For more information, see [Attribute Relationships](#).

Member properties are either *intrinsic* or *custom*:

Intrinsic member properties

All members support intrinsic member properties, such as the formatted value of a member, while dimensions and levels supply additional intrinsic dimension and level member properties, such as the ID of a member.

For more information, see [Intrinsic Member Properties \(MDX\)](#).

User-defined member properties

Members often have additional properties associated with them. For example, the Products level may offer the SKU, SRP, Weight, and Volume properties for each product. These properties are not members, but contain additional information about members at the Products level.

For more information, see [User-Defined Member Properties \(MDX\)](#).

Both intrinsic and user-defined member properties can be retrieved through the use of the **PROPERTIES** keyword or the **Properties** function.

Using the PROPERTIES Keyword

The **PROPERTIES** keyword specifies the member properties that are to be used for a given axis dimension. The **PROPERTIES** keyword is buried within the `<axis specification>` clause of the MDX **SELECT** statement:

```
SELECT [<axis_specification>
        [, <axis_specification>...]]
       FROM [<cube_specification>]
      [WHERE [<slicer_specification>]]
```

The `<axis_specification>` clause includes an optional `<dim_props>` clause, as shown in the following syntax:

```
<axis_specification> ::= <set> [<dim_props>] ON <axis_name>
```

NOTE

For more information about the `<set>` and `<axis_name>` values, see [Specifying the Contents of a Query Axis \(MDX\)](#).

The `<dim_props>` clause lets you query dimension, level, and member properties using the **PROPERTIES** keyword. The following syntax shows the formatting of the `<dim_props>` clause:

```
<dim_props> ::= [DIMENSION] PROPERTIES <property> [,<property>...]
```

The breakdown of the `<property>` syntax varies depending on the property that you are querying:

- Context sensitive intrinsic member properties must be preceded with the name of the dimension or level. However, non-context sensitive intrinsic member properties cannot be qualified by the dimension or level name. For more information about how to use the **PROPERTIES** keyword with intrinsic member properties, see [Intrinsic Member Properties \(MDX\)](#).
- User-defined member properties should be preceded by the name of the level in which they reside. For more information about how to use the **PROPERTIES** keyword with user-defined member properties, see [User-Defined Member Properties \(MDX\)](#).

See Also

[Creating and Using Property Values \(MDX\)](#)

MDX Member Properties – Intrinsic Member Properties

7/16/2019 • 9 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services exposes intrinsic properties on dimension members that you can include in a query to return additional data or metadata for use in a custom application, or to assist in model investigation or construction. If you are using the SQL Server client tools, you can view intrinsic properties in SQL Server Management Studio (SSMS).

Intrinsic properties include **ID**, **KEY**, **KEYx**, and **NAME**, which are properties exposed by every member, at any level. You can also return positional information, such as **LEVEL_NUMBER** or **PARENT_UNIQUE_NAME**, among others.

Depending on how you construct the query, and on the client application you are using to execute queries, member properties may or may not be visible in the result set. If you are using SQL Server Management Studio to test or run queries, you can double-click a member in the result set to open the Member Properties dialog box, showing the values for each intrinsic member property.

For an introduction to using and viewing dimension member properties, see [Viewing SSAS Member Properties within an MDX Query Window in SSMS](#).

NOTE

As a provider that is compliant with the OLAP section of the OLE DB specification dated March 1999 (2.6), Microsoft SQL Server Analysis Services supports the intrinsic member properties listed in this topic.

Providers other than SQL Server Analysis Services may support additional intrinsic member properties. For more information about the intrinsic member properties supported by other providers, refer to the documentation that comes with those providers.

Types of Member Properties

The intrinsic member properties supported by SQL Server Analysis Services are of two types:

Context sensitive member properties

These member properties must be used in the context of a specific hierarchy or level, and supply values for each member of the specified dimension or level.

Notice how the following example includes the path for the **KEY** property:

```
MEMBER [Measures].[Parent Member Key] AS [Product].[Product Categories].CurrentMember.Parent.PROPERTIES("KEY") .
```

Non-context sensitive member properties

These member properties cannot be used in the context of a specific dimension or level, and return values for all members on an axis.

Context-insensitive properties standalone and do not include path information. Notice how there is no dimension or level specified for **PARENT_UNIQUE_NAME** in the following example:

```
DIMENSION PROPERTIES PARENT_UNIQUE_NAME ON COLUMNS
```

Regardless of whether the intrinsic member property is context sensitive or not, the following usage rules apply:

- You can specify only those intrinsic member properties that relate to dimension members that are projected on the axis.
- You can mix requests for context sensitive member properties in the same query with non-context sensitive intrinsic member properties.
- You use the **PROPERTIES** keyword to query for the properties.

The following sections describe both the various context sensitive and non-context sensitive intrinsic member properties available in SQL Server Analysis Services, and how to use the **PROPERTIES** keyword with each type of property.

Context Sensitive Member Properties

All dimension members and level members support a list of intrinsic member properties that are context sensitive. The following table lists these context-sensitive properties.

PROPERTY	DESCRIPTION
ID	The internally maintained ID for the member.
Key	The value of the member key in the original data type. MEMBER_KEY is for backward-compatibility. MEMBER_KEY has the same value as KEY0 for non-composite keys, and MEMBER_KEY property is null for composite keys.
KEYx	<p>The key for the member, where x is the zero-based ordinal of the key. KEY0 is available for composite and non-composite keys, but primarily used for composite keys.</p> <p>For composite keys, KEY0, KEY1, KEY2, and so on, collectively form the composite key. You can use each one independently in a query to return that portion of the composite key. For example, specifying KEY0 returns the first part of the composite key, specifying KEY1 returns the next part of the composite key, and so on.</p> <p>If the key is non-composite, then KEY0 is equivalent to Key.</p> <p>Note that KEYx can be used in context as well as without context. For this reason, it appears in both lists.</p> <p>For an example of how to use this member property, see A Simple MDX Tidbit: Key0, Key1, Key2.</p>
Name	The name of the member.

PROPERTIES Syntax for Context Sensitive Properties

You use these member properties in the context of a specific dimension or level, and supply values for each member of the specified dimension or level.

For dimension member properties, you precede the name of the property with the name of the dimension to which the property applies. The following example shows the appropriate syntax:

```
DIMENSION PROPERTIES Dimension.Property_name
```

For a level member property, you can precede the name of the property with just the level name or, for additional specification, both the dimension and level name. The following example shows the appropriate syntax:

```
DIMENSION PROPERTIES [Dimension.]Level.Property_name
```

To illustrate, you would like to return all the names of each referenced member in the `[Sales]` dimension. To return these names, you would use the following statement in a Multidimensional Expressions (MDX) query:

```
DIMENSION PROPERTIES [Sales].Name
```

Non-Context Sensitive Member Properties

All members support a list of intrinsic member properties that are the same regardless of context. These properties provide additional information that can be used by applications to enhance the user's experience.

The following table lists the non-context sensitive intrinsic properties supported by SQL Server Analysis Services.

NOTE

Columns in the **MEMBERS** schema rowset support the intrinsic member properties listed in the following table. For more information about the **MEMBERS** schema rowset, see [MDSCHHEMA_MEMBERS Rowset](#).

PROPERTY	DESCRIPTION
CATALOG_NAME	The name of the cube to which this member belongs.
CHILDREN_CARDINALITY	The number of children that the member has. This can be an estimate, so you should not rely on this to be the exact count. Providers should return the best estimate possible.
CUSTOM_ROLLUP	The custom member expression.
CUSTOM_ROLLUP_PROPERTIES	The custom member properties.
DESCRIPTION	A human-readable description of the member.
DIMENSION_UNIQUE_NAME	The unique name of the dimension to which this member belongs. For providers that generate unique names by qualification, each component of this name is delimited.
HIERARCHY_UNIQUE_NAME	The unique name of the hierarchy. If the member belongs to more than one hierarchy, there is one row for each hierarchy to which the member belongs. For providers that generate unique names by qualification, each component of this name is delimited.
IS_DATAMEMBER	A Boolean that indicates whether the member is a data member.
IS_PLACEHOLDERMEMBER	A Boolean that indicates whether the member is a placeholder.

PROPERTY	DESCRIPTION
KEYx	<p>The key for the member, where x is the zero-based ordinal of the key. KEY0 is available for composite and non-composite keys.</p> <p>If the key is non-composite, then KEY0 is equivalent to Key.</p> <p>For composite keys, KEY0, KEY1, KEY2, and so on, collectively form the composite key. You can reference each one independently in a query to return that portion of the composite key. For example, specifying KEY0 returns the first part of the composite key, specifying KEY1 returns the next part of the composite key, and so on.</p> <p>Note that KEYx can be used in context as well as without context. For this reason, it appears in both lists.</p> <p>For an example of how to use this member property, see A Simple MDX Tidbit: Key0, Key1, Key2.</p>
LCID x	<p>The translation of the member caption in the locale ID hexadecimal value, where x is the locale ID decimal value (for example, LCID1009 as English-Canada). This is only available if the translation has the caption column bound to the data source.</p>
LEVEL_NUMBER	<p>The distance of the member from the root of the hierarchy. The root level is zero.</p>
LEVEL_UNIQUE_NAME	<p>The unique name of the level to which the member belongs. For providers that generate unique names by qualification, each component of this name is delimited.</p>
MEMBER_CAPTION	<p>A label or caption associated with the member. The caption is primarily for display purposes. If a caption does not exist, the query returns MEMBER_NAME.</p>
MEMBER_KEY	<p>The value of the member key in the original data type. MEMBER_KEY is for backward-compatibility. MEMBER_KEY has the same value as KEY0 for non-composite keys, and MEMBER_KEY property is null for composite keys.</p>
MEMBER_NAME	<p>The name of the member.</p>

PROPERTY	DESCRIPTION
MEMBER_TYPE	<p>The type of the member. This property can have one of the following values:</p> <p>MDMEMBER_TYPE_REGULAR</p> <p>MDMEMBER_TYPE_ALL</p> <p>MDMEMBER_TYPE_FORMULA</p> <p>MDMEMBER_TYPE_MEASURE</p> <p>MDMEMBER_TYPE_UNKNOWN</p> <p>Note: MDMEMBER_TYPE_FORMULA takes precedence over MDMEMBER_TYPE_MEASURE. Therefore, if there is a formula (calculated) member on the Measures dimension, the MEMBER_TYPE property for the calculated member is MDMEMBER_TYPE_FORMULA.</p>
MEMBER_UNIQUE_NAME	The unique name of the member. For providers that generate unique names by qualification, each component of this name is delimited.
MEMBER_VALUE	The value of the member in the original type.
PARENT_COUNT	The number of parents that this member has.
PARENT_LEVEL	The distance of the member's parent from the root level of the hierarchy. The root level is zero.
PARENT_UNIQUE_NAME	The unique name of the member's parent. NULL is returned for any members at the root level. For providers that generate unique names by qualification, each component of this name is delimited.
SKIPPED_LEVELS	The number of skipped levels for the member.
UNARY_OPERATOR	The unary operator for the member.
UNIQUE_NAME	The fully-qualified name of the member, in this format: [dimension].[level].[key6.]

PROPERTIES Syntax for Non-Context Sensitive Properties

Use the following syntax to specify an intrinsic, non-context sensitive member property using the **PROPERTIES** keyword:

```
DIMENSION PROPERTIES Property
```

Notice that this syntax does not allow the property to be qualified by a dimension or level. The property cannot be qualified because an intrinsic member property that is not context sensitive applies to all members of an axis.

For example, an MDX statement that specifies the **DESCRIPTION** intrinsic member property would have the following syntax:

```
DIMENSION PROPERTIES DESCRIPTION
```

This statement returns the description of each member in the axis dimension. If you tried to qualify the property with a dimension or level, as in *Dimension* .DESCRIPTION or *Level* .DESCRIPTION, the statement would not validate.

Example

The following examples show MDX queries that return intrinsic properties.

Example 1: Use context-sensitive intrinsic properties in query

The following example returns parent ID, key, and name for each product category. Notice how the properties are exposed as measures. This lets you view the properties in a cellset when you run the query, rather than the Member Properties dialog in SSMS. You might run a query like this to retrieve member metadata from a cube that is already deployed.

```
WITH
MEMBER [Measures].[Parent Member ID] AS
    [Product].[Product Categories].CurrentMember.Parent.PROPERTIES("ID")
MEMBER [Measures].[Parent Member Key] AS
    [Product].[Product Categories].CurrentMember.Parent.PROPERTIES("KEY")
MEMBER [Measures].[Parent Member Name] AS
    [Product].[Product Categories].CurrentMember.Parent.PROPERTIES("Name")
SELECT
{[Measures].[Parent Member ID], [Measures].[Parent Member Key], [Measures].[Parent Member Name]} on COLUMNS,
[Product].[Product Categories].AllMembers on ROWS
FROM [Adventure Works]
```

Example 2: Non-context-sensitive intrinsic properties

The following example is the full list of non-context-sensitive intrinsic properties. After running the query in SSMS, click individual members to view properties in the Member Properties dialog box.

```
SELECT [Measures].[Sales Amount Quota] on COLUMNS,
[Employee].[Employees].members
DIMENSION PROPERTIES
CATALOG_NAME ,
CHILDREN_CARDINALITY ,
CUSTOM_ROLLUP ,
CUSTOM_ROLLUP_PROPERTIES ,
DESCRIPTION ,
DIMENSION_UNIQUE_NAME ,
HIERARCHY_UNIQUE_NAME ,
IS_DATAMEMBER ,
IS_PLACEHOLDERMEMBER ,
KEY0 ,
LCID ,
LEVEL_NUMBER ,
LEVEL_UNIQUE_NAME ,
MEMBER_CAPTION ,
MEMBER_KEY ,
MEMBER_NAME ,
MEMBER_TYPE ,
MEMBER_UNIQUE_NAME ,
MEMBER_VALUE ,
PARENT_COUNT ,
PARENT_LEVEL ,
PARENT_UNIQUE_NAME ,
SKIPPED_LEVELS ,
UNARY_OPERATOR ,
UNIQUE_NAME
ON ROWS
FROM [Adventure Works]
WHERE [Employee].[Employee Department].[Department].&[Sales]
```

Example 3: Return member properties as data in a result set

The following example returns the translated caption for the product category member in the Product dimension in the Adventure Works cube for specified locales.

```
WITH
MEMBER Measures.CategoryCaption AS Product.Category.CurrentMember.MEMBER_CAPTION
MEMBER Measures.SpanishCategoryCaption AS Product.Category.CurrentMember.Properties("LCID3082")
MEMBER Measures.FrenchCategoryCaption AS Product.Category.CurrentMember.Properties("LCID1036")
SELECT
{ Measures.CategoryCaption, Measures.SpanishCategoryCaption, Measures.FrenchCategoryCaption } ON 0
,[Product].[Category].MEMBERS ON 1
FROM [Adventure Works]
```

MDX Member Properties – User-Defined Member Properties

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

User-defined member properties can be added to a specific named level in a dimension as attribute relationships. User-defined member properties cannot be added to the **(All)** level of a hierarchy, or to the hierarchy itself.

Creating User-Defined Member Properties

User-defined member properties can be added to server-based dimensions or cubes either through the user interface or programmatically:

- To add user-defined member properties through the user interface, you use Dimension Designer in Visual Studio with Analysis Services projects. For more information, see [Define Attribute Relationships](#).
- To add user-defined member properties programmatically, your application can use either Analysis Manager Objects (AMO) or a combination of XML for Analysis (XMLA) and Analysis Services Scripting Language (ASSL). For more information, see [Attribute Relationships](#).

Retrieving User-Defined Member Properties

You can retrieve user-defined member properties using either the **PROPERTIES** keyword or the [Properties](#) function.

Using the PROPERTIES Keyword to Retrieve User-Defined Member Properties

The syntax that retrieves user-defined member properties is similar to that used to retrieve intrinsic level member properties, as shown in the following syntax:

```
DIMENSION PROPERTIES [Dimension.]Level.<Custom_Member_Property>
```

The **PROPERTIES** keyword appears after the set expression of the axis specification. For example, the following MDX query the **PROPERTIES** keyword retrieves the `List Price` and `Dealer Price` user-defined member properties and appears after the set expression that identifies the products sold in January:

```
SELECT
    CROSSJOIN([Ship Date].[Calendar].[Calendar Year].Members,
              [Measures].[Sales Amount]) ON COLUMNS,
    NON EMPTY Product.Product.MEMBERS
DIMENSION PROPERTIES
    Product.Product.[List Price],
    Product.Product.[Dealer Price]  ON ROWS
FROM [Adventure Works]
WHERE ([Date].[Month of Year].[January])
```

Using the Properties Function to Retrieve User-Defined Member Properties

Alternatively, you can access custom member properties with the **Properties** function. For example, the following MDX query uses the **WITH** keyword to create a calculated member consisting of the `List Price` member property:

```
WITH
  MEMBER [Measures].[Product List Price] AS
    [Product].[Product].CurrentMember.Properties("List Price")
SELECT
  [Measures].[Product List Price] on COLUMNS,
  [Product].[Product].MEMBERS  ON Rows
FROM [Adventure Works]
```

For more information about building calculated members, see [Building Calculated Members in MDX \(MDX\)](#).

MDX Cell Properties - Using Cell Properties

7/16/2019 • 4 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Cell properties in Multidimensional Expressions (MDX) contain information about the content and format of cells in a multidimensional data source, such as a cube.

MDX supports the **CELL PROPERTIES** keyword in an MDX SELECT statement to retrieve intrinsic cell properties. Intrinsic cell properties are most commonly used to assist in the visual presentation of cell data.

CELL PROPERTIES Keyword Syntax

Use the following syntax for the **CELL PROPERTIES** keyword of the MDX **SELECT** statement:

```
SELECT [<axis_specification>
        [, <axis_specification>...]]
      FROM [<cube_specification>]
      [WHERE [<slicer_specification>]]
      [<cell_props>]
```

The following syntax shows the format of the `<cell_props>` value and how this value uses the **CELL PROPERTIES** keyword along with one or more intrinsic cell properties:

```
<cell_props> ::= CELL PROPERTIES <property> [, <property>...]
```

Supported Intrinsic Cell Properties

The following table lists the supported intrinsic cell properties that are used in the `<property>` value.

PROPERTY	DESCRIPTION
----------	-------------

PROPERTY	DESCRIPTION
ACTION_TYPE	<p>A bitmask that indicates which types of actions exist on the cell. This property can have one of the following values:</p> <ul style="list-style-type: none"> <li data-bbox="817 265 1060 294">MDACTION_TYPE_URL <li data-bbox="817 327 1080 357">MDACTION_TYPE_HTML <li data-bbox="817 390 1144 420">MDACTION_TYPE_STATEMENT <li data-bbox="817 453 1117 482">MDACTION_TYPE_DATASET <li data-bbox="817 516 1107 545">MDACTION_TYPE_ROWSET <li data-bbox="817 579 1187 608">MDACTION_TYPE_COMMANDLINE <li data-bbox="817 642 1164 673">MDACTION_TYPE_PROPRIETARY <li data-bbox="817 707 1096 736">MDACTION_TYPE_REPORT <li data-bbox="817 770 1187 799">MDACTION_TYPE_DRILLTHROUGH <p>Note: Drillthrough actions are not included for queries containing a set in the where clause.</p>
BACK_COLOR	<p>The background color for displaying the VALUE or FORMATTED_VALUE property. For more information, see FORE_COLOR and BACK_COLOR Contents (MDX).</p>
CELL_ORDINAL	<p>The ordinal number of the cell in the dataset.</p>
FONT_FLAGS	<p>The bitmask detailing effects on the font. The value is the result of a bitwise OR operation of one or more of the following constants:</p> <ul style="list-style-type: none"> <li data-bbox="817 1352 985 1381">MDFF_BOLD = 1 <li data-bbox="817 1414 996 1444">MDFF_ITALIC = 2 <li data-bbox="817 1477 1053 1507">MDFF_UNDERLINE = 4 <li data-bbox="817 1540 1049 1569">MDFF_STRIKEOUT = 8 <p>For example, the value 5 represents the combination of bold (MDFF_BOLD) and underline (MDFF_UNDERLINE) font effects.</p>
FONT_NAME	<p>The font to be used to display the VALUE or FORMATTED_VALUE property.</p>
FONT_SIZE	<p>Font size to be used to display the VALUE or FORMATTED_VALUE property.</p>
FORE_COLOR	<p>The foreground color for displaying the VALUE or FORMATTED_VALUE property. For more information, see FORE_COLOR and BACK_COLOR Contents (MDX).</p>

PROPERTY	DESCRIPTION
FORMAT	Same as FORMAT_STRING .
FORMAT_STRING	The format string used to create the FORMATTED_VALUE property value. For more information, see FORMAT_STRING Contents (MDX) .
FORMATTED_VALUE	The character string that represents a formatted display of the VALUE property.
LANGUAGE	The locale where the FORMAT_STRING will be applied. LANGUAGE is usually used for currency conversion.
UPDATEABLE	A value that indicates whether the cell can be updated. This property can have one of the following values:
	MD_MASK_ENABLED (0x00000000) The cell can be updated.
	MD_MASK_NOT_ENABLED (0x10000000) The cell cannot be updated.
	CELL_UPDATE_ENABLED (0x00000001) Cell can be updated in the cellset.
	CELL_UPDATE_ENABLED_WITH_UPDATE (0x00000002) The cell can be updated with an update statement. The update may fail if a leaf cell is updated that is not write-enabled.
	CELL_UPDATE_NOT_ENABLED_FORMULA (0x10000001) The cell cannot be updated because the cell has a calculated member among its coordinates; the cell was retrieved with a set in the where clause. A cell can be updated even though a formula affects, or a calculated cell is on, the value of a cell (is somewhere along the aggregation path). In this scenario, the final value of the cell may not be the updated value, because the calculation will affect the result
	CELL_UPDATE_NOT_ENABLED_NONSUM_MEASURE (0x10000002) The cell cannot be updated because non-sum measures (count, min, max, distinct count, semi-additive) can not be updated.
	CELL_UPDATE_NOT_ENABLED_NACELL_VIRTUALCUBE (0x10000003) The cell cannot be updated because the cell does not exist as it is at the intersection of a measure and a dimension member unrelated to the measure's measure group.
	CELL_UPDATE_NOT_ENABLED_SECURE (0x10000005) The cell cannot be updated because the cell is secured.
	CELL_UPDATE_NOT_ENABLED_CALCLEVEL (0x10000006) Reserved for future use.

PROPERTY	DESCRIPTION
	CELL_UPDATE_NOT_ENABLED_CANNOTUPDATE (0x10000007) The cell cannot be updated because of internal reasons.
	CELL_UPDATE_NOT_ENABLED_INVALIDDIMENSIONTYPE (0x10000009) The cell cannot be updated because update is not supported in mining model, indirect, or data mining dimensions.
VALUE	The unformatted value of the cell.

Only the **CELL_ORDINAL**, **FORMATTED_VALUE**, and **VALUE** cell properties are required. All cell properties, intrinsic or provider-specific, are defined in the **PROPERTIES** schema rowset, including their data types and provider support. For more information about the **PROPERTIES** schema rowset, see [MDSchema_PROPERTIES Rowset](#).

By default, if the **CELL PROPERTIES** keyword is not used, the cell properties returned are **VALUE**, **FORMATTED_VALUE**, and **CELL_ORDINAL** (in that order). If the **CELL PROPERTIES** keyword is used, only those cell properties explicitly stated with the keyword are returned.

The following example demonstrates the use of the **CELL PROPERTIES** keyword in an MDX query:

```
SELECT
  {[Measures].[Reseller Gross Profit]} ON COLUMNS,
  {[Reseller].[Reseller Type].[Reseller Name].Members} ON ROWS
FROM [Adventure Works]
CELL PROPERTIES VALUE, FORMATTED_VALUE, FORMAT_STRING, FORE_COLOR, BACK_COLOR
```

Cell properties are not returned for MDX queries that return flattened rowsets; in this case, each cell is represented as if only the **FORMATTED_VALUE** cell property were returned.

Setting Cell Properties

Cell properties can be set in Microsoft SQL Server Analysis Services in various places. For example, the Format String property can be set for regular measures on the Cube Structure tab of the Cube Editor in Visual Studio with Analysis Services projects; the same property can be set for calculated measures defined on the cube on the Calculations tab of the Cube Editor; calculated measures defined in the WITH clause of a query have their format string defined there too. The following query demonstrates how cell properties can be set on a calculated measure::

```
WITH MEMBER MEASURES.CELLPROPERTYDEMO AS [Measures].[Internet Sales Amount]
  , FORE_COLOR=RGB(0,0,255)
  , BACK_COLOR=IIF([Measures].[Internet Sales Amount]>7000000, RGB(255,0,0), RGB(0,255,0))
  , FONT_SIZE=10
  , FORMAT_STRING='#,#.000'
SELECT MEASURES.CELLPROPERTYDEMO ON 0,
  [Date].[Calendar Year].[Calendar Year].MEMBERS ON 1
FROM [Adventure Works]
CELL PROPERTIES VALUE, FORMATTED_VALUE, FORE_COLOR, BACK_COLOR, FONT_SIZE
```

MDX Cell Properties - FORMAT_STRING Contents

7/16/2019 • 12 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The **FORMAT_STRING** cell property formats the **VALUE** cell property, creating the value for the **FORMATTED_VALUE** cell property. The **FORMAT_STRING** cell property handles both string and numeric raw values, applying a format expression against the value to return a formatted value for the **FORMATTED_VALUE** cell property. The following tables detail the syntax and formatting characters used to handle string and numeric values.

String Values

A format expression for strings can have one section or two sections separated by a semicolon (:).

USAGE	RESULT
One section	The format applies to all string values.
Two sections	The first section applies to string data, whereas the second section applies to null values and zero-length strings ("").

The characters described in the following table can appear in the format string for character strings.

CHARACTER	DESCRIPTION
@	Represents a character placeholder that displays a character or a space. If the string has a character in the position where the at sign (@) appears in the format string, the formatted string displays the character. Otherwise, the formatted string displays a space in that position. Placeholders are filled from right to left unless there is an exclamation point (!) in the format string.
&	Represents a character placeholder that displays a character or nothing. If the string has a character in the position where the ampersand (&) appears, the formatted string displays the character. Otherwise, the formatted string displays nothing. Placeholders are filled from right to left unless there is an exclamation point (!) in the format string.
<	Forces lowercase. The formatted string displays all characters in lowercase format.
>	Forces uppercase. The formatted string displays all characters in uppercase format.
!	Forces left-to-right fill of placeholders. (The default is to fill placeholders from right to left.)

Numeric Values

A user-defined format expression for numbers can have anywhere from one to four sections separated by semicolons. If the format argument contains one of the named numeric formats, only one section is allowed.

USAGE	RESULT
One section	The format expression applies to all values.
Two sections	The first section applies to positive values and zeros, the second to negative values.
Three sections	The first section applies to positive values, the second to negative values, and the third to zeros.
Four sections	The first section applies to positive values, the second to negative values, the third to zeros, and the fourth to null values.

The following example has two sections. The first section defines the format for positive values and zeros, and the second section defines the format for negative values.

```
"$#,##0;($#,##0)"
```

If you include semicolons with nothing between them, the missing section prints using the format of the positive value. For example, the following format displays positive and negative values using the format in the first section and displays "Zero" if the value is zero:

```
"$#,##0;;\Z\e\r\o"
```

The following table identifies the characters that can appear in the format string for numeric formats.

CHARACTER	DESCRIPTION
None	Displays the number without any formatting.
0	<p>Represents a digit placeholder that displays a digit or a zero (0).</p> <p>If the number has a digit in the position where the zero appears in the format string, the formatted value displays the digit. Otherwise, the formatted value displays a zero in that position.</p> <p>If the number has fewer digits than there are zeros (on either side of the decimal) in the format string, the formatted value displays leading or trailing zeros.</p> <p>If the number has more digits to the right of the decimal separator than there are zeros to the right of the decimal separator in the format expression, the formatted value rounds the number to as many decimal places as there are zeros.</p> <p>If the number has more digits to the left of the decimal separator than there are zeros to the left of the decimal separator in the format expression, the formatted value displays the additional digits without modification.</p>

CHARACTER	DESCRIPTION
#	<p>Represents a digit placeholder that displays a digit or nothing.</p> <p>If the expression has a digit in the position where the number sign (#) appears in the format string, the formatted value displays the digit. Otherwise, the formatted value displays nothing in that position.</p> <p>The number sign (#) placeholder works like the zero (0) digit placeholder except that leading and trailing zeros are not displayed if the number has the same or fewer digits than there are # characters on either side of the decimal separator in the format expression.</p>
.	<p>Represents a decimal placeholder that determines how many digits are displayed to the left and right of the decimal separator.</p> <p>If the format expression contains only number sign (#) characters to the left of the period (.), numbers smaller than 1 start with a decimal separator. To display a leading zero displayed with fractional numbers, use zero (0) as the first digit placeholder to the left of the decimal separator.</p> <p>The actual character used as a decimal placeholder in the formatted output depends on the number format recognized by the computer system.</p> <p>Note: In some locales, a comma is used as the decimal separator.</p>
%	<p>Represents a percentage placeholder. The expression is multiplied by 100. The percent character (%) is inserted in the position where the percentage appears in the format string.</p>
,	<p>Represents a thousand separator that separates thousands from hundreds within a number that has four or more places to the left of the decimal separator.</p> <p>Standard use of the thousand separator is specified if the format contains a thousand separator enclosed in digit placeholders (0 or #).</p> <p>Two adjacent thousand separators, or a thousand separator immediately to the left of the decimal separator (whether or not a decimal is specified), means "scale the number by dividing the number by 1000, rounding as required." For example, you can use the format string "##0," to represent 100 million as 100. Numbers smaller than 1 million are displayed as 0. Two adjacent thousand separators in any position other than immediately to the left of the decimal separator are treated as specifying the use of a thousand separator.</p> <p>The actual character used as the thousand separator in the formatted output depends on the number format recognized by the computer system.</p> <p>Note: In some locales, a period is used as the thousand separator.</p>

CHARACTER	DESCRIPTION
:	<p>Represents a time separator that separates hours, minutes, and seconds when time values are formatted.</p> <p>Note: In some locales, other characters may be used as the time separator.</p> <p>The actual character used as the time separator in formatted output is determined by the system settings on the computer.</p>
/	<p>Represents a date separator that separates the day, month, and year when date values are formatted.</p> <p>The actual character used as the date separator in formatted output is determined by the system settings on the computer.</p> <p>Note: In some locales, other characters may be used as the date separator.</p>
E- E+ e- e+	<p>Represents scientific format.</p> <p>If the format expression contains at least one digit placeholder (0 or #) to the right of E-, E+, e-, or e+, the formatted value displays in scientific format and E or e is inserted between the number and the number's exponent. The number of digit placeholders to the right determines the number of digits in the exponent. Use E- or e- to include a minus sign next to negative exponents. Use E+ or e+ to include a minus sign next to negative exponents and a plus sign next to positive exponents.</p>
- + \$ ()	<p>Displays a literal character.</p> <p>To display a character other than one of those listed, put a backslash (\) before the character or enclose the character in double quotation marks (" ").</p>
\	<p>Displays the next character in the format string.</p> <p>To display a character that has special meaning as a literal character, put a backslash (\) before the character. The backslash itself is not displayed. Using a backslash is the same as enclosing the next character in double quotation marks. To display a backslash, use two backslashes (\\). Examples of characters that cannot be displayed as literal characters include the following characters:</p> <p>The date-formatting and time-formatting characters-a, c, d, h, m, n, p, q, s, t, w, y, /, and :</p> <p>The numeric-formatting characters-#, 0, %, E, e, comma, and period</p> <p>The string-formatting characters-@, &, <, >, and !</p>

CHARACTER	DESCRIPTION
"ABC"	<p>Displays the string inside the double quotation marks (" ").</p> <p>To include a string in format from within code, use Chr(34) to enclose the text. (The character code for a double quotation mark is 34.)</p>

Named Numeric Formats

The following table identifies the predefined numeric format names:

FORMAT NAME	DESCRIPTION
General Number	Displays the number with no thousand separator.
Currency	<p>Displays the number with a thousand separator, if appropriate.</p> <p>Displays two digits to the right of the decimal separator.</p> <p>Output is based on system locale settings.</p>
Fixed	Displays at least one digit to the left and two digits to the right of the decimal separator.
Standard	Displays the number with thousand separator, at least one digit to the left and two digits to the right of the decimal separator.
Percent	Displays the number multiplied by 100 with a percent sign (%) appended to the right. Always displays two digits to the right of the decimal separator.
Scientific	Uses standard scientific notation.
Yes/No	Displays No if the number is 0; otherwise, displays Yes.
True/False	Displays False if the number is 0; otherwise, displays True.
On/Off	Displays Off if the number is 0; otherwise, displays On.

Date Values

The following table identifies characters that can appear in the format string for date/time formats.

CHARACTER	DESCRIPTION
:	<p>Represents a time separator that separates hours, minutes, and seconds when time values are formatted.</p> <p>The actual character used as the time separator in formatted output is determined by the system settings of the computer.</p> <p>Note: In some locales, other characters may be used as the time separator.</p>

CHARACTER	DESCRIPTION
/	<p>Represents a date separator that separates the day, month, and year when date values are formatted.</p> <p>The actual character used as the date separator in formatted output is determined by the system settings of the computer.</p> <p>Note: In some locales, other characters may be used to represent the date separator</p>
c	<p>Displays the date as dddddd and displays the time as ttttt, in that order.</p> <p>Displays only date information if there is no fractional part to the date serial number. Displays only time information if there is no integer portion.</p>
d	Displays the day as a number without a leading zero (1-31).
dd	Displays the day as a number with a leading zero (01-31).
ddd	Displays the day as an abbreviation (Sun-Sat).
dddd	Displays the day as a full name (Sunday-Saturday).
dddddd	<p>Displays the date as a complete date (including day, month, and year), formatted according to your system's short date format setting.</p> <p>For Microsoft Windows, the default short date format is m/d/yy.</p>
ddddddd	<p>Displays a date serial number as a complete date (including day, month, and year), formatted according to the long date setting recognized by the computer system.</p> <p>For Windows, the default long date format is mmmm dd, yyyy.</p>
w	Displays the day of the week as a number (1 for Sunday through 7 for Saturday).
ww	Displays the week of the year as a number (1-54).
m	<p>Displays the month as a number without a leading zero (1-12).</p> <p>If m immediately follows h or hh, the minute instead of the month is displayed.</p>
mm	<p>Displays the month as a number with a leading zero (01-12).</p> <p>If m immediately follows h or hh, the minute instead of the month is displayed.</p>
mmm	Displays the month as an abbreviation (Jan-Dec).

CHARACTER	DESCRIPTION
mmmm	Displays the month as a full month name (January-December).
q	Displays the quarter of the year as a number (1-4).
y	Displays the day of the year as a number (1-366).
yy	Displays the year as a two-digit number (00-99).
yyyy	Displays the year as a four-digit number (100-9999).
h	Displays the hour as a number without leading zeros (0-23).
hh	Displays the hour as a number with leading zeros (00-23).
n	Displays the minute as a number without leading zeros (0-59).
nn	Displays the minute as a number with leading zeros (00-59).
s	Displays the second as a number without leading zeros (0-59).
ss	Displays the second as a number with leading zeros (00-59).
tttt	<p>Displays a time as a complete time (including hour, minute, and second), formatted using the time separator defined by the time format recognized by the computer system.</p> <p>A leading zero is displayed if the leading zero option is selected, and the time is earlier than 10:00 in either the A.M. or the P.M. cycle. For example, 09:59,</p> <p>For Windows, the default time format is h:mm:ss.</p>
AM/PM	<p>Displays an uppercase AM with any hour from midnight until noon; displays an uppercase PM with any hour from noon until midnight.</p> <p>Note: Uses the 12-hour clock.</p>
am/pm	<p>Displays a lowercase am with any hour from midnight until noon; displays a lowercase pm with any hour from noon until midnight.</p> <p>Note: Uses the 12-hour clock.</p>
A/P	<p>Displays an uppercase A with any hour from midnight until noon; displays an uppercase P with any hour from noon until midnight.</p> <p>Note: Uses the 12-hour clock.</p>
a/p	<p>Displays a lowercase a with any hour from midnight until noon; displays a lowercase p with any hour from noon until midnight.</p> <p>Note: Uses the 12-hour clock.</p>

CHARACTER	DESCRIPTION
AMPM	<p>Displays the AM string literal as defined by the computer system with any hour from midnight until noon; displays the PM string literal as defined by the computer system with any hour from noon until midnight.</p> <p>AMPM can be either uppercase or lowercase, but the case of the string displayed matches the string as defined by the system settings of the computer.</p> <p>For Windows, the default format is AM/PM.</p> <p>Note: Uses the 12-hour clock.</p>

Named Date Formats

The following table identifies the predefined date and time format names:

FORMAT NAME	DESCRIPTION
General Date	Displays a date and/or time. For real numbers, displays a date and time, for example, 4/3/93 05:34 PM. If there is no fractional part, displays only a date, for example, 4/3/93. If there is no integer part, displays a time only, for example, 05:34 PM. The format of the date display is determined by your system settings.
Long Date	Displays a date according to your system's long date format.
Medium Date	Displays a date using the medium date format appropriate for the language version of the host application.
Short Date	Displays a date using your system's short date format.
Long Time	Displays a time using your system's long time format; includes hours, minutes, and seconds.
Medium Time	Displays a time in the 12-hour format using hours and minutes and the AM/PM designator.
Short Time	Displays a time using the 24-hour format, for example, 17:45.

MDX Cell Properties - FORE_COLOR and BACK_COLOR Contents

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

The **FORE_COLOR** and **BACK_COLOR** cell properties store color information for the text and the background of a cell, respectively, in the Microsoft Windows operating system red-green-blue (RGB) format.

The valid range for an ordinary RGB color is zero (0) to 16,777,215 (&H00FFFFFF). The high byte of a number in this range always equals 0; the lower 3 bytes, from least to most significant byte, determine the amount of red, green, and blue, respectively. The red, green, and blue components are each represented by a number between 0 and 255 (&HFF).

MDX Cell Properties - FORMATTED_VALUE Property

7/16/2019 • 6 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The FORMATTED_VALUE property is built on the interactions of the VALUE, FORMAT_STRING and LANGUAGE properties of the cell. This topic explains how these properties interact to build the FORMATTED_VALUE property.

VALUE, FORMAT_STRING, LANGUAGE properties

The following table explains what these properties are, to help prepare us to use them in combination.

VALUE

The unformatted value of the cell.

FORMAT_STRING

The formatting template to be applied to the value of the cell to generate FORMATTED_VALUE property

LANGUAGE

The locale specification to be applied alongside FORMAT_STRING to generate a localized version of FORMATTED_VALUE

FORMATTED_VALUE constructed

The FORMATTED_VALUE property is constructed by using the value from the VALUE property and applying the format template specified in the FORMAT_STRING property to that value. In addition, whenever the formatting value is a **named formatting literal** the LANGUAGE property specification modifies the output of FORMAT_STRING to follow the language usage for the named formatting. Named formatting literals are all defined in a way that can be localized. For example, "General Date" is a specification that can be localized, as opposed to the following template "YYYY-MM-DD hh:nn:ss", which states that the date is to be presented as defined by the template regardless of the language specification.

If there is a conflict between the FORMAT_STRING template and the LANGUAGE specification, the FORMAT_STRING template overrides the LANGUAGE specification. For example, if FORMAT_STRING="\$ #0" and LANGUAGE=1034 (Spain), and VALUE=123.456 then FORMATTED_VALUE="\$ 123" instead of FORMATTED_VALUE="€ 123", the expected format is in Euros, because the value of the format template overrides the language specified.

Examples

The following examples show the output obtained when LANGUAGE is used in conjunction with FORMAT_STRING.

The first example explains formatting numerical values; the second example explains formatting date and time values.

For each example the Multidimensional Expressions (MDX) code is given.

with

```
member measures.A as 5040, FORMAT_STRING="Currency"
```

```
member measures.B as measures.A, LANGUAGE=1034
```

```
member measures.C as measures.A, LANGUAGE=1034 , FORMAT_STRING="$#,##0.00"
```

```

member measures.D as measures.A, FORMAT_STRING="Scientific"

member measures.E as measures.A, LANGUAGE=1034 , FORMAT_STRING="Scientific"

member measures.F as 0.5040, FORMAT_STRING="Percent"

member measures.G as measures.F, LANGUAGE=1034

member measures.H as 0, LANGUAGE=1034 , FORMAT_STRING="Yes/No"

member measures.I as 59, LANGUAGE=1034 , FORMAT_STRING="Yes/No"

member measures.J as 0, LANGUAGE=1034 , FORMAT_STRING="ON/OFF"

member measures.K as -312, LANGUAGE=1034 , FORMAT_STRING="ON/OFF"

```

```
Select {measures.A, measures.B, measures.C, measures.D, measures.E, measures.F, measures.G, measures.H, measures.I, measures.J, measures.K} on 0
```

```
from [Adventure Works]
```

```
cell properties VALUE, FORMAT_STRING, LANGUAGE, FORMATTED_VALUE
```

The results, transposed, when the above MDX query was run using SQL Server Management Studio over a server and client with locale 1033 are as follows:

MEMBER	FORMATTED_VALUE	EXPLANATION
A	\$5,040.00	FORMAT_STRING is set to <code>Currency</code> and LANGUAGE is <code>1033</code> , inherited from system locale value
B	€5.040,00	FORMAT_STRING is set to <code>Currency</code> (inherited from A) and LANGUAGE is explicitly set to <code>1034</code> (Spain) hence the Euro sign, the different decimal separator and the different thousand separator.
C	\$5.040,00	FORMAT_STRING is set to <code>\$#,##0.00</code> an override to Currency, from A, and LANGUAGE is explicitly set to <code>1034</code> (Spain). Because the FORMAT_STRING property explicitly set the currency symbol to \$, the FORMATTED_VALUE is presented with the \$ sign. However, because <code>.</code> (dot) and <code>,</code> (comma) are placeholders for decimal separator and thousand separator respectively, the language specification affects them generating an output that is localized for decimal and thousand separators.
D	5.04E+03	FORMAT_STRING is set to <code>Scientific</code> and LANGUAGE is set to <code>1033</code> , inherited from system locale value, hence <code>.</code> (dot) is the decimal separator.

MEMBER	FORMATTED_VALUE	EXPLANATION
E	5,04E+03	FORMAT_STRING is set to <code>Scientific</code> and LANGUAGE is set explicitly to <code>1034</code> , hence <code>,</code> (comma) is the decimal separator.
F	50.40%	FORMAT_STRING is set to <code>Percent</code> and LANGUAGE is set to <code>1033</code> , inherited from system locale value, hence <code>.</code> (dot) is the decimal separator. Note that VALUE was changed from 5040 to 0.5040
G	50,40%	FORMAT_STRING is set to <code>Percent</code> , inherited from F, and LANGUAGE is set explicitly to <code>1034</code> hence <code>,</code> (comma) is the decimal separator. Note that VALUE was inherited from F value.
H	No	FORMAT_STRING is set to <code>YES/NO</code> , VALUE is set to 0 and LANGUAGE is set explicitly to <code>1034</code> ; because there is no difference between English NO and Spanish NO the user sees no difference in the FORMATTED_VALUE.
I	SI	FORMAT_STRING is set to <code>YES/NO</code> , VALUE is set to 59 and LANGUAGE is set explicitly to <code>1034</code> ; as defined for YES/NO formatting, any value different from zero (0) is a YES and because language is set to Spanish then the FORMATTED_VALUE is SI.
J	Desactivado	FORMAT_STRING is set to <code>ON/OFF</code> , VALUE is set to 0 and LANGUAGE is set explicitly to <code>1034</code> ; as defined for ON/OFF formatting, any value equal to zero (0) is an OFF and because language is set to Spanish then the FORMATTED_VALUE is Desactivado.
K	Activado	FORMAT_STRING is set to <code>ON/OFF</code> , VALUE is set to -312 and LANGUAGE is set explicitly to <code>1034</code> ; as defined for ON/OFF formatting, any value different from zero (0) is an ON and because language is set to Spanish then the FORMATTED_VALUE is Activado.

with

```
member measures.A as 'CDate("1959-03-12 06:30")'
```

```
member measures.B as measures.A, FORMAT_STRING="Long Date"
```

```

member measures.C as measures.A, LANGUAGE=1034 , FORMAT_STRING="General Date"

member measures.D as measures.A, LANGUAGE=1034, FORMAT_STRING="Long Date"

member measures.E as measures.A, LANGUAGE=1041 , FORMAT_STRING="General Date"

member measures.F as measures.A, LANGUAGE=1041 , FORMAT_STRING="Long Date"

member measures.G as measures.A, FORMAT_STRING="Long Time"

member measures.H as measures.A, FORMAT_STRING="Short Time"

member measures.I as measures.A, LANGUAGE=1034 , FORMAT_STRING="Long Time"

member measures.J as measures.A, LANGUAGE=1034 , FORMAT_STRING="Short Time"

member measures.K as measures.A, LANGUAGE=1041 , FORMAT_STRING="Long Time"

member measures.L as measures.A, LANGUAGE=1041 , FORMAT_STRING="Short Time"

Select {measures.A, measures.B, measures.C, measures.D, measures.E, measures.F
, measures.G, measures.H, measures.I, measures.J, measures.K, measures.L} on 0

from [Adventure Works]

cell properties VALUE, FORMAT_STRING, LANGUAGE, FORMATTED_VALUE

```

The results, transposed, when the above MDX query was run using SQL Server Management Studio over a server and client with locale 1033 are as follows:

MEMBER	FORMATTED_VALUE	EXPLANATION
A	3/12/1959 6:30:00 AM	FORMAT_STRING is set implicitly to General Date by the CDate() expression and LANGUAGE is 1033 (English), inherited from system locale value
B	Thursday, March 12, 1959	FORMAT_STRING is set explicitly to Long Date and LANGUAGE is 1033 (English), inherited from system locale value
C	12/03/1959 6:30:00	FORMAT_STRING is set explicitly to General Date and LANGUAGE is explicitly 1034 (Spanish). Note that month and day are switched when compared to U.S. formatting style
D	jueves, 12 de marzo de 1959	FORMAT_STRING is set explicitly to Long Date and LANGUAGE is explicitly 1034 (Spanish). Note that month and day of the week are worded in Spanish

MEMBER	FORMATTED_VALUE	EXPLANATION
E	1959/03/12 6:30:00	FORMAT_STRING is set explicitly to General Date and LANGUAGE is explicitly 1041 (Japanese). Note that the date is now formatted Year/Month/Day Hour:Minutes:Seconds
F	1959年3月12日	FORMAT_STRING is set explicitly to Long Date and LANGUAGE is explicitly 1041 (Japanese).
G	6:30:00 AM	FORMAT_STRING is set explicitly to Long Time and LANGUAGE is 1033 (English), inherited from system locale value.
H	06:30	FORMAT_STRING is set explicitly to Short Time and LANGUAGE is 1033 (English), inherited from system locale value.
I	6:30:00	FORMAT_STRING is set explicitly to Long Time and LANGUAGE is set explicitly to 1034 (Spanish).
J	06:30	FORMAT_STRING is set explicitly to Short Time and LANGUAGE is set explicitly to 1034 (Spanish).
K	6:30:00	FORMAT_STRING is set explicitly to Long Time and LANGUAGE is set explicitly to 1041 (Japanese).
L	06:30	FORMAT_STRING is set explicitly to Short Time and LANGUAGE is set explicitly to 1041 (Japanese).

MDX Data Manipulation - Manipulating Data

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Multidimensional Expressions (MDX) can be used to manipulate the data in a variety of ways. The following topics cover some of the more advanced concepts of data manipulation in the MDX language.

In This Section

TOPIC	DESCRIPTION
Using DRILLTHROUGH to Retrieve Source Data (MDX)	Discusses the use of the MDX DRILLTHROUGH statement to retrieve the rowsets of source data applicable to a cell in a multidimensional data source
Working with the RollupChildren Function (MDX)	Discusses the impact of the MDX RollupChildren function on the analysis of multidimensional data.
Understanding Pass Order and Solve Order (MDX)	Details the concepts of solve order, and how this feature affects MDX expressions, statements, and scripts.

[MDX Query Fundamentals \(Analysis Services\)](#)

MDX Data Manipulation - Retrieve Source Data Using DRILLTHROUGH

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Multidimensional Expressions (MDX) uses the **DRILLTHROUGH** statement to retrieve a rowset from the source data for a cube cell.

In order to run a **DRILLTHROUGH** statement on a cube, a drillthrough action must be defined for that cube. To define a drillthrough action, in Visual Studio with Analysis Services projects, in Cube Designer, on the **Actions** pane, on the toolbar, click **New Drillthrough Action**. In the new drillthrough action, specify the action name, target, condition, and the columns that are returned by a **DRILLTHROUGH** statement.

DRILLTHROUGH Statement Syntax

The **DRILLTHROUGH** statement uses the following syntax:

```
<drillthrough> ::= DRILLTHROUGH [<Max_Rows>] [<First_Rowset>] <MDX select> [<Return_Columns>]
  < Max_Rows> ::= MAXROWS <positive number>
  <First_Rowset> ::= FIRSTROWSET <positive number>
  <Return_Columns> ::= RETURN <member or attribute> [, <member or attribute>]
```

The **SELECT** clause identifies the cube cell that contains the source data to be retrieved. This **SELECT** clause is the same to an ordinary MDX **SELECT** statement, except that in the **SELECT** clause only one member can be specified on each axis. If more than one member is specified on an axis, an error occurs.

The **<Max_Rows>** syntax specifies the maximum number of the rows in each returned rowset. If the OLE DB provider that is used to connect to the data source does not support **DBPROP_MAXROWS**, the **<Max_Rows>** setting is ignored.

The **<First_Rowset>** syntax identifies the partition whose rowset is returned first.

The **<Return_Columns>** syntax identifies the underlying database columns to be returned.

DRILLTHROUGH Statement Example

The following example demonstrates the use of the **DRILLTHROUGH** statement. In this example, the **DRILLTHROUGH** statement queries the leaves of the Store, Product, and Time dimensions along the Stores dimension (the slicer axis), and then returns the department measure group, department ID, and employee's first name.

```
DRILLTHROUGH
Select {Leaves(Store), Leaves(Product), Leaves(Time),*} on 0
From Stores
RETURN [Department MeasureGroup].[Department Id], [Employee].[First Name]
```

[Manipulating Data \(MDX\)](#)

MDX Data Manipulation - RollupChildren Function

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

The Multidimensional Expressions (MDX) **RollupChildren** function rolls up the children of a member, applying a different unary operator to each child, and returns the value of this rollup as a number. The unary operator can be supplied by a member property associated with the child member, or the operator can be a string expression provided directly to the function.

RollupChildren Function Examples

The use of the **RollupChildren** function in Multidimensional Expressions (MDX) statements is simple to explain, but the effect of this function on MDX queries can be wide-ranging.

The effect of the **RollupChildren** function occurs in MDX queries designed to perform selective analysis on existing cube data. For example, the following table contains a list of child members for the Net Sales parent member, with their unary operators (represented by the **UNARY_OPERATOR** member property) shown in parentheses.

PARENT MEMBER	CHILD MEMBER
Net Sales	Domestic Sales (+) Domestic Returns (-) Foreign Sales (+) Foreign Returns (-)

The Net Sales parent member currently provides a total of net sales minus the gross domestic and foreign sales values, with the domestic and foreign returns subtracted as part of the rollup.

However, you want to provide a quick and easy forecast of domestic and foreign gross sales plus 10%, ignoring the domestic and foreign returns. To calculate this value, you can use the **RollupChildren** function in one of two ways: with a custom member property or with the **IIf** function.

Using a Custom Member Property

If the rollup calculation is to be a frequently performed operation, one method is to create a member property that stores the operator that will be used for each child for a specific function. The following table displays valid unary operators and describes the expected result.

OPERATOR	RESULT
+	total = total + current child
-	total = total - current child
*	total = total * current child
/	total = total / current child

OPERATOR	RESULT
~	Child is not used in the rollup. The child's value is ignored.

For example, a member property called **SALES_OPERATOR** could be created, and the following unary operators would be assigned to that member property, as shown in the following table.

PARENT MEMBER	CHILD MEMBER
Net Sales	Domestic Sales (+) Domestic Returns (~) Foreign Sales (+) Foreign Returns (~)

With this new member property, the following MDX statement would perform the gross sales estimate operation quickly and efficiently (ignoring Foreign and Domestic returns):

```
RollupChildren([Net Sales], [Net Sales].CurrentMember.Properties("SALES_OPERATOR")) * 1.1
```

When the function is called, the value of each child is applied to a total using the operator stored in the member property. The members for domestic and foreign returns are ignored, and the rollup total returned by the **RollupChildren** function is multiplied by 1.1.

Using the IIf Function

If the example operation is not commonplace or if the operation applies only to one MDX query, the **IIf** function can be used with the **RollupChildren** function to provide the same result. The following MDX query provides the same result as the earlier MDX example, but does so without resorting to the use of a custom member property:

```
RollupChildren([Net Sales], IIf([Net Sales].CurrentMember.Properties("UNARY_OPERATOR") = "-", "~", [Net Sales].CurrentMember.Properties("UNARY_OPERATOR")) * 1.1
```

The MDX statement examines the unary operator of the child member. If the unary operator is used for subtraction (as in the case with the domestic and foreign returns members), the **IIf** function substitutes the tilde (~) unary operator. Otherwise, the **IIf** function uses the unary operator of the child member. Finally, the returned rollup total is then multiplied by 1.1 to provide the domestic and foreign gross sales forecast value.

MDX Data Manipulation - Understanding Pass Order and Solve Order

7/16/2019 • 7 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

When a cube is calculated as the result of an MDX script, it can go through many stages of computation depending on the use of various calculation-related features. Each of these stages is referred to as a calculation pass.

A calculation pass can be referred to by an ordinal position, called the calculation pass number. The count of calculation passes that are required to fully compute all the cells of a cube is referred to as the calculation pass depth of the cube.

Fact table and writeback data only impact pass 0. Scripts populate data after pass 0; each assignment and calculate statement in a script creates a new pass. Outside the MDX script, references to absolute pass 0 refer to the last pass created by the script for the cube.

Calculated members are created at all passes, but the expression is applied at the current pass. Prior passes contain the calculated measure, but with a null value.

Solve Order

Solve order determines the priority of calculation in the event of competing expressions. Within a single pass, solve order determines two things:

- The order in which Microsoft SQL Server Analysis Services evaluates dimensions, members, calculated members, custom rollups, and calculated cells.
- The order in which Analysis Services calculates custom members, calculated members, custom rollup, and calculated cells.

The member with the highest solve order takes precedence.

NOTE

The exception to this precedence is the Aggregate function. Calculated members with the Aggregate function have a lower solve order than any intersecting calculated measure.

Solve Order Values and Precedence

Solve order values can range from -8181 to 65535. In this range, some solve order values correspond to specific kinds of calculations, as shown in the following table.

CALCULATION	SOLVE ORDER
Custom member formulas	-5119
Unary operators	-5119

CALCULATION	SOLVE ORDER
Visual totals calculation	-4096
All other calculations (if not otherwise specified)	0

It is highly recommended that you use only positive integers when setting solve order values. If you assign values that are lower than the solve order values shown in the previous table, the calculation pass can become unpredictable. For example, the calculation for a calculated member receives a solve order value that is lower than the default custom rollup formula value of -5119. Such a low solve order value causes the calculated members to be calculated before the custom rollup formulas, and can produce incorrect results.

Creating and Changing Solve Order

In Cube Designer, on the **Calculations Pane**, you can change the solve order for calculated members and calculated cells by changing the order of the calculations.

In MDX, you can use the **SOLVE_ORDER** keyword to create or change calculated members and calculated cells.

Solve Order Examples

To illustrate the potential complexities of solve order, the following series of MDX queries starts with two queries that each individually have no solve order issues. These two queries are then combined into a query that requires solve order.

Query 1-Differences in Income and Expenses

For the first MDX query, calculate the difference in sales and costs for each year by constructing a simple MDX query similar to the following example:

```
WITH
MEMBER
[Date].[Calendar].[Year Difference] AS ([Date].[Calendar].[Calendar Year]&[2008] - [Date].[Calendar].[Calendar Year]&[2007])
SELECT
{[Measures].[Internet Sales Amount], [Measures].[Internet Total Product Cost] }
ON COLUMNS ,
{ [Date].[Calendar].[Calendar Year]&[2007], [Date].[Calendar].[Calendar Year]&[2008], [Date].[Year Difference] }
ON ROWS
FROM [Adventure Works]
```

In this query, there is only one calculated member, `Year Difference`. Because there is only one calculated member, solve order is not an issue, as long as the cube does not use any calculated members.

This MDX query produces a result set similar to the following table.

	INTERNET SALES AMOUNT	INTERNET TOTAL PRODUCT COST
CY 2007	\$9,791,060.30	\$5,718,327.17
CY 2008	\$9,770,899.74	\$5,721,205.24
Year Difference	(\$20,160.56)	\$2,878.06

Query 2-Percentage of Income after Expenses

For the second query, calculate the percentage of income after expenses for each year using the following MDX

query:

```
WITH
MEMBER
[Measures].[Profit Margin] AS
([Measures].[Internet Sales Amount] - [Measures].[Internet Total Product Cost] ) / [Measures].[Internet Sales
Amount] ,
FORMAT_STRING="Percent"
SELECT
{[Measures].[Internet Sales Amount], [Measures].[Internet Total Product Cost], [Measures].[Profit Margin] }
ON COLUMNS ,
{ [Date].[Calendar].[Calendar Year].&[2007], [Date].[Calendar].[Calendar Year].&[2008] }
ON ROWS
FROM [Adventure Works]
```

This MDX query, like the previous one, has only a single calculated member, `Profit Margin`, and therefore does not have any solve order complications.

This MDX query produces a slightly different result set, similar to the following table.

	INTERNET SALES AMOUNT	INTERNET TOTAL PRODUCT COST	PROFIT MARGIN
CY 2007	\$9,791,060.30	\$5,718,327.17	41.60%
CY 2008	\$9,770,899.74	\$5,721,205.24	41.45%

The difference in result sets between the first query and the second query comes from the difference in placement of the calculated member. In the first query, the calculated member is part of the ROWS axis, not the COLUMNS axis shown in the second query. This difference in placement becomes important in the next query, which combines the two calculated members in a single MDX query.

Query 3-Combined Year Difference and Net Income Calculations

In this final query combining both of the previous examples into a single MDX query, solve order becomes important because of the calculations on both columns and rows. To make sure that the calculations occur in the correct sequence, define the sequence in which the calculations occur by using the **SOLVE_ORDER** keyword.

The **SOLVE_ORDER** keyword specifies the solve order of calculated members in an MDX query or a **CREATE MEMBER** command. The integer values used with the **SOLVE_ORDER** keyword are relative, do not need to start at zero, and do not need to be consecutive. The value simply tells MDX to calculate a member based on values derived from calculating members with a higher value. If a calculated member is defined without the **SOLVE_ORDER** keyword, the default value of that calculated member is zero.

For example, if you combine the calculations used in the first two example queries, the two calculated members, `Year Difference` and `Profit Margin`, intersect at a single cell in the result dataset of the MDX query example. The only way to determine how Analysis Services will evaluate this cell is by the solve order. The formulas that are used to construct this cell will produce different results depending upon the solve order of the two calculated members.

First, try combining the calculations used in the first two queries in the following MDX query:

```

WITH
MEMBER
[Date].[Calendar].[Year Difference] AS ([Date].[Calendar].[Calendar Year].&[2008] - [Date].[Calendar].[Calendar Year].&[2007] ) ,
SOLVE_ORDER = 1
MEMBER
[Measures].[Profit Margin] AS
( [Measures].[Internet Sales Amount] - [Measures].[Internet Total Product Cost] ) / [Measures].[Internet Sales Amount] ,
FORMAT_STRING="Percent" ,
SOLVE_ORDER = 2
SELECT
{[Measures].[Internet Sales Amount], [Measures].[Internet Total Product Cost], [Measures].[Profit Margin] }
ON COLUMNS ,
{ [Date].[Calendar].[Calendar Year].&[2007], [Date].[Calendar].[Calendar Year].&[2008], [Date].[Year Difference] }
ON ROWS
FROM [Adventure Works]

```

In this combined MDX query example, `Profit Margin` has the highest solve order, so it takes precedence when the two expressions interact. Analysis Services evaluates the cell in question by using the `Profit Margin` formula. The results of this nested calculation, as shown in the following table.

	INTERNET SALES AMOUNT	INTERNET TOTAL PRODUCT COST	PROFIT MARGIN
CY 2007	\$9,791,060.30	\$5,718,327.17	41.60%
CY 2008	\$9,770,899.74	\$5,721,205.24	41.45%
Year Difference	(\$20,160.56)	\$2,878.06	114.28%

The result in the shared cell is based on the formula for `Profit Margin`. That is, Analysis Services calculates the result in the shared cell with the `Year Difference` data, producing the following formula (the result is rounded for clarity):

$((9,770,899.74 - 9,791,060.30) - (5,721,205.24 - 5,718,327.17)) / (9,770,899.74 - 9,791,060.30) = 1.14275744$

◀
▶

or

$(23,038.63) / (20,160.56) = 114.28\%$

This is clearly incorrect. However, Analysis Services calculates the result in the shared cell differently if you switch the solve orders for the calculated members in the MDX query. The following combined MDX query reverses the solve order for the calculated members:

```

WITH
MEMBER
[Date].[Calendar].[Year Difference] AS ([Date].[Calendar].[Calendar Year].&[2008] - [Date].[Calendar].[Calendar Year].&[2007] ) ,
SOLVE_ORDER = 2
MEMBER
[Measures].[Profit Margin] AS
( [Measures].[Internet Sales Amount] - [Measures].[Internet Total Product Cost] ) / [Measures].[Internet Sales Amount] ,
FORMAT_STRING="Percent" ,
SOLVE_ORDER = 1
SELECT
{[Measures].[Internet Sales Amount], [Measures].[Internet Total Product Cost], [Measures].[Profit Margin] }
ON COLUMNS ,
{ [Date].[Calendar].[Calendar Year].&[2007], [Date].[Calendar].[Calendar Year].&[2008], [Date].[Year Difference] }
ON ROWS
FROM [Adventure Works]

```

As the order of the calculated members has been switched, Analysis Services uses the `Year Difference` formula to evaluate the cell, as shown in the following table.

	INTERNET SALES AMOUNT	INTERNET TOTAL PRODUCT COST	PROFIT MARGIN
CY 2007	\$9,791,060.30	\$5,718,327.17	41.60%
CY 2008	\$9,770,899.74	\$5,721,205.24	41.45%
Year Difference	(\$20,160.56)	\$2,878.06	(0.15%)

Because this query uses the `Year Difference` formula with the `Profit Margin` data, the formula for the shared cell resembles the following calculation:

$$((\$9,770,899.74 - 5,721,205.24) / \$9,770,899.74) - ((9,791,060.30 - 5,718,327.17) / 9,791,060.30) = -0.15$$

Or

$$0.4145 - 0.4160 = -0.15$$

Additional Considerations

Solve order can be a very complex issue to deal with, especially in cubes with a high number of dimensions involving calculated member, custom rollup formulas, or calculated cells. When Analysis Services evaluates an MDX query, Analysis Services takes into account the solve order values for everything involved within a given pass, including the dimensions of the cube specified in the MDX query.

MDX Data Modification - Modifying Data

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO:  SQL Server Analysis Services  Azure Analysis Services  Power BI Premium

Besides using Multidimensional Expressions (MDX) to retrieve and handle data from dimensions and cubes, you can use MDX to update or *writeback* dimension and cube data. These updates can be temporary, as with speculative, or "what if", analysis, or permanent, as when changes must occur based upon data analysis.

Updates to data can occur at the dimension or cube level:

Dimension writebacks

You use the [ALTER CUBE Statement \(MDX\)](#) statement to change a write-enabled dimension's data and the [REFRESH CUBE Statement \(MDX\)](#) to reflect the deletion, creation, and updating of attribute values. You can also use the ALTER CUBE statement to perform complex operations, such as deleting a whole sub-tree in a hierarchy and promoting the children of a deleted member.

Cube writebacks

You use the [UPDATE CUBE](#) statement to make updates to a write-enabled cube. The UPDATE CUBE statement lets you update a tuple with a specific value. You use the [REFRESH CUBE Statement \(MDX\)](#) to refresh data in a client session with updated data from the server.

For more information, see [Using Cube Writebacks \(MDX\)](#).

See Also

[MDX Query Fundamentals \(Analysis Services\)](#)

MDX Data Modification - Using Cube Writebacks

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

You update a cube by using the **UPDATE CUBE** statement. This statement lets you update a tuple with a specific value. To effectively use the UPDATE CUBE statement to update a cube, you have to understand the syntax for the statement, the error conditions that can occur, and the affect that updates can have on a cube.

UPDATE CUBE Statement Syntax

The following syntax describes the UPDATE CUBE statement:

```
UPDATE [CUBE] <Cube_Name> SET <tuple>.VALUE = <value> [,<tuple>.VALUE = <value>...]
[ USE_EQUAL_ALLOCATION | USE_EQUAL_INCREMENT |
USE_WEIGHTED_ALLOCATION [BY <weight value_expression>] |
USE_WEIGHTED_INCREMENT [BY <weight value_expression>] ]
```

If a full set of coordinates is not specified for the tuple, the unspecified coordinates will use the default member of the hierarchy. The tuple identified must reference a cell that is aggregated with the **Sum** function, and must not use a calculated member as one of the cell's coordinates.

You can think of the UPDATE CUBE statement as a subroutine that generates a series of individual writeback operations to atomic cells. All these individual writeback operations then roll up into the specified sum.

NOTE

When updated cells do not overlap, the **Update Isolation Level** connection string property can be used to enhance performance for UPDATE CUBE. For more information, see [ConnectionString](#).

Example

You can test UPDATE CUBE using the Sales Targets measure group in the Adventure Works cube. This measure group consists of measures aggregated by SUM, which is a requirement for UPDATE CUBE.

1. Enable writeback for the Sales Targets measure group in the Adventure Works database. In Management Studio, right-click a measure group, point to **Write Back Options**, choose **Enable Writeback**.

You should see a new writeback table in the Writeback folder. The table name is WriteTable_Fact Sales Quota.

2. Open an MDX query window. Run the following select statement to view the original value:

```
SELECT [Measures].[Sales Amount Quota] on 0 ,
[Employee].[Employee Department].[Title].&[Sales Representative].children on 1
FROM [Adventure Works]
```

You should see sales amount quotas for each representative.

3. Run the update cube statement to write back a new value. In this example, we are setting the sales amount quota to 0. Because the new value is 0, do not specify an allocation method.

```

UPDATE CUBE [Adventure Works]
SET ([Measures].[Sales Amount Quota], [Employee].[Employee Department].[Department].&[Sales]) = 0

```

- Re-run the SELECT statement. You should now see zero for the quotas.

The writeback value is constrained to the current session. To persist the value across users and sessions, process the writeback table. In Management Studio, right-click WriteTable_Fact Sales Quota and choose **Process**.

To specify an allocation method, the new value must be greater than zero. In this example, the new value for Sales Amount Quota is two million and the allocation method distributes the amount across all sales representatives.

```

UPDATE CUBE [Adventure Works]
SET ([Measures].[Sales Amount Quota], [Employee].[Employee Department].[Department].&[Sales]) = 2000000
USE_EQUAL_ALLOCATION

```

Error Conditions

The following table describes both what can cause writebacks to fail and the result of those errors.

ERROR CONDITION	RESULT
Update includes members from the same dimension that do not exist with one another.	Update will fail. The cube space will not contain the referenced cell.
Update includes a measure sourced to a measure of an unsigned type.	Update will fail. Increments require that the measure be able to take a negative value.
Update includes a measure that aggregates other than sum.	An error is raised.
Update was tried on a subcube.	An error is raised.

Affect of Cube Changes

The following changes will not have an effect on a writeback:

- Processing of a cube, the cube's measure groups, or the cube's dimensions.
- Adding attributes to any dimension.
- Adding a new dimension.
- Deleting a dimension that does not include the writeback.
- Adding, modifying, or removing a hierarchy.
- Adding a new measure.

The following changes cannot be made without removing the writeback data:

- Deleting an attribute, or its attribute hierarchy, if the attribute is included in the writeback. This includes explicitly removing the attribute, or its attribute hierarchy, or removing the attribute's parent dimension.
- Deleting a measure included in the writeback.
- Adding an attribute without an **(All)** level to a dimension included in the writeback.

- Changing the dimension granularity for a dimension included in the writeback.

[Modifying Data \(MDX\)](#)

Using Variables and Parameters (MDX)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, you can parameterize a Multidimensional Expressions (MDX) statement. A parameterized statement lets you create generic statements that can be customized at runtime.

In creating a parameterized statement, you identify the parameter name by prefixing the name with the at sign (@). For example, @Year would be a valid parameter name

MDX supports only parameters for literal or scalar values. To create a parameter that references a member, set, or tuple, you would have to use a function such as [StrToMember](#) or [StrToSet](#).

In the following XML for Analysis (XMLA) example, the @CountryName parameter will contain the country for which customer data is retrieved:

```
<Envelope xmlns="http://schemas.xmlsoap.org/soap/envelope/">
  <Body>
    <Execute xmlns="urn:schemas-microsoft-com:xml-analysis">
      <Command>
        <Statement>
          select [Measures].members on 0,
            Filter(Customer.[Customer Geography].Country.members,
                  Customer.[Customer Geography].CurrentMember.Name =
                  @CountryName) on 1
          from [Adventure Works]
        </Statement>
      </Command>
      <Properties />
      <Parameters>
        <Parameter>
          <Name>CountryName</Name>
          <Value>'United Kingdom'</Value>
        </Parameter>
      </Parameters>
    </Execute>
  </Body>
</Envelope>
```

To use this functionality with OLE DB, you would use the **ICommandWithParameters** interface. To use this functionality with ADOMD.Net, you would use the **AdomdCommand.Parameters** collection.

[MDX Scripting Fundamentals \(Analysis Services\)](#)

MDX Scripting Fundamentals (Analysis Services)

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, a Multidimensional Expressions (MDX) script is made up of one or more MDX expressions or statements that populate a cube with calculations.

An MDX script defines the calculation process for a cube. An MDX script is also considered part of the cube itself. Therefore, changing an MDX script associated with a cube immediately changes the calculation process for the cube.

To create MDX scripts, you can use Cube Designer in the Visual Studio with Analysis Services projects. For more information, see [Define Assignments and Other Script Commands](#) and [Introduction to MDX Scripting in Microsoft SQL Server 2005](#).

For performance issues related to MDX queries and calculations, see the MDX optimization section in the [SQL Server Analysis Services Performance Guide](#).

In This Section

TOPIC	DESCRIPTION
The Basic MDX Script (MDX)	Details the basic MDX script, including the default MDX script provided in each cube, and how MDX scripts generally function within a cube in Analysis Services.
Managing Scope and Context (MDX)	Describes how to use the <code>CALCULATE</code> statement, the <code>SCOPE</code> statement, and the <code>This</code> function to manage context and scope within an MDX script.
Using Variables and Parameters (MDX)	Describes how to use variables and parameters in an MDX script.
Error Handling (MDX)	Explains error handling within an MDX script.
Supported MDX (MDX)	Provides a list of supported MDX operators, statements, and functions within an MDX script.

See Also

[MDX Language Reference \(MDX\)](#)

The Basic MDX Script (MDX)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

A Multidimensional Expressions (MDX) script defines the calculation process for a cube in Microsoft SQL Server Analysis Services. There are two types of MDX scripts:

The default MDX script

At the time that you create a cube, Analysis Services creates a default MDX script for that cube. This script defines a calculation pass for the whole cube.

User-defined MDX script

After you have created a cube, you can add user-defined MDX scripts that extend the calculation capabilities of the cube.

The Default MDX Script

The default MDX script that Analysis Services creates when you define a cube contains a single CALCULATE statement. This single CALCULATE statement is at the beginning of the default MDX script, and indicates that the entire cube should be calculated during the first calculation pass.

The default MDX script also contains the script commands that create named sets, assignments, and calculated members created in Cube Designer:

- Analysis Services directly adds script commands to the default MDX script.
- For each named set in the cube, a corresponding CREATE SET statement exists in the default MDX script.
- For each calculated member defined in the cube, a corresponding CREATE MEMBER statement exists in the default MDX script.

You can control the order of script commands, named sets, and calculated members in the default MDX script by using the **Calculations** tab of Cube Designer. For more information on defining calculations stored in the default MDX script, see [Calculations in Multidimensional Models](#).

If there is no MDX script associated with a cube, the cube assumes the default MDX script. A cube needs to be associated with at least one MDX script because a cube relies on the MDX script to determine calculation behavior. In other words, a cube that was not associated with an MDX script or was associated with an empty MDX script could not and would not be able to calculate any cells. If you programmatically create cubes, either by using Analysis Services Scripting Language (ASSL) commands or by using Analysis Management Objects (AMO), it is recommended that you create a default MDX script containing a single CALCULATE statement for the cube.

MDX Script Content

An MDX script can contain the following statements and expressions:

All MDX scripting statements

In MDX scripts, MDX scripting statements control the context and scope of calculations, and manage the behavior of other statements in the MDX script. This category includes the following statements:

- [CALCULATE](#)

- [FREEZE](#)
- [SCOPE](#)

For more information on MDX scripting statements, see [MDX Scripting Statements \(MDX\)](#).

[CREATE MEMBER](#)

The CREATE MEMBER statement creates calculated members. For more information about how to create calculated members, see [Building Calculated Members in MDX \(MDX\)](#).

[CREATE SET](#)

The CREATE SET statement creates named sets. For more information about how to create names sets, see [Building Named Sets in MDX \(MDX\)](#).

Conditional statements

Conditional statements add conditional logic to MDX scripts. This category includes the [CASE](#) and [IF](#) statements.

Assignment expressions

An assignment expression assigns an expression, such as a value, to a constrained subcube. A constrained subcube expression is a collection of constrained set expressions that define the "edges" of a subcube within an MDX script. The following codes shows the syntax for a constrained subcube expression:

```
<Constrained subcube> ::= (
    <Constrained set> [<Crossjoin operator> <Constrained set>...] |
    <ROOT function> |
    <TREE function> |
    LEAVES() |
    * ) [, <Constrained subcube>...]
<Constrained set> ::=
    <Natural hierarchy>.MEMBERS |
    <Natural hierarchy>.LEVEL(<numeric expression>).MEMBERS |
    { <Natural hierarchy member> } |
    DESCENDANTS( <Natural hierarchy member>, <Level expression>, ( SELF | AFTER | SELF_AND_AFTER ) ) |
    DESCENDANTS( <Natural hierarchy member>, , LEAVES )
<Natural hierarchy> ::= <Hierarchy identifier>
<Natural hierarchy member> ::= <Natural hierarchy>.<identifier>[.<identifier>...]
```

[MDX Scripting Fundamentals \(Analysis Services\)](#)

Managing Scope and Context (MDX)

7/16/2019 • 3 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

In Microsoft SQL Server Analysis Services, a Multidimensional Expressions (MDX) script can apply to the entire cube, or to specific portions of the cube, at specific points within the execution of the script. The MDX script can take a layered approach to calculations within a cube through the use of calculation passes.

NOTE

For more information on how calculation passes can affect calculations, see [Understanding Pass Order and Solve Order \(MDX\)](#).

To control the calculation pass, scope, and context within an MDX script, you specifically use the CALCULATE statement, the **This** function, and the SCOPE statement.

Using the CALCULATE Statement

The CALCULATE statement populates each cell in the cube with aggregated data. For example, the default MDX script has a single CALCULATE statement at the beginning of the script.

For more information on the syntax of the CALCULATE statement, see [CALCULATE Statement \(MDX\)](#).

NOTE

If the script contains a SCOPE statement that contains a CALCULATE statement, MDX evaluates the CALCULATE statement within the context of the subcube defined by the SCOPE statement, not against the whole cube.

Using the This Function

The **This** function lets you retrieve the current subcube within an MDX script. You can use the **This** function to quickly set the value of cells within the current subcube to an MDX expression. You often use the **This** function in conjunction with the SCOPE statement to change the contents of a specific subcube during a specific calculation pass.

NOTE

If the script contains a SCOPE statement that contains a **This** function, MDX evaluates the **This** function within the context of the subcube defined by the SCOPE statement, not against the whole cube.

This Function Example

The following MDX script command example uses the **This** function to increase the value of the Amount measure, in the Finance measure group of the Adventure Works DW Multidimensional 2012 sample cube, to 10% higher for the children of the Redmond member in the Customer dimension:

```

/* This SCOPE statement defines the current subcube */
SCOPE([Customer].&[Redmond].MEMBERS,
      [Measures].[Amount], *);
      /* This expression sets the value of the Amount measure */
      THIS = [Measures].[Amount] * 1.1;
END SCOPE;

```

For more information on the syntax of the **This** function, see [This \(MDX\)](#).

Using the SCOPE Statement

The SCOPE statement defines the current subcube that contains, and specifies the scope of, other MDX expressions and statements within an MDX script. MDX evaluates this other MDX expressions and statements, including the **This** function and the CALCULATE statement, within the context of the subcube.

A SCOPE statement is dynamic, but not iterative in nature. The statements contained within a SCOPE statement run once, but the subcube itself can be dynamically determined. For example, you have a cube named SampleCube. Against the SampleCube cube, you apply the following SCOPE statement to define a subcube that defines the context as the ALLMEMBERS within the Measures dimension:

```
SCOPE([Measures].ALLMEMBERS);
```

```
THIS = [Measures].ALLMEMBERS.COUNT;
```

```
END SCOPE;
```

The statements and expressions within this SCOPE statement run once.

Now, a business user runs the following MDX query that contains one measure, named ExistingMeasure, against the SampleCube cube:

```
WITH MEMBER [Measures].[NewMeasure] AS '1'
```

```
SELECT
```

```
[Measures].ALLMEMBERS ON COLUMNS,
```

```
[Customer].DEFAULTMEMBER ON ROWS
```

```
FROM
```

```
[SampleCube]
```

The cellset returned from the query resembles the output shown in the following table.

	[EXISTINGMEASURE]	[NEWMEASURE]
[Customer].[All]	2	2

Looking at the returned cellset, notice how the ExistingMeasure value, included in the SCOPE statement within the MDX script, is dynamically updated after the measure NewMeasure was defined.

A SCOPE statement can be nested within another SCOPE statement. However, as the SCOPE statement is not iterative, the primary purpose for nesting SCOPE statements is to further subdivide a subcube for special treatment.

SCOPE Statement Example

The following MDX script example uses a SCOPE statement to set the value of the Amount measure, in the Finance measure group of the Adventure Works DW Multidimensional 2012 sample cube, to 10% higher for the

children of the Redmond member in the Customer dimension. However, another SCOPE statement changes the subcube to include the Amount measure for the children of the 2002 calendar year. Finally, the Amount measure is then aggregated only for that subcube, leaving the aggregated values for the Amount measure in other calendar years unchanged.

```
/* Calculate the entire cube first. */
CALCULATE;
/* This SCOPE statement defines the current subcube */
SCOPE([Customer].&[Redmond].MEMBERS,
      [Measures].[Amount], *);
      /* This expression sets the value of the Amount measure */
      THIS = [Measures].[Amount] * 1.1;
END SCOPE;
```

For more information on the syntax of the SCOPE statement, see [SCOPE Statement \(MDX\)](#).

Data Mining Programming

7/16/2019 • 2 minutes to read • [Edit Online](#)

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

If you find that the built-in tools and viewers in Analysis Services do not meet your requirements, you can extend the power of Analysis Services by coding your own extensions. In this approach, you have two options:

- **XMLA**

Analysis Services supports XML for Analysis (XMLA) as a protocol for communication with client applications. Additional commands are supported by Analysis Services that extend the XML for Analysis specification.

Because Analysis Services uses XMLA for data definition, data manipulation, and data control support, you can create mining structures and mining models by using the visual tools provided by Visual Studio with Analysis Services projects, and then extend the data mining objects that you have created by using Data Mining Extensions (DMX) and Analysis Services Scripting Language (ASSL) scripts.

You can create and modify data mining objects entirely in XMLA scripts, and run prediction queries against the models programmatically from your own applications.

- **Analysis Management Objects (AMO)**

Analysis Services also provides a complete framework that enables third-party data mining providers to integrate the data mining objects into Analysis Services.

You can create mining structures and mining models by using AMO. See the following samples in CodePlex:

- AMO Browser

Connects to the SSAS instance you specify and lists all server objects and their properties, including mining structure and mining models.

- AMO Simple Sample

The AS Simple Sample covers programmatic access to most major objects, and demonstrates metadata browsing, and access to the values in objects.

The sample also demonstrates how to create and process a data mining structure and model, as well as browse an existing data mining model.

- **DMX**

You can use DMX to encapsulate command statements, prediction queries, and metadata queries and return results in a tabular format, assuming you have created a connection to an Analysis Services server.

APPLIES TO: SQL Server Analysis Services Azure Analysis Services Power BI Premium

Analysis Services PowerShell cmdlets are included in the [SqlServer module](#).

NOTE

Azure Analysis Services database operations use the same SqlServer module as SQL Server Analysis Services. However, not all cmdlets are supported for Azure Analysis Services. To learn more, see [Manage Azure Analysis Services with PowerShell](#).

Analysis Services Cmdlets

Analysis Services provides cmdlets correspond to methods in the **Microsoft.AnalysisServices** namespace. The following table describes each cmdlet and provides a link to the corresponding AMO method.

If you want to use PowerShell to perform a task that is not represented in the following list (for example to create or synchronize a database), you can write TMSL or XMLA script for that action, and then execute it using the **Invoke-ASCmd** cmdlet.

CMDLET	DESCRIPTION	EQUIVALENT AMO METHODS
Add-RoleMember cmdlet	Add a member to a database role.	Add
Backup-ASDatabase cmdlet	Backup an Analysis Services database.	Database.Backup
Invoke-ASCmd cmdlet	Execute a query or script in XMLA or TSM (JSON) format.	Execute
Invoke-ProcessASDatabase	Process a database.	Process
Invoke-ProcessCube cmdlet	Process a cube.	Process
Invoke-ProcessDimension cmdlet	Process a dimension.	Process
Invoke-ProcessPartition cmdlet	Process a partition.	Process
Invoke-ProcessTable cmdlet	Process a table in a Tabular model, compatibility model 1200 or higher.	Process
Merge-Partition cmdlet	Merge a partition.	Merge
New-RestoreFolder cmdlet	Create a folder to contain a database backup.	RestoreFolder
New-RestoreLocation cmdlet	Specify one or more remote servers on which to restore the database.	RestoreLocation

CMDLET	DESCRIPTION	EQUIVALENT AMO METHODS
Remove-RoleMember cmdlet	Remove a member from a database role.	Remove
Restore-ASDatabase cmdlet	Restore a database on a server instance.	Restore
